Infection usually presents 6 to 8 days after delivery. The patient usually complains of a fever, perineal pain, and a purulent discharge that may be foul smelling. Management includes local perineal care and exploration with debridement under adequate anesthesia to drain a potential abscess. Carefully examine the patient and explore the area to rule out necrotizing fasciitis.[25] Unless the patient is septic, begin intravenous antibiotics after consulting with the Obstetrician–Gynecologist and obtaining wound cultures.

Pain at the episiotomy site is common. It usually resolves in 3 to 5 days. The pain usually responds to acetaminophen and nonsteroidal anti-inflammatory drugs. If the patient is complaining of intense pain, a hematoma or an infection must be ruled out. Dyspareunia is more common with a mediolateral episiotomy.[11] Prospective studies have not found differences in the resumption of intercourse at 3 months when compared to patients without an episiotomy.[8]

Dehiscence is reported in 0.1% to 2% of episiotomies. Early closure within 1 week is preferable to the delayed closure at 2 to 3 months. It is necessary to remove all necrotic tissue and copiously irrigate

the area with a diluted povidone iodine solution. This should be followed by twice daily scrubbings of the wound with a scrub brush and povidone iodine. The wound can be repaired once it is free of exudates and begins to show granulation tissue. Intravenous antibiotics might be necessary in the presence of infection.[29] The repair procedure should be performed by a Gynecologist or a Colorectal Surgeon if the dehiscence involves the anal sphincter.

The use of a midline episiotomy may increase the risk of third-degree and fourth-degree lacerations.[30–33] A third-degree laceration is diagnosed when the capsule and/or the muscle of the anal sphincter is interrupted. A fourth-degree laceration involves the anal sphincter and the mucosa of the anus or rectum. Third-degree and fourth-degree lacerations may result in incontinence of feces, incontinence of flatus, and/or rectovaginal fistula formation if not properly repaired. Complications include increased blood loss, especially if the incision is made too early.

The midline episiotomy has been shown to be associated with an increased risk of third-degree and fourth-degree perineal lacerations in operative vaginal deliveries. Perineal and pelvic floor morbidity was greatest among women receiving a median episiotomy versus those remaining intact or sustaining spontaneous perineal tears in a study of the relationship between episiotomy and maternal morbidity. Severe lacerations were nearly 50 times more likely in parturients with midline episiotomies and over 8 times more likely in women with mediolateral episiotomies than in women who did not undergo an episiotomy.

SUMMARY

Episiotomies are not performed routinely but should be utilized on a selective basis for the appropriate indication. Surgical judgment, patient assessment, acknowledgment of surgical expertise level, and common sense should be employed. The midline episiotomy is the preferred technique for non-Obstetricians. It is easier to perform and easier to repair when compared to the mediolateral episiotomy.

133 Shoulder Dystocia Management

Eric F. Reichman and Camaran E. Roberts

INTRODUCTION

Shoulder dystocia is a rare obstetric emergency that immediately places the mother and the fetus at risk for significant morbidity and mortality. It is diagnosed when, after delivery of the fetal head, further expulsion of the fetus is prevented by impaction of the fetal shoulders within the maternal pelvis.[1] **Shoulder dystocia is considered an emergent situation that the Emergency Physician must recognize and quickly respond to by promptly delivering the fetus.**

The incidence of shoulder dystocia varies and is seen in up to 4% of cephalic spontaneous vaginal deliveries depending upon the source.[2–7] Differing definitions of shoulder dystocia may account for some of this variability. Some reports require that maneuvers for shoulder release be documented on the chart whereas others accept the Physician's clinical diagnosis of shoulder dystocia. Other definitions look at the timing of the delivery of the head, the delivery of the shoulders, or the completion of the birth. The rare occurrences of shoulder dystocia make designing prospective studies difficult, both in describing the incidence and in evaluating the efficacy of various release maneuvers.[8]

Shoulder dystocia may not be anticipated in advance. Many risk factors are associated with shoulder dystocia. However, many patients with shoulder dystocia have none of these risk factors. Emergency Physicians usually do not have knowledge of the patient's prenatal history, ultrasound reports, or previous deliveries. This makes it difficult to predict shoulder dystocia. It is imperative for the Emergency Physician to be knowledgeable and comfortable with the various release maneuvers in the event that shoulder dystocia is encountered during a precipitous delivery. When the baby is being delivered, there is not time to look up references.

ANATOMY AND PATHOPHYSIOLOGY

Shoulder dystocia is usually diagnosed after delivery of the fetal head, when the fetal shoulders fail to deliver despite standard gentle traction on the fetal head. It results from impingement of the biacromial diameter of the fetus against the maternal pubic symphysis anteriorly and the maternal sacral promontory posteriorly.[9]

Shoulder dystocia is a rare and potentially catastrophic obstetrical emergency. **The Emergency Physician must deliver the fetus quickly and without applying excessive forces that may result in fetal injury.** Always be prepared for the possibility of shoulder dystocia. Recognize the possible associated risk factors that include fetal macrosomia, maternal diabetes, a prior history of shoulder dystocia or macrosomia, prolonged second stage of labor, post-term pregnancy, multiparity, obesity, and operative vaginal delivery from the midpelvis.[9]

Fetal macrosomia is defined as fetal growth beyond a specific weight, usually 4000 to 4500 g, regardless of the fetal gestational age. The risk of shoulder dystocia is 9.2% to 24% in nondiabetic pregnant women, and 19.9% to 50% in diabetic women when birth weight is greater than 4500 g.[10] The ability to predict fetal macrosomia is limited. Shoulder dystocia can occur unexpectedly in infants of normal birth weights.[10] A simple algorithm to help determine if shoulder dystocia or fetal macrosomia may be present is shown in **Figure 133-1**.

INDICATIONS

The presence of shoulder dystocia is the unique indication for the procedures described in this chapter. They should be utilized in the approximate order described, from the least invasive and easiest to perform to the most invasive and difficult to perform.

A symphysiotomy is indicated for shoulder dystocia unresponsive to less invasive techniques and for fetal head entrapment by presumed cephalopelvic disproportion. It is an alternative to the cesarean section when a qualified Obstetrician or Surgeon is unavailable.[10] Refer to Chapter 137 for the complete details regarding a symphysiotomy.

CONTRAINDICATIONS

There are few contraindications to the release maneuvers in an emergent situation of shoulder dystocia and imminent fetal demise. The only absolute contraindication is if the procedure might endanger the mother.

The indications to perform a cesarean delivery are relative contraindications for release maneuvers. Fetal macrosomia has been associated with shoulder dystocia.[10] The American College of Obstetricians and Gynecologists (ACOG) supported the recommendation that planned cesarean delivery may be a reasonable

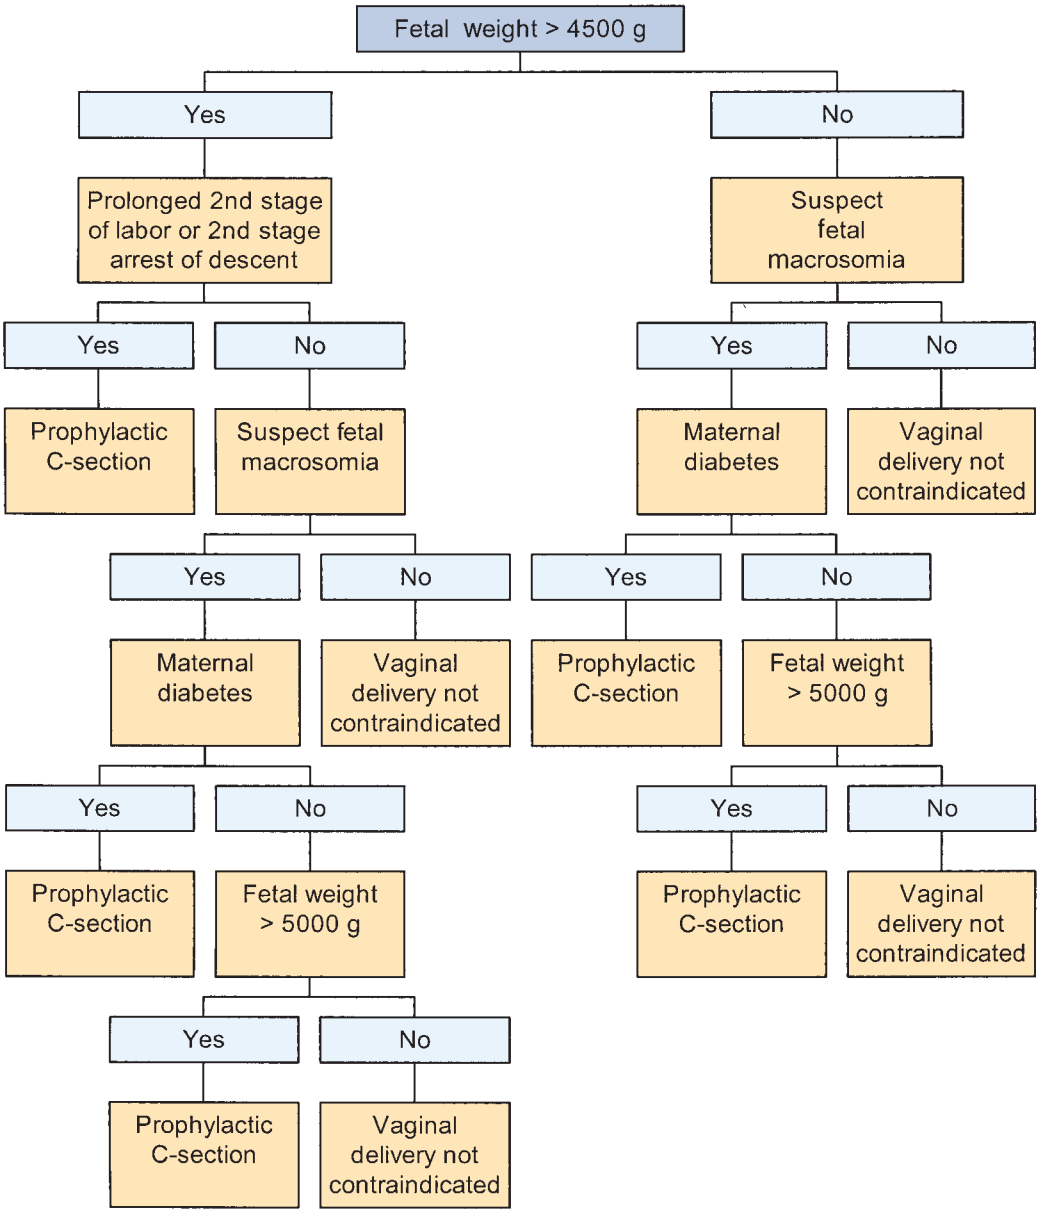

FIGURE 133-1. An algorithm providing a sequence of decisions for evaluation and anticipation of shoulder dystocia.[10]

strategy for diabetic pregnant women with estimated fetal weights exceeding 4250 to 4500 g.[8] ACOG issued guidelines on fetal macrosomia in 2001. The guidelines were based upon limited or inconsistent scientific evidence. ACOG recommended that an estimated fetal weight of more than 4500 g, a prolonged second stage of labor, or arrest of descent in the second stage of labor are indications for cesarean delivery.[10] ACOG noted that the diagnosis of fetal macrosomia is imprecise and recommended prophylactic cesarean delivery be considered with estimated fetal weights of more than 5000 g in nondiabetic pregnant women and more than 4500 g in diabetic pregnant women.[10]

EQUIPMENT

General Supplies

- Electronic fetal monitor
- Sterile towels
- Clock or timer watch
- Sterile perineal drapes
- Sterile gloves
- Chromic suture, 2-0 and 4-0
- Vicryl suture, 2-0 and 3-0
- Bulb syringe
- Clean towels/blanket for baby
- Umbilical cord clamp
- Sterile scissors to trim umbilical cord
- Infant warmer

Delivery Instrument Pack

- Bandage scissors
- Towel clips
- Two Allis forceps

- Four ring forceps
- Six straight Kocher clamps
- Straight Mayo scissors
- Two suture scissors
- Adson forceps, or other forceps with teeth
- Russian forceps, 5½ inches and 8 inches
- Gelpi retractor
- Richardson retractors, small and medium
- Army/Navy retractors
- 6 inch needle driver

Symphysiotomy

- #10 or #15 scalpel blade on a handle
- Finger guard
- Foley catheter
- Povidone iodine or chlorhexidine solution

PATIENT PREPARATION

Pain associated with the first stage of labor can be relieved with a paracervical block (Chapter 131). Inject 5 mL of local anesthetic solution into the submucosa of the lateral vaginal fornix. Repeat the injection in the contralateral lateral vaginal fornix. Pain transmission is interrupted for all visceral sensory nerve fibers from the uterus, cervix, and upper vagina. The somatosensory fibers from the perineum are not blocked. This technique is effective only during the first stage of labor and before shoulder dystocia occurs.[11,12]

A pudendal nerve block and local perineal infiltration anesthesia are usually administered just before delivery (Chapter 131).[12] Refer to Chapters 131 and 132 regarding the complete details of these anesthetic techniques. Unfortunately, these techniques must also be performed prior to the occurrence of shoulder dystocia.

The patient should already be in the lithotomy position on a bed with stirrups. Preparation begins with suspicion of fetal macrosomia by clinical examination and/or fetal ultrasonography. Retraction of the fetal head immediately after its delivery and the fetal chin against the maternal thigh (turtle sign) with difficulty suctioning the mouth may signal impending shoulder dystocia (**Figure 133-2**).

The fetal sagittal suture generally lies oblique to the maternal anteroposterior diameter with the fetal shoulders occupying the opposite oblique diameter after delivery of the fetal head (**Figure 133-3**). The shoulder may become impacted behind the pubic symphysis and impede delivery if the anterior shoulder descends in the anteroposterior diameter. Apply gentle and downward pressure on the fetal head to move the posterior shoulder into the hollow of the sacrum and deliver the anterior shoulder (**Figure 133-4**). **Resist applying excessive downward or lateral traction on the fetal head and neck.**

TECHNIQUES

Perform attempts at gentle traction coordinated with maternal expulsive efforts before attempting maneuvers to relieve shoulder dystocia. Initiate a planned sequence of events if delivery is impeded. **Avoid applying fundal pressure and discontinue maternal pushing efforts until disimpaction has occurred.** Fundal pressure and maternal pushing may further impact the fetal shoulders. Contact an Anesthesiologist for pain control. Summon extra personnel for help, with one person designated as a timekeeper. Notify a Neonatologist of the impending delivery. Maneuvers for shoulder

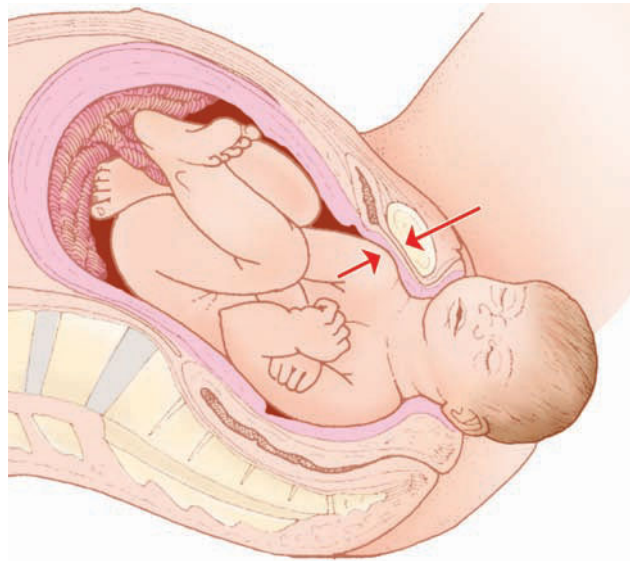

FIGURE 133-2. The head may retract toward the perineum (turtle sign) when delivery of the fetal head is not followed by delivery of the shoulders.

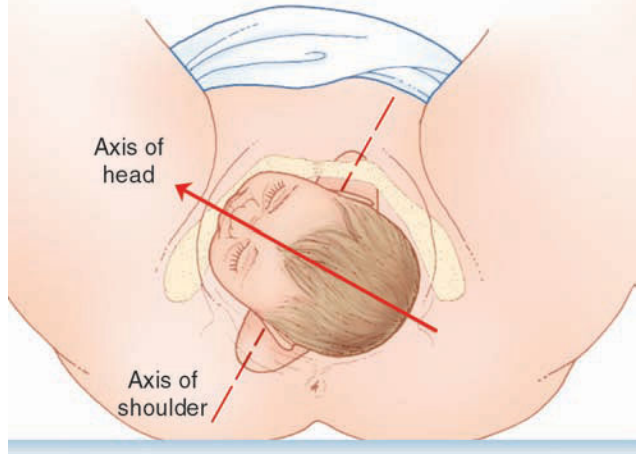

FIGURE 133-3. Restitution (external rotation) of the fetal head normally results in a natural perpendicular relationship of the head to the shoulders.

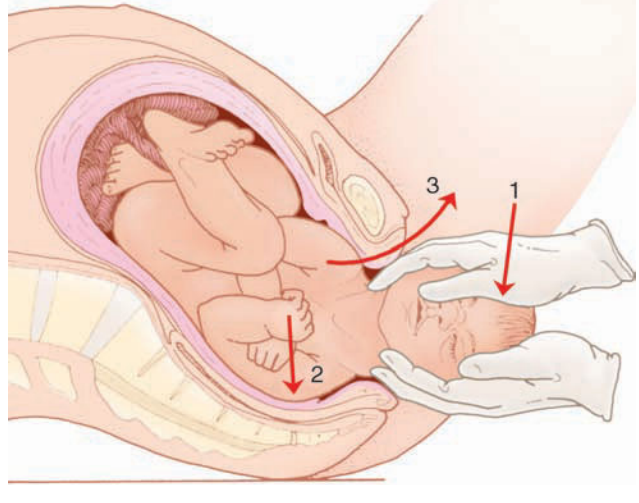

FIGURE 133-4. Apply gentle and downward pressure on the fetal head (1) to move the posterior shoulder into the hollow of the sacrum (2) and deliver the anterior shoulder (3).

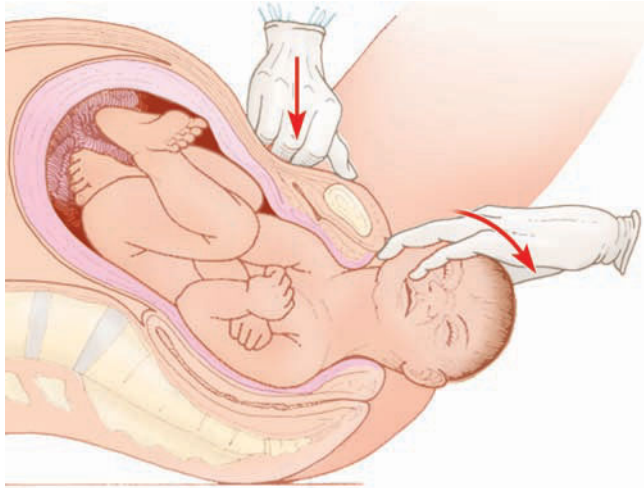

FIGURE 133-5. Moderate suprapubic pressure is applied to disimpact the fetal shoulder while gentle downward traction is applied to the fetal head.

dystocia disimpaction will be described in order of ease of implementation and from least invasive to more invasive.

SUPRAPUBIC PRESSURE

This maneuver can be used alone or in combination with the McRoberts maneuver. Apply gentle downward traction to the fetal head while an assistant simultaneously applies moderate suprapubic pressure (**Figure 133-5**). **Do not apply heavy pressure to prevent injury to the fetus's brachial plexus, neck, and spinal cord.**

McROBERTS MANEUVER

The McRoberts maneuver is easy to perform (**Figure 133-6**). Place an assistant on each side of the patient. Hyperflex the mother's thighs onto her abdomen (**Figure 133-6A**). Instruct the assistants to maintain support of the hyperflexion while simultaneously applying suprapubic pressure (**Figure 133-6B**). This results in a flattening of the maternal lumbosacral curve and a rotation of the pubic symphysis cephalad (**Figure 133-6C**). Rotation of the maternal pelvis may free the impacted anterior fetal shoulder.[7,13] This maneuver has the advantages of reducing shoulder extraction forces, brachial plexus stretching, and the incidence of clavicular fractures.[7,13] The McRoberts maneuver is effective in disimpacting the fetal shoulders in 50% to 90% of cases of shoulder dystocia.[7,13]

RUBIN MANEUVER

The Rubin maneuver is simple and may lead to the descent and delivery of the anterior fetal shoulder (**Figure 133-7**). Insert the dominant hand into the vagina. Place the fingers of the hand against the posterior aspect of the anterior fetal shoulder. Rotate the fetal shoulder counterclockwise in a small arc to approximately the 10 o'clock position. The Rubin maneuver compresses and diminishes the size of the fetal shoulder girdle to disimpact the anterior shoulder. Rotation of the anterior fetal shoulder in the opposite direction (i.e., clockwise) will open the shoulder girdle, increase the size of the shoulder girdle, and further impact the fetus.

WOOD'S CORKSCREW MANEUVER

The Wood's corkscrew maneuver (**Figure 133-8**) is an alternative to the Rubin maneuver. Insert the dominant hand into the vagina.

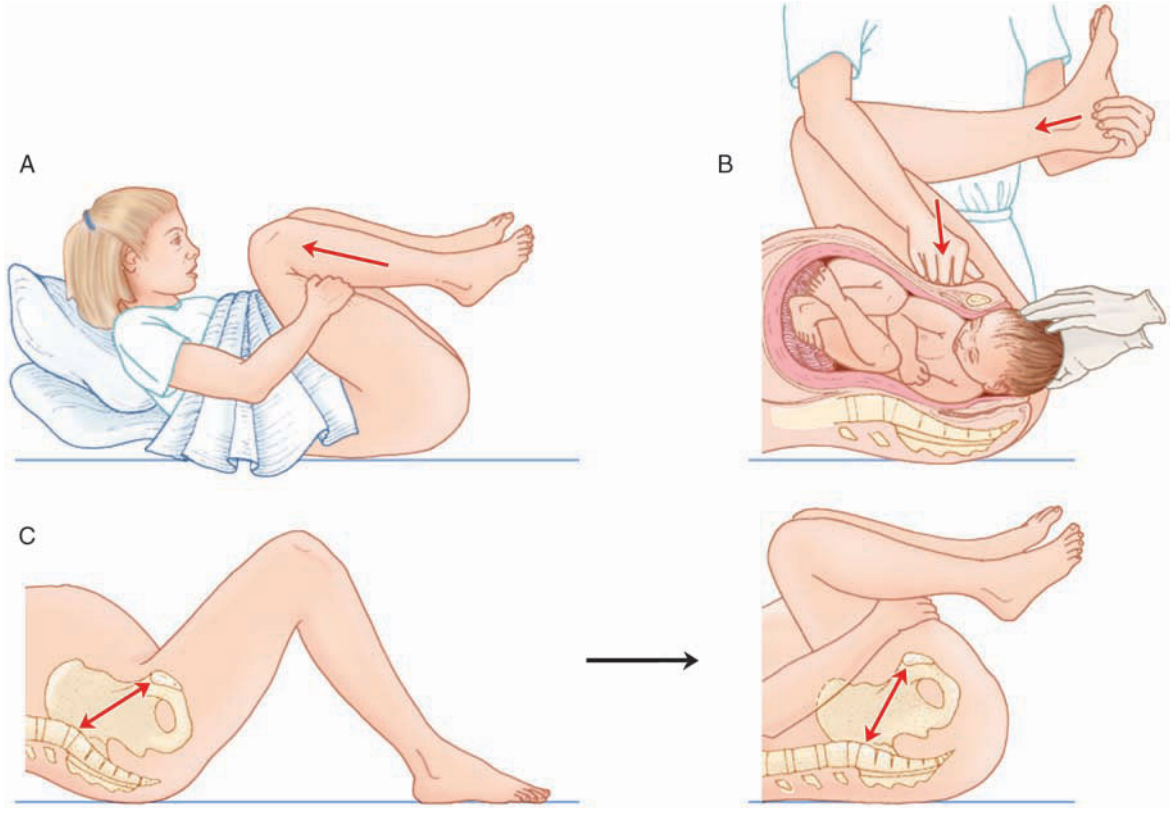

FIGURE 133-6. The McRoberts maneuver. **A.** Hyperflex the maternal thighs upon the abdomen. **B.** An assistant applies suprapubic pressure while maintaining flexion of the legs. **C.** This maneuver results in cephalad rotation of the maternal pelvis and an increase in the size of the pelvic outlet.

FIGURE 133-7. The Rubin maneuver. Rotation of the anterior shoulder counterclockwise through a small arc to the oblique position.

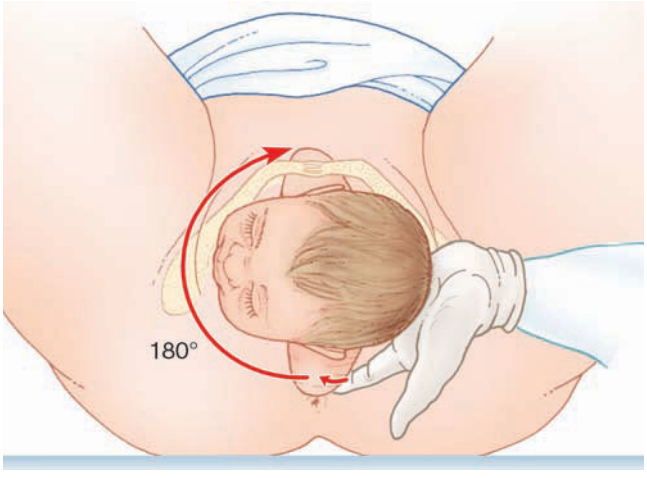

FIGURE 133-8. The Wood's corkscrew maneuver. Rotation of the posterior shoulder through a 180° arc.

Place the fingers of the hand against the posterior aspect of the posterior fetal shoulder. Gently rotate the posterior shoulder 180° clockwise (**Figure 133-8**).[15] This maneuver, like the Rubin maneuver, compresses and diminishes the size of the fetal shoulder girdle to disimpact the anterior shoulder. Rotation in the opposite direction (i.e., counterclockwise) will open the shoulder girdle, increase the size of the shoulder girdle, and further impact the fetus.

DELIVERY OF THE POSTERIOR ARM

Attempt to deliver the posterior arm if the previous maneuvers are unsuccessful (**Figure 133-9**). Insert the dominant hand into the vagina. Place the fingers of the hand against the posterior fetal humerus (**Figure 133-9A**). Sweep the fetal arm across the chest (**Figure 133-9B**). Palpate for and grasp the fetal hand (**Figure 133-9C**). Gently pull the hand along the side of the face. Continue to gently pull the hand to deliver the posterior arm and shoulder (**Figure 133-9D**). Apply gentle downward traction on the fetal head and arm while an assistant simultaneously applies suprapubic pressure to release and deliver the anterior shoulder (**Figure 133-9E**). Rotate the shoulder girdle into the oblique diameter if traction on the fetal head and arm does not deliver the anterior shoulder.[9] This will usually disimpact the anterior shoulder and allow it to be delivered. **The major disadvantage of this maneuver is that it may result in a clavicle fracture or a humerus fracture.**

DELIBERATE FRACTURE OF THE CLAVICLE

Fracture the fetal clavicle by pressing the anterior clavicle against the maternal pubic symphysis. This will decrease the rigidity and the size of the fetal shoulder girdle. Exert the pressure in a direction away from the lungs to avoid a pneumothorax. **Never use an instrument to fracture the clavicle.** It may penetrate into the thoracic cavity, cause a pneumothorax, or result in subsequent osteomyelitis if the skin is punctured.[14] The fracture will heal quickly and is much less serious than a brachial plexus injury, asphyxia, or death. This maneuver is difficult to perform.[15] It is physically and mentally difficult to deliberately fracture the clavicle of a large infant.

ZAVANELLI MANEUVER

The Zavanelli maneuver involves replacement of the fetal head followed by a cesarean section (**Figure 133-10**). The expulsed head must undergo two maneuvers to reverse the mechanisms of labor. Manually rotate the fetal head into the prerestitution position (**Figure 133-10A**). This is usually the direct occiput anterior position with full extension of the neck (**Figure 133-10B**). The second maneuver is flexion of the fetal head followed by gentle upward pressure on the head to replace it into the maternal vagina (**Figure 133-10B**). The Emergency Physician must maintain their hand in the vagina and maintain gentle pressure on the fetal head to prevent re-expulsion. The Emergency Physician, or an assistant, must keep their hand in the vagina and holding the fetal head during the entire transport to the Operating Room and until a cesarean section is performed.

This series of maneuvers decompresses the fetus. Immediately transport the mother to the Operating Room for a cesarean section. The Zavanelli maneuver was found to be successful in 84% of initial attempts and 91% of attempts when uterine relaxing anesthesia or uterine relaxing medication (usually 0.25 mg terbutaline subcutaneously) was administered.[16,17] More importantly, it was successful on the first attempt by untrained practitioners in 69% of the cases.

SYMPHYSIOTOMY

A symphysiotomy is an uncommon procedure utilized primarily in two situations. The first is shoulder dystocia unresponsive to less invasive techniques. The second is when the head of a breech delivery is trapped by presumed cephalopelvic disproportion. It serves as an alternative to the more invasive cesarean section. It is especially useful in situations where an Obstetrician or Surgeon is unavailable.[17,18] Refer to Chapter 137 for the complete details regarding a symphysiotomy.

AFTERCARE

Disimpaction of the shoulder girdle is usually followed by delivery of the infant. Clamp and cut the umbilical cord. Immediately assess and implement any resuscitative measures for the infant without delay. Deliver the placenta. Repair any lacerations, Dührssen's incisions, episiotomy incisions, perineal lacerations, and vaginal lacerations. Refer to Chapter 132 for the complete details regarding episiotomy repair. Refer to Chapter 135 for the complete details regarding postpartum hemorrhage management. Initiate uterine massage and administer intramuscular pitocin following delivery of the placenta to prevent postpartum hemorrhage. Clearly and completely document the series of events in the medical record.

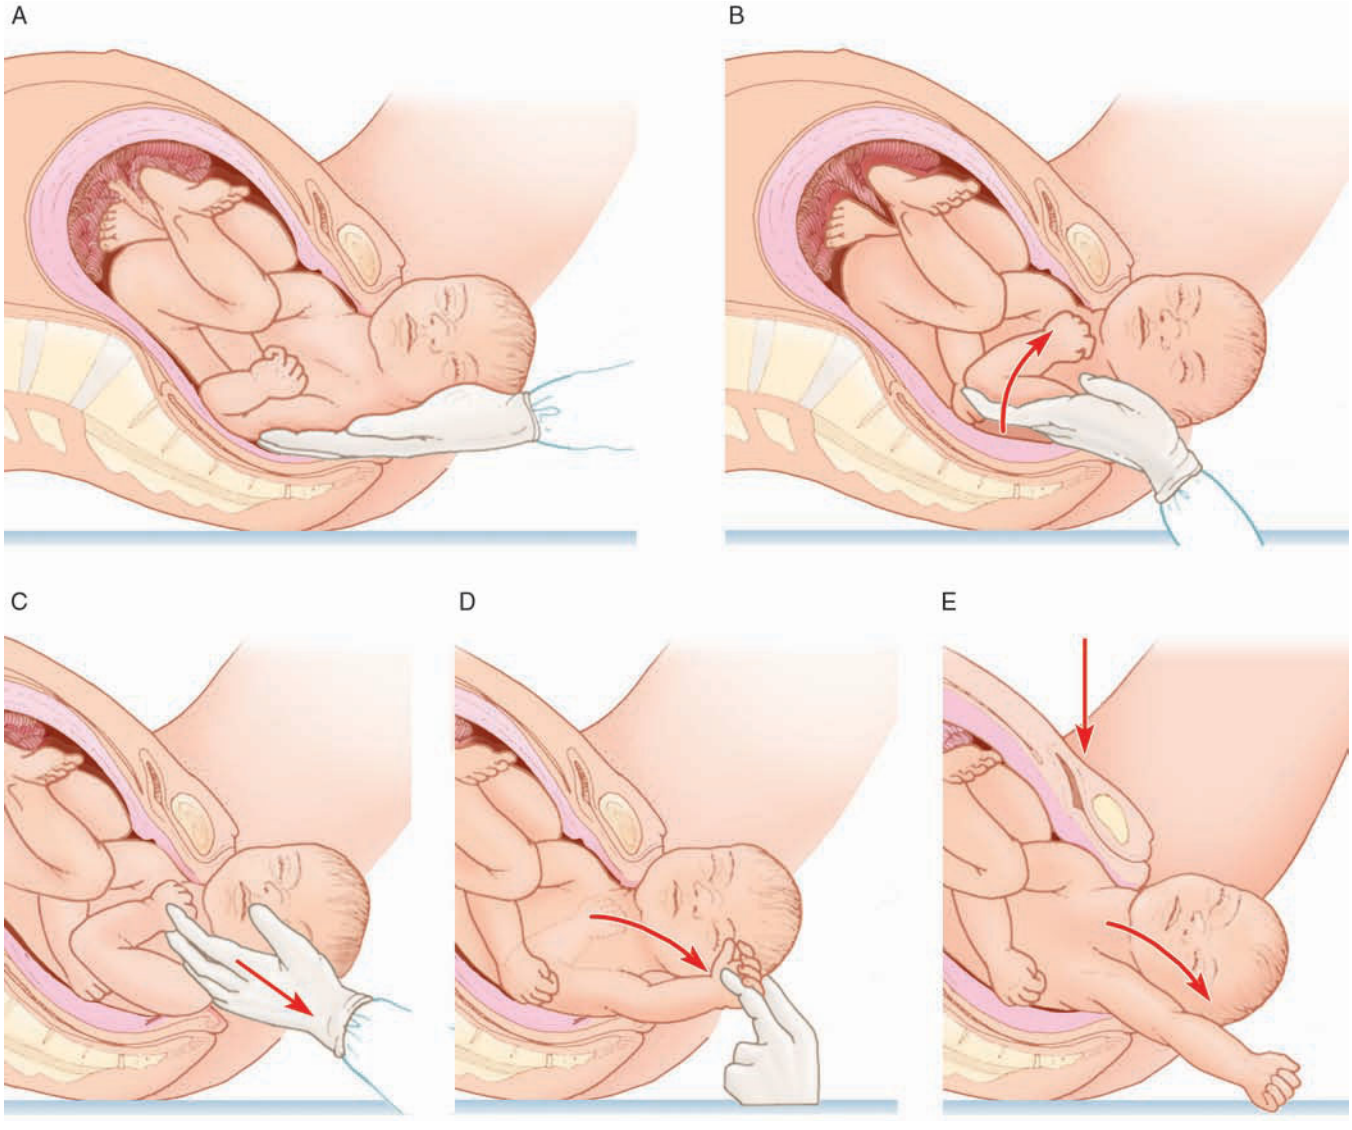

FIGURE 133-9. Delivery of the posterior arm. **A.** Insert a hand into the vagina and along the posterior fetal humerus. **B.** Sweep the fetal arm across the chest. **C.** Grasp the hand and extend the arm along the side of the face. **D.** Deliver the posterior arm and shoulder from the vagina. **E.** Apply gentle downward traction on the fetal head and arm while an assistant simultaneously applies suprapubic pressure to deliver the anterior shoulder.

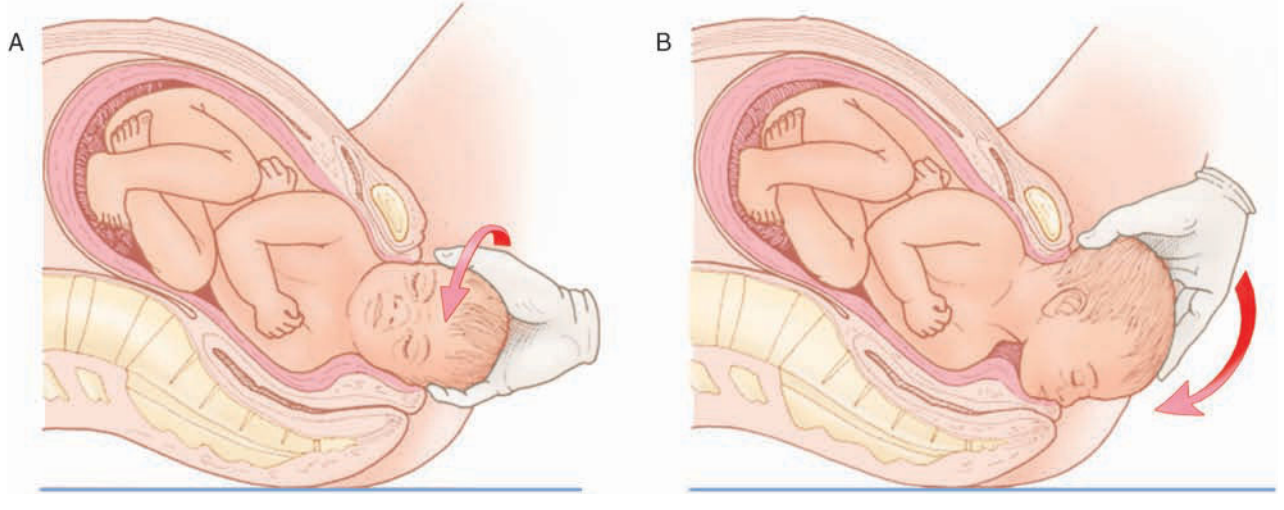

FIGURE 133-10. The Zavanelli maneuver. **A.** Manually return the fetal head to the preretitution position, if restitution has occurred. This position is usually the direct occiput anterior position. **B.** Flex the fetal head and apply gentle upward pressure to place the fetal head back into the vagina.

COMPLICATIONS

Complications can occur for both the mother and the fetus when shoulder dystocia occurs. The most common maternal complications are lower genital tract lacerations, postpartum hemorrhage (secondary to uterine atony or lacerations), and infection.[2,19]

Significant fetal morbidity and mortality is attributable to asphyxia from delayed delivery or trauma sustained during delivery.[9] Perinatal mortality ranges from 2% to 29% when shoulder dystocia occurs. Neonatal morbidity is immediately apparent in 20% of the affected infants.[2] Neonatal trauma may occur in utero secondary to chronic nerve compression from malposition and during delivery.[9] Birth trauma occurring during shoulder dystocia may include brachial plexus injuries or Erb's palsy (6% to 16%), Klumpke palsy, clavicular fractures (5% to 13%), or humeral fractures.[3,5,6,14,15,19,20]

SUMMARY

The successful management of shoulder dystocia requires considerable judgment by the clinician in a timely fashion. Warning signals such as fetal macrosomia based on clinical estimate, maternal diabetes, and labor disorders should alert the clinician to be prepared for possible shoulder dystocia. Any or all of the maneuvers described will usually resolve shoulder dystocia if performed in a methodical fashion. Begin with the simplest and least invasive maneuver and work toward the more invasive maneuvers. Reduction of the time interval from delivery of the head to delivery of the body is crucial to fetal survival.

134 Breech Delivery

Irene E. Aga

INTRODUCTION

The breech presentation exists when the cephalic pole of the fetus is positioned in a longitudinal lie and the buttocks or feet of the fetus enter the maternal pelvis before the head.[1] Management of the breech presentation in labor is an area of much trepidation and controversy, even among seasoned clinicians. A breech delivery is considered a high-risk obstetric complication that is best handled by an Obstetrician.

There are, however, unavoidable situations when a pregnant woman will present to the Emergency Department in active labor with a fetus in the breech position. A vaginal breech delivery may be the best delivery option in situations such as advanced labor, the absence of surgical assistance, the presence of an acute situation, fetal distress, or umbilical cord prolapse. Knowledge and preparedness facilitate comfort and promote success in approaching any emergent procedure. The breech delivery is no exception to this rule.

ANATOMY AND PATHOPHYSIOLOGY

The breech presentation may be associated with a variety of maternal and fetal conditions.[1,2] Maternal abnormalities that increase the risk of a breech presentation include a small pelvis and uterine anomalies. Fetal conditions associated with a breech presentation include low birth weight, prematurity, abnormal amniotic fluid volume, fetal malformations (e.g., hydrocephalus, cystic hygroma, and anencephaly), neurologic disorders, and genetic abnormalities.

Prematurity is a risk factor for a breech presentation. The incidence of breech presentations is inversely related to the fetal gestational age.[1,2] At 28 weeks of gestation, 24% of fetuses are in the breech presentation. The fetus usually turns spontaneously to a cephalic presentation so that at term, only 3% to 4% are in the breech presentation.[1,2]

There are three main types of breech presentation (**Figure 134-1**). The most common is the frank breech, accounting for 50% to 73% of breech presentations. The fetus is flexed at the hips and extended at the knees (**Figure 134-1A**). The fetus is in the "pike" position. The complete breech is the least common type and accounts for approximately 5% to 11% of breech presentations. The fetus is flexed at both the hips and the knees (**Figure 134-1B**). The footling or incomplete breech accounts for approximately 12% to 38% of breech presentations. The fetus is incompletely deflexed at one or both knees or hips (**Figure 134-1C**). This results in one or both feet presenting before the buttocks. The risks of umbilical cord prolapse and prematurity associated with the breech presentation are listed in **Table 134-1**.

A breech presentation may be suspected upon clinical examination. The abdominal examination may reveal the hardness of

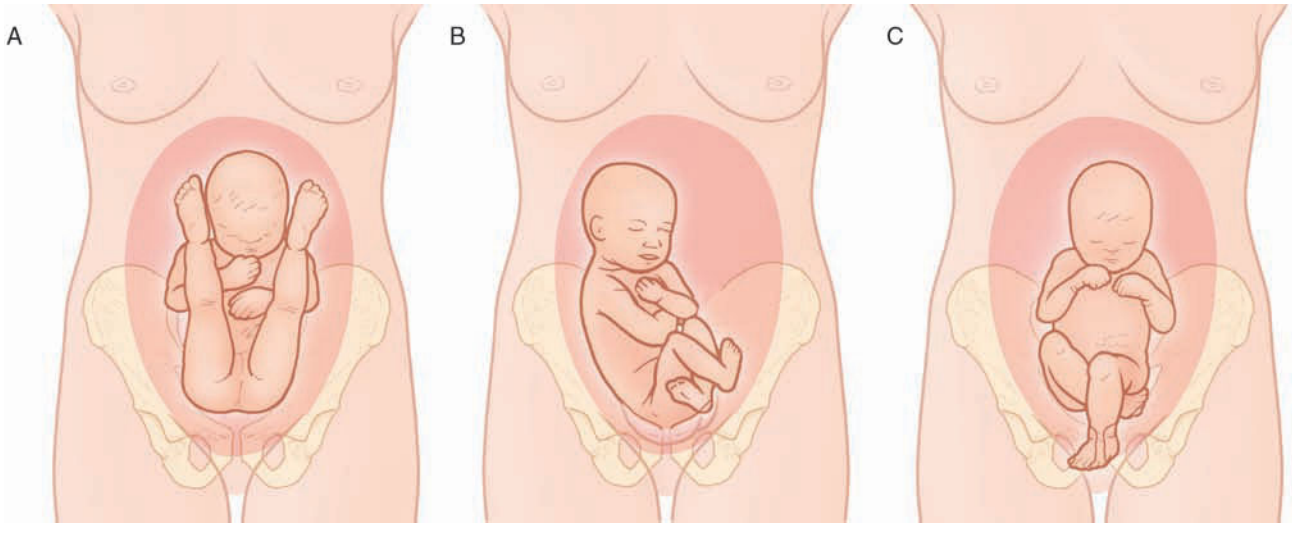

FIGURE 134-1. The main types of breech presentations. **A.** The frank breech. **B.** The complete breech. **C.** The incomplete breech.

TABLE 134-1 Breech Presentations and Associated Complications[1]

Breech presentation	Breech deliveries (%)	Umbilical cord prolapse (%)	Prematurity (%)
Frank	50–73	0.5	38
Complete	5–11	5	12
Incomplete	12–38	14	50

the fetal head palpable in the fundus rather than above the pelvic inlet. A vaginal examination can confirm this suspicion. When a breech presentation in labor is suspected, an ultrasound examination is recommended to confirm presentation and exclude a fetal abnormality.[1]

Breech delivery is divided into three categories. These include unassisted or spontaneous expulsion, partial breech extraction, and total breech extraction.[3] Unassisted or spontaneous expulsion of the fetus occurs when there is no assistance from the provider in the delivery of the infant. This generally occurs only with very premature infants or in precipitous deliveries where the baby delivers so rapidly as not to allow the provider to arrive.

Partial breech extraction is defined as spontaneous delivery of the infant to the level of the umbilicus followed by assistance from the provider. This is the usual manner of breech delivery. **Allowing the fetus to descend naturally into the pelvis avoids an increased incidence of head entrapment, deflexion of the fetal head, nuchal arms, and umbilical cord prolapse.** This is the preferred method of delivery for the Emergency Physician confronted with an actively laboring breech presentation and little hope of obtaining an Obstetrician before delivery.

Total breech extraction occurs when the provider reaches into the uterus and literally pulls or extracts the fetal feet into the vagina and through the vulva, followed by the assisted delivery of the remainder of the infant. Total breech extraction is indicated when expedient delivery is preferred in the absence of an experienced Obstetrician to perform a cesarean section and if performed for the breech presentation of a second twin, acute and profound fetal distress, and/or umbilical cord prolapse.[2]

Regardless of the mode of delivery, the breech presentation has been associated with an increased risk of cerebral palsy and perinatal mortality. Thus, failure to adopt the cephalic presentation may in some cases be a marker for some type of preexisting fetal impairment.[4] The cesarean section has been suggested as the way to reduce perinatal problems associated with the breech presentation.[5] Cesarean section has become the normal mode of breech delivery in many European countries and in North America. The rate of cesarean section for the breech presentation in the United States has increased from 12% in 1970 to 87% in 2002.[6] However, prospective and retrospective studies over the last two decades are now beginning to refute this practice.[7–10]

No consensus exists concerning the absolute preferred method of breech delivery due to the conflicting data.[11] Currently, the American College of Obstetricians and Gynecologists recommends that the decision regarding the mode of delivery should be based on the experience of the healthcare provider. It is recognized that cesarean delivery will be the preferred mode of delivery for most Physicians. Maternal morbidity and mortality are higher if an emergency cesarean delivery is performed when compared to an elective cesarean delivery. There are circumstances such as patient preference, an obstetric indication, or a precipitous delivery in which a vaginal breech delivery will be preferable.[12]

Obstetricians will often perform external cephalic version prior to the delivery date if a breech presentation is identified during prenatal visits.[1,2,10] This technique is reserved for the experienced Obstetrician as it can be associated with significant complications. External cephalic version cannot be performed if the mother is in active labor and the fetus is engaged in the maternal pelvis.

INDICATIONS

Vaginal breech delivery by the Emergency Physician is indicated when the mother is in active labor and an Obstetrician is not available to perform the delivery or a cesarean section.

CONTRAINDICATIONS

There are no agreed upon absolute contraindications to a vaginal breech delivery. Recommendations have been made based upon factors that increase morbidity and mortality in vaginal and cesarean breech deliveries.[1–3,8] Maternal risk factors for increased morbidity and mortality with a vaginal breech delivery include a small pelvis, pelvic anomalies, uterine masses, uterine malformations, and arrest of labor. Fetal risk factors for increased morbidity and mortality with a vaginal breech delivery include extremes of fetal weight, fetal head extension, prematurity, nonfrank breech, and a nonreassuring fetal heart rate pattern.

There are factors regarded as unfavorable for a vaginal breech birth.[13–15] Contraindications include placenta previa, a compromised fetal condition, a clinically inadequate maternal pelvis, and the arrest of active labor. Large infants (larger than 4000 g) and low birth weight infants (smaller than 2500 g) should not be vaginally delivered if in the breech position. The footling breech presentation can result in more complications than other breech presentations when delivered vaginally. A hyperextended fetal neck makes delivery more complicated and risks injury to the fetus. A Physician not experienced in the technique should not vaginally deliver a breech fetus.

Unfortunately, many of these conditions are not known in an emergent breech presentation. The Emergency Physician may not have the time or experience to assess these conditions. Emergent cesarean delivery is indicated if any of the conditions listed above are known and the setting permits it.

The normal progress of labor with breech presentation has not been extensively evaluated. Poor progress in the active phase of labor may be a sign of fetopelvic disproportion. Failure of the breech to descend once the cervix is completely dilated should be managed with a cesarean section.[13–15]

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Electronic fetal monitor
- Delivery instrument pack (see Chapter 131)
- Piper forceps
- Towels
- Clock or timer watch
- Sterile gowns and gloves
- Chromic or Vicryl suture, 2-0 or 3-0
- Richardson or right-angle retractors
- Ring forceps
- Straight Mayo scissors
- 8 inch needle driver
- Sterile drapes

Personnel

- Two medical practitioners if available
- Nursing personnel
- Timekeeper
- Anesthesiologist or Anesthetist if available
- Pediatric or neonatal team if available

PATIENT PREPARATION

Perform an abdominal examination and cervical examination to assess the fetal position. Apply a fetal monitor and tocodynamometer to the maternal abdomen. Perform ultrasonography if available to confirm the fetal position, to estimate fetal weight, and to evaluate for any gross fetal anomaly.

Obtain an informed consent for the delivery if possible and time permits. Epidural anesthesia or a spinal block by an Anesthesiologist is recommended if available and time permits. A pudendal nerve block with local perineal infiltration may be used as an alternative. Refer to Chapter 131 for the details regarding the pudendal nerve block. Place the mother in the lithotomy position. Scrub the perineum with povidone iodine solution, chlorhexidine solution, or antibacterial soap. The Emergency Physician should apply a mask with eye protection or goggles, a sterile gown, and sterile gloves. Apply sterile drapes to isolate the patient's perineum (**Figure 131-10**).

ASSISTED VAGINAL FRANK BREECH DELIVERY

This method is appropriate for all breech presentations. The fetus enters the maternal pelvis with the bitrochanteric diameter in an oblique position (**Figure 134-2A**). The sacrum is the point of designation for these presentations. The fetus rotates with labor and

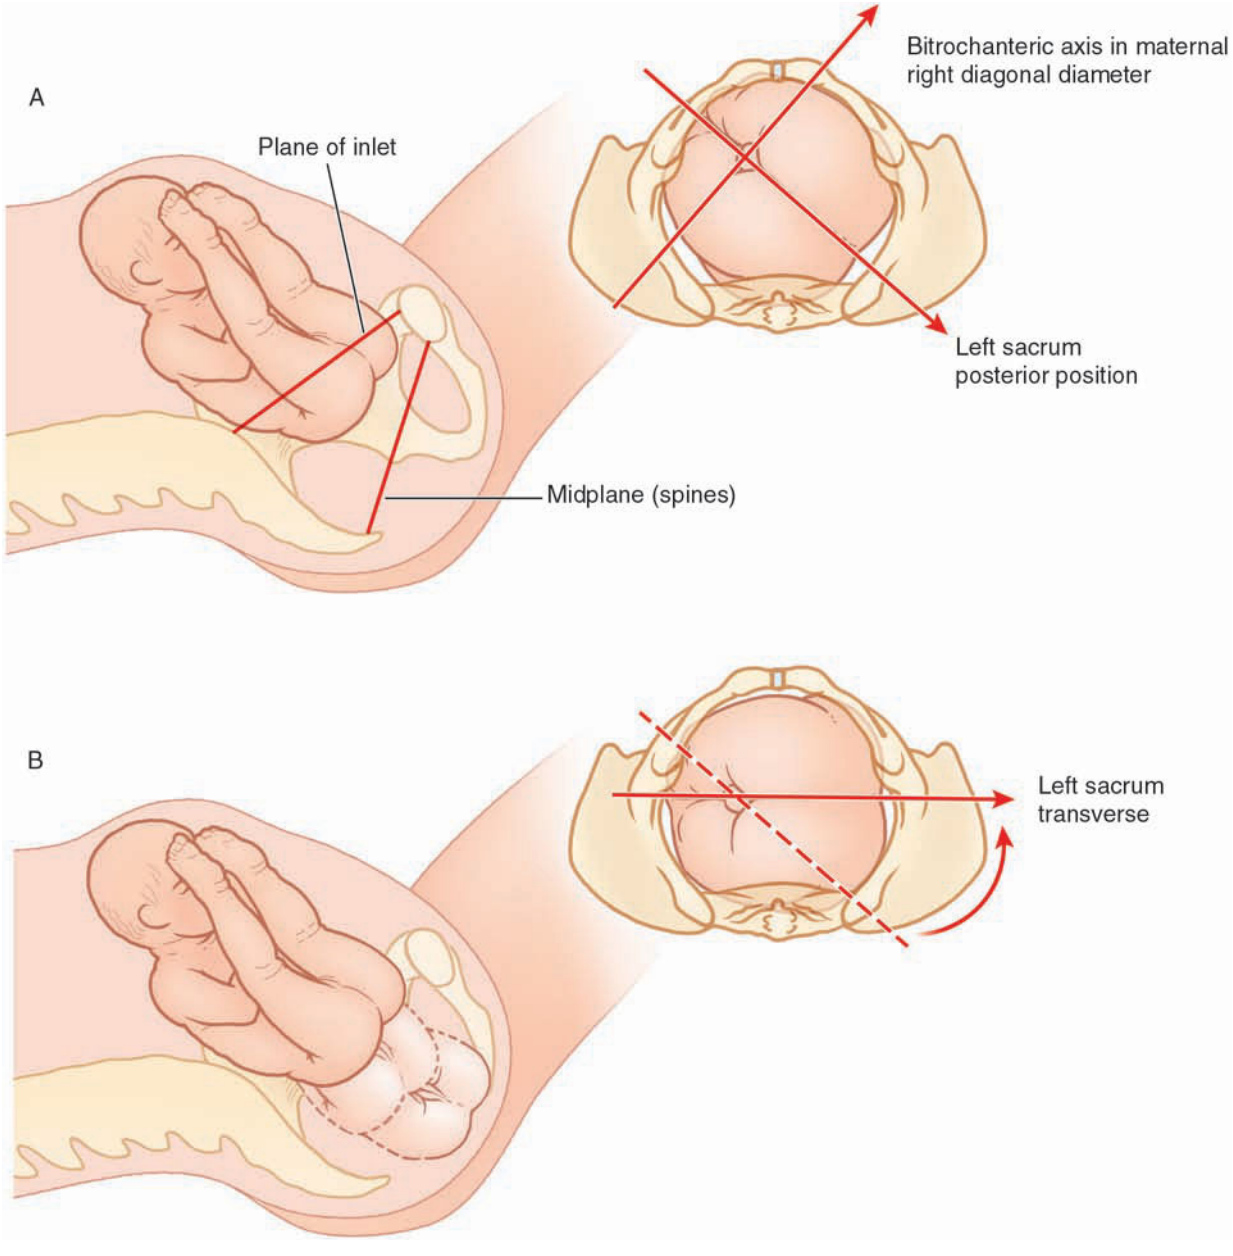

FIGURE 134-2. Breech engagement of the maternal pelvis. **A.** The bitrochanteric diameter is aligned with one of the diagonal diameters. **B.** Descent causes the bitrochanteric diameter to rotate into the anteroposterior axis and the sacrum to rotate into the transverse axis.

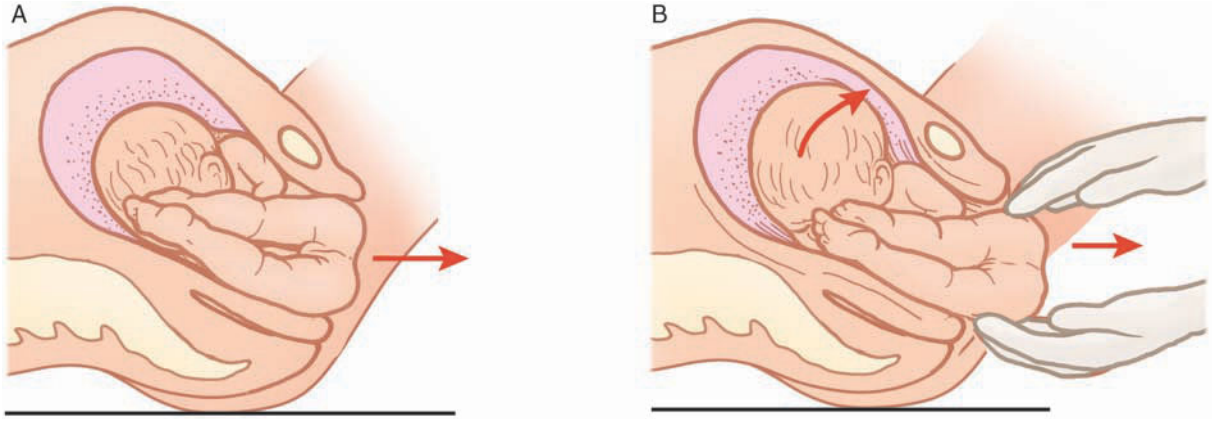

FIGURE 134-3. Delivery of the buttocks. **A.** Uterine contractions result in spontaneous emergence of the buttocks while maintaining cephalic flexion. **B.** Premature traction can result in deflexion of the vertex, head entrapment, or nuchal arms.

descent, so that the bitrochanteric diameter is in the anteroposterior axis and the sacrum is in the transverse axis (**Figure 134-2B**).

Encourage maternal "pushing" to expel the fetal buttocks (**Figure 134-3A**). Support the fetal buttocks with a toweled hand. **Do not assist with the delivery of the buttocks as they emerge (Figure 134-3B). Allow the fetus to deliver spontaneously to the level of the umbilicus with only maternal uterine propulsive efforts.** Early extraction of the buttocks increases the risk of head entrapment in a partially dilated cervix, results in deflexion of the fetal head, and increases the risk of nuchal arm entrapment. Perform a midline episiotomy when the buttocks crown. **Do not perform the episiotomy too early, as this may lead to excessive maternal blood loss.** Refer to Chapter 132 for complete details regarding an episiotomy.

Proceed with the delivery of the fetal legs when the umbilicus emerges (**Figure 134-4**). The legs will likely have delivered themselves by this time if the fetus is in the complete or incomplete breech position. Insert the fingers of the dominant hand along the long axis of the medial fetal thigh (**Figure 134-4A**). Apply laterally directed pressure on the fetal thigh to flex the knee and externally rotate the leg out and down through the vulva (**Figure 134-4A**). Simultaneously apply opposite rotation on the fetal hip and pelvis. Deliver the other leg in a similar manner (**Figure 134-4B**). **Rotation of the hip in a direction opposite the direction of knee flexion facilitates the delivery of the distal extremities. Therefore, rotate the left leg clockwise and the right leg counterclockwise.**

Prepare to deliver the fetal arms (**Figure 134-5**). Place a sterile towel around the legs and trunk of the fetus for support (**Figure 134-5A**). Continue to support the fetal body and encourage maternal pushing efforts. **Do not actively assist in the delivery until the fetal scapulae are visible. Aggressive extraction of the fetus following the delivery of the legs may cause deflexion of the vertex or nuchal entrapment of the arms.**

Proceed with active delivery of the shoulders and arms as the scapulae emerge from the vagina (**Figure 134-5**). Rotate the fetal trunk to present the anterior arm and shoulder (**Figure 134-5A**). Insert the fingers of the dominant hand longitudinally along the humerus of the presenting arm (**Figure 134-5A**). Apply traction to the humerus to flex the elbow. Sweep the arm across the chest and deliver it through the mother's vulva (**Figure 134-5B**). Rotate the fetus in a manner to bring the alternate shoulder into the anterior position (**Figure 134-5C**). Gently rotate the fetus clockwise to deliver the left arm and counterclockwise to deliver the right

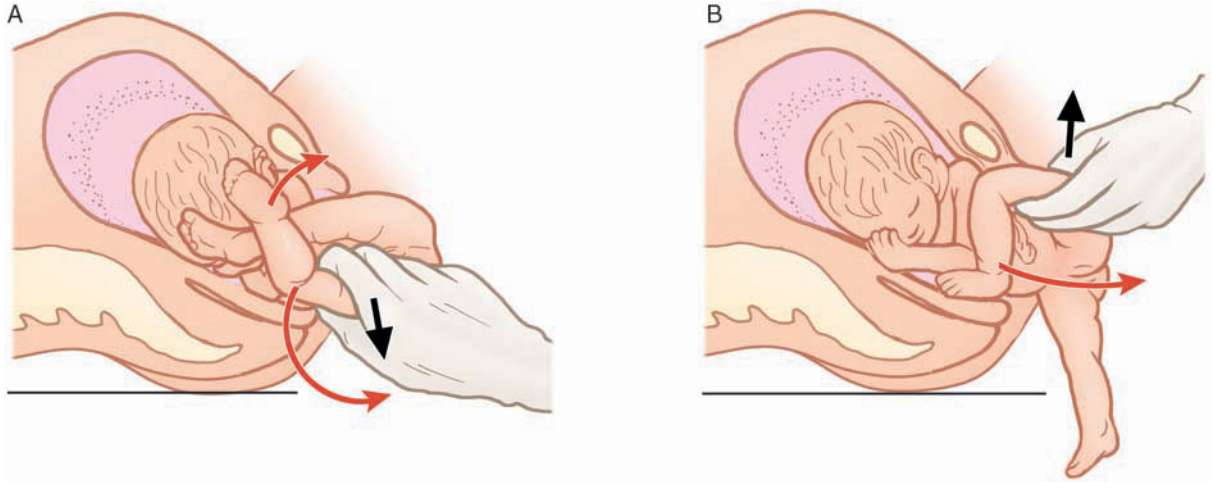

FIGURE 134-4. Delivery of the legs. **A.** Apply laterally directed pressure on the medial thigh with opposite rotation of the pelvis to deliver the leg. **B.** Repeat the procedure to deliver the other leg.

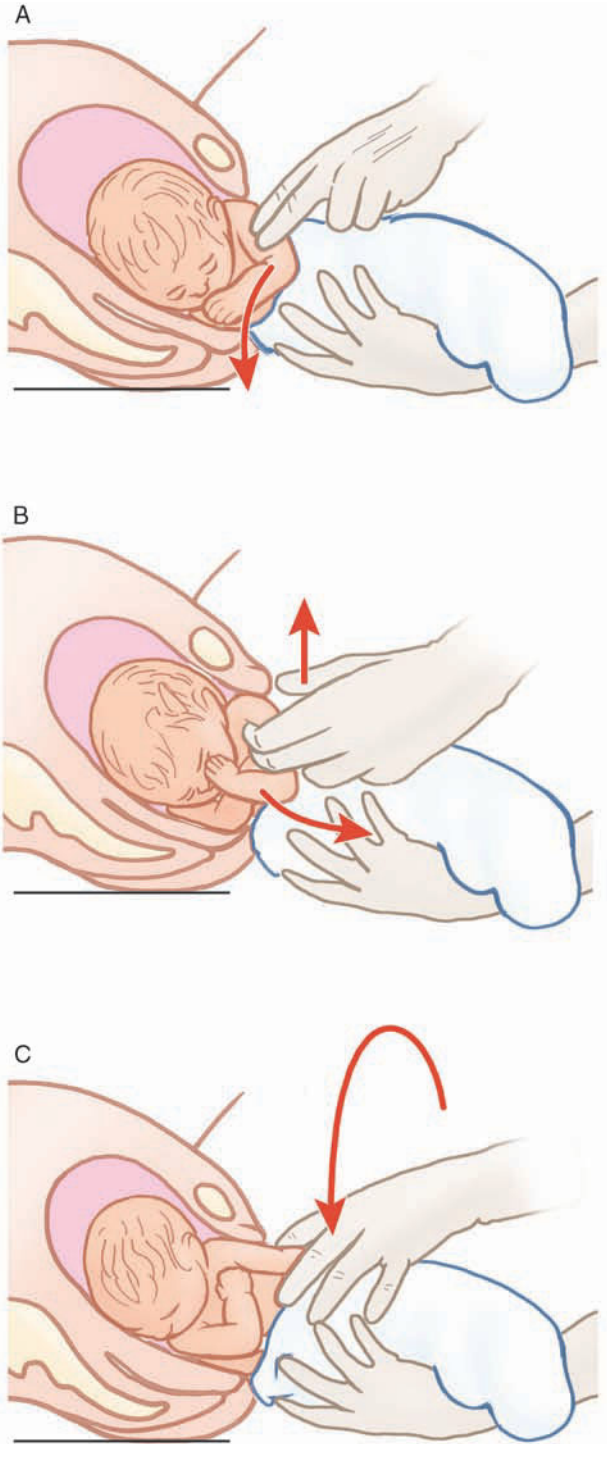

FIGURE 134-5. Delivery of the arms. **A.** Insert the dominant hand along the humerus of the anterior arm. Apply traction (*arrow*) to flex the elbow. **B.** Deliver the arm. **C.** Gently rotate the fetus so that the other arm presents anteriorly.

arm. This direction of motion prevents the arm from becoming entrapped on the neck. Repeat the procedure to deliver the second arm.

The fetal shoulders and arms may not easily deliver utilizing the above technique. Perform this alternate technique if the arms and shoulders do not deliver. Place the thumbs of both hands over the fetal posterior iliac spines and sacroiliac area. Place the palms and fingers over the fetal hips. **Apply pressure only over the iliac spines. Never grasp the fetal abdomen. The adrenal glands, kidney, liver, and spleen may be injured with excessive pressure during the delivery process.** Elevate the fetal body to deliver the posterior shoulder over the more pliable posterior perineum. Deliver the posterior arm as described above. Lower the fetal trunk. Deliver the anterior shoulder from under the maternal pubic symphysis as described above.

FIGURE 134-6. Delivery of the fetal head.

The fetal vertex will generally rotate into the anteroposterior orientation after delivery of the arms and shoulders. The fetal vertex will lie against the maternal pubic symphysis. The fetal chin will lie in the posterior aspect of the vagina and/or lower uterine segment. Wrap the fetal arms and trunk in a towel. Encourage maternal pushing efforts. The fetal head may deliver spontaneously. Note when the fetal chin and mouth appear at the posterior perineum. **Instruct the mother to stop pushing.** Suction the fetal mouth. Gently lift the infant upward to deliver the head in a controlled manner (**Figure 134-6**). **Avoid hyperextending the fetal back.**

Complete the delivery of the infant. Clamp and cut the umbilical cord. Place the infant in the warmer for examination and resuscitation. The Apgar scores for infants delivered from a breech position are generally slightly lower than from a vertex delivery. The infant may show some initial signs of short-term and generally clinically insignificant hypoxia.

DELIVERY OF THE FETAL HEAD

Cervical entrapment (inadequate cervical dilation) is a more common occurrence in the delivery of a fetus in the breech presentation. It is most frequently observed when rapid labor results in the fetal trunk being delivered through a partially dilated cervix or during the delivery of a premature breech when the fetal head is relatively larger than the fetal trunk.

The fetal head often delivers spontaneously with maternal pushing efforts, but it may occasionally fail to do so. Several options exist to aid in the delivery of the fetal head. These include manual extraction, manual extraction with the McRoberts maneuver or the Mauriceau–Smellie–Viet maneuver, forceps-assisted delivery, and Dührssen's incisions.

Adequate anesthesia is vital to the extraction of the fetal head. A pudendal block and peroneal infiltration should have been performed previously. If not, consider the administration of parenteral sedation and analgesia (Chapter 129) and local infiltration. Inhaled halogenated agents, intravenous beta-mimetics (i.e., terbutaline or ritodrine), or intravenous nitroglycerin are all useful for uterine relaxation in the event of entrapment of the after-coming head or if

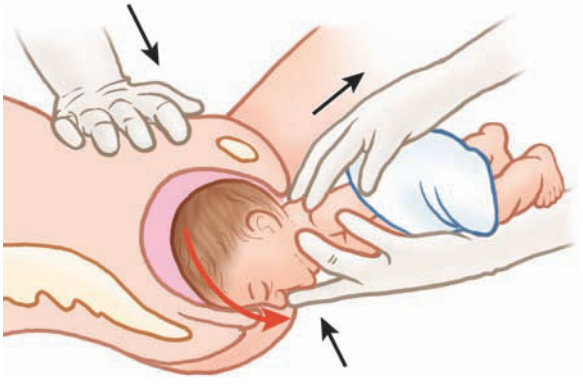

FIGURE 134-7. The Mauriceau-Smellie-Viet maneuver.

intrauterine manipulation is necessary. Utilize assistants as needed to offer adequate visualization. Gently place Richardson or Pratt retractors in the vagina to maximize the view.

McROBERTS MANEUVER

Apply the McRoberts maneuver if the fetal head does not deliver. The McRoberts maneuver is easy to perform (**Figure 133-6**). Place an assistant on each side of the patient. Hyperflex the mother's thighs onto her abdomen (**Figure 133-6A**). Instruct the assistants to maintain support of the hyperflexion while applying suprapubic pressure (**Figure 133-6B**). This results in flattening of the lumbosacral curve with rotation of the pubic symphysis cephalad (**Figure 133-6C**). Perform the manual extraction.

MAURICEAU–SMELLIE–VIET MANEUVER

Perform the Mauriceau–Smellie–Viet maneuver if the McRoberts maneuver is unsuccessful in the spontaneous delivery of the head (**Figure 134-7**). Rest the body of the infant on the dominant arm. Place the index and middle finger of the dominant hand on the fetal maxilla. Apply pressure to the maxilla to maintain the fetal head in flexion. **Do not place the fingers on the fetal mandible or in the fetal mouth.** Place the nondominant hand on the posterior aspect of the fetal neck and shoulders. Slightly elevate the fetal body from the horizontal plane.

Exert continued and gentle downward traction with both hands until the occiput moves under the mother's pubic symphysis. **Never hyperextend the fetal trunk to avoid spinal cord injuries. Never apply pressure to the mandible or the fetal mouth during this maneuver. The force applied to the mandible or mouth can dislocate the mandible.** Instruct an assistant to apply firm and gentle suprapubic pressure in conjunction with gentle downward traction by the operator. Continue this process until the head delivers.

FORCEPS-ASSISTED DELIVERY OF THE HEAD

The utilization of forceps may be warranted if none of these maneuvers is successful.[14,17] The Piper forceps have a minimal pelvic curve, allowing direct application to the fetal head. They are used solely for the delivery of an after-coming head in the breech delivery. **Forceps-assisted delivery can result in significant injury to the fetus and the mother. The use of the Piper forceps is not recommended unless the Emergency Physician has training and experience in their proper use.**

Apply the Piper forceps. Instruct an assistant to elevate the fetal trunk slightly above the horizontal plane (**Figure 134-8A**). Kneel below the fetus. Insert the forceps directly into the vagina and along the fetal head. Apply the right forceps blade. Grasp the blade in the left hand. Place the right hand along the left fetal parietal bone, between the fetal head and the right maternal pelvic side wall. Insert and apply the forceps blade. Instruct the assistant to hold the blade in this position. Apply the left forceps blade. Grasp the blade in the right hand. Place the left hand along the right fetal parietal bone, between the fetal head and the left maternal pelvic side wall. Insert

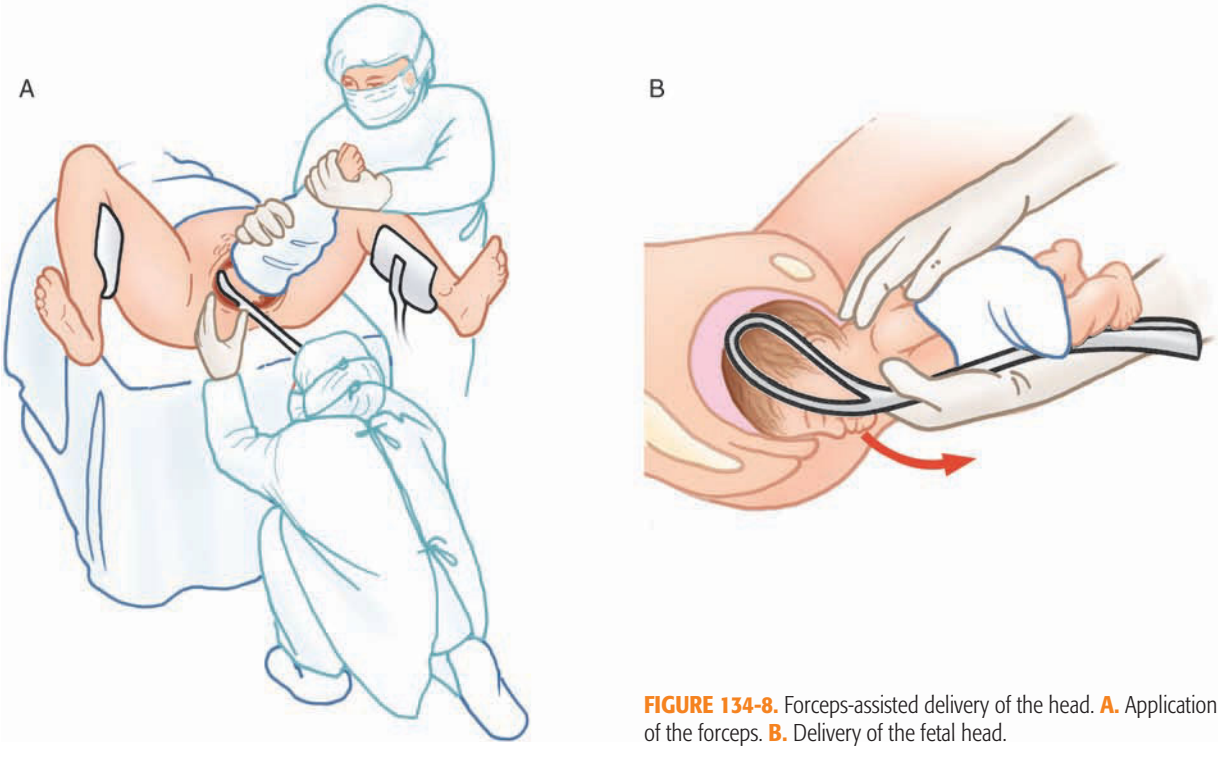

FIGURE 134-8. Forceps-assisted delivery of the head. **A.** Application of the forceps. **B.** Delivery of the fetal head.

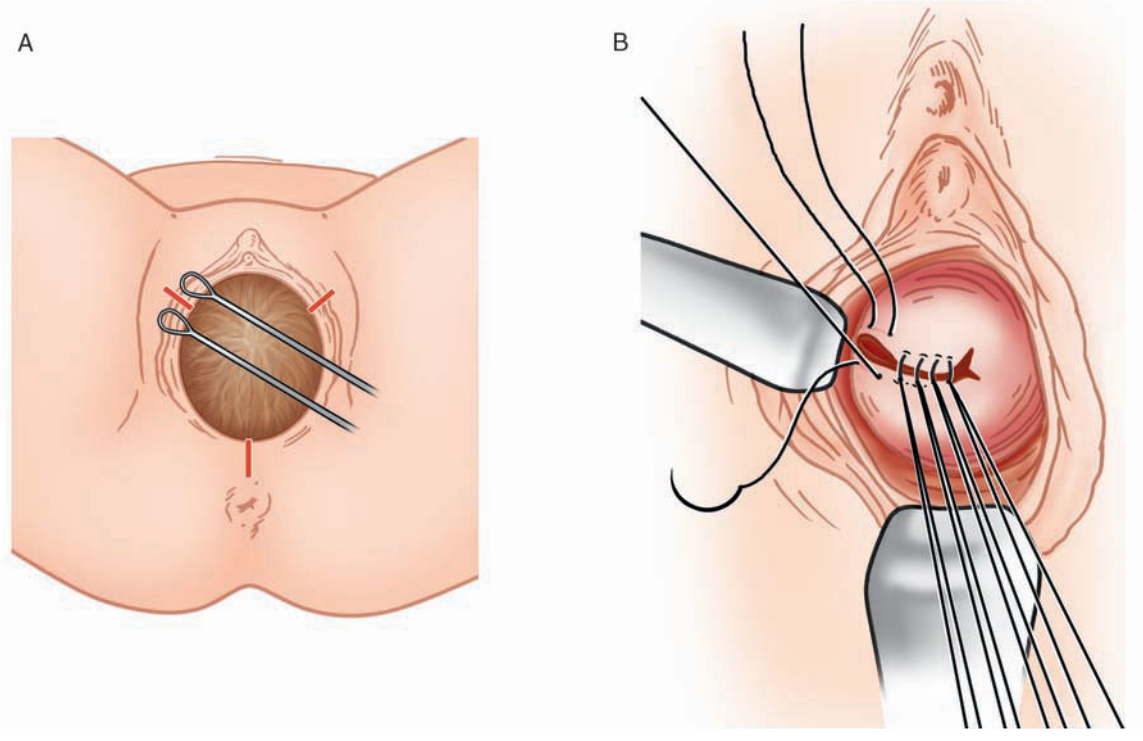

FIGURE 134-9. Dührssen's incisions. **A.** The incisions. **B.** Repair of the incisions.

and apply the forceps blade. Gently join the forceps handles while avoiding excessive pressure.

Apply gentle downward and outward traction to the forceps blades to deliver the fetal head (**Figure 134-8B**). Slowly elevate the plane of the fetal trunk toward the maternal abdomen as the fetal face delivers. **Do not hyperextend the fetal neck.** Stop the extraction as the mouth appears. Gently suction the fetal mouth. Deliver the head.

DÜHRSSEN'S INCISIONS

Perform Dührssen's incisions if the fetal head is entrapped, if other methods of extraction have failed, and if you are unfamiliar with the use of forceps. Dührssen's incisions consist of two to four incisions placed circumferentially around the cervix (**Figure 134-9**). **The two required incisions are at the 10 and 2 o'clock positions.** Additional incisions can be made at the 5, 6, and/or 7 o'clock positions. **The cervix must be more than 70% effaced and dilated more than 6 cm for the procedure to be successful and to prevent significant hemorrhage.**

Grasp two pairs of ring forceps. Grasp the cervix around the point of the incision. For example, place ring forceps at the 9 and 11 o'clock positions to make the 10 o'clock incision (**Figure 134-9A**). Make the incisions 2 to 3 cm in length with a straight Mayo scissors. Deliver the fetal head.

PERSISTENT FETAL HEAD ENTRAPMENT

The fetal head may fail deliver despite the maneuvers described above. True cephalopelvic disproportion must be differentiated from cervical entrapment (inadequate cervical dilation). The options are limited in the rare case of a true cephalopelvic disproportion. The Emergency Physician can perform a symphysiotomy (Chapter 137), the fetal body can be pushed back into the uterus and a cesarean section performed, or an experienced Obstetrician may perform a destructive procedure if the fetus is nonviable.

TOTAL BREECH EXTRACTION

Breech extraction is to be performed only in the rare instances of a second twin presenting in a breech position, extreme fetal distress without the capability of performing a cesarean section, and/or umbilical cord prolapse that does not allow time for setup or performance of a cesarean section.[2,17–19]

If available, utilize ultrasound to identify the fetal legs and feet. This will ensure you grasp the appropriate extremity. Reach into the lower uterine segment with the dominant hand and firmly grasp the fetal feet. Place the fingers around the fetus's ankles, with the index finger between the two ankles (**Figure 134-10A**). Apply continuous and firm traction in a downward and outward direction. Deliver the fetal feet and legs through the vaginal opening (**Figure 134-10A**). Continue to apply traction to deliver the fetus to the level of the buttocks (**Figure 134-10B**). Instruct an assistant to support the fetus. Perform a midline episiotomy if necessary. Deliver the fetus to the level of the umbilicus. Grasp the bony sacrum and pelvis. The remainder of the technique is as described above.

COMPLETE AND INCOMPLETE BREECH DELIVERIES

Complete and incomplete breech deliveries may occur in the same fashion as the frank vaginal breech delivery. The one exception is that one or both feet may already be extended and not require attention.[2] There is an increased risk of umbilical cord prolapse, umbilical cord entanglement, and entrapment of the after-coming head.[2,7,10] This is the basis for the recommendation for cesarean delivery in these cases.[2,7,10] However, one randomized trial reported nonfrank vaginal breech delivery to be relatively safe as well.[2,10]

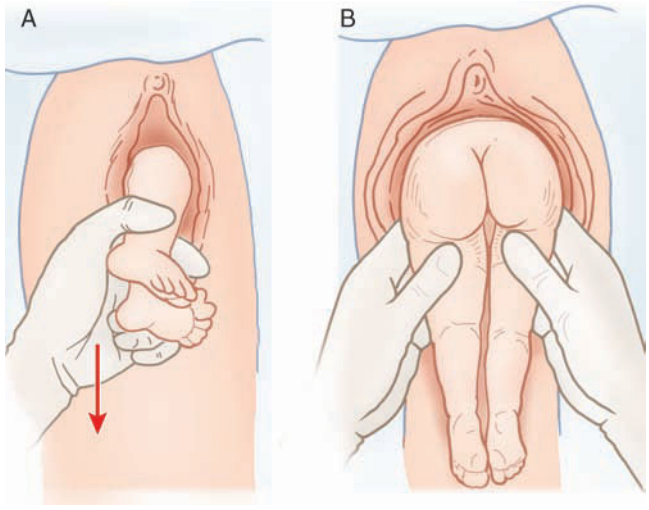

FIGURE 134-10. Breech extraction. Reach into the uterus and grasp the fetal ankles. **A.** Apply traction to deliver the feet and ankles. **B.** Delivery of the buttocks.

ASSESSMENT

The two patients must now be assessed and treated. If available, a second Physician or neonatal team can evaluate and resuscitate the infant. Determine the infant's Apgar score. Examine the infant for birth trauma and signs of prematurity (e.g., fusing of eyelids), as both correlate with perinatal morbidity and mortality.

The maternal assessment should occur simultaneously with that of the neonate. Offering reassurance to the mother while delivering the placenta and evaluating for postpartum hemorrhage is of the utmost importance.

AFTERCARE

The Apgar scores for infants delivered from a breech position are generally slightly lower than from a vertex delivery. The infant may show some initial signs of short-term and generally clinically insignificant hypoxia.

Postpartum recovery for the mother is generally uneventful. She should be observed for evidence of infection or symptomatic anemia. If regional anesthesia is used or if there is significant perineal trauma, urinary output should be monitored for the presence of urinary retention.

Deliver the placenta and repair the cervix if there are any lacerations or Dührssen's incisions. An episiotomy, perineal laceration, and/or vaginal laceration must be repaired (Chapters 132 and 135). Initiate uterine massage. Administer pitocin intramuscularly following delivery of the placenta.

It is vital that postpartum hemorrhage be managed to prevent maternal morbidity and mortality. Refer to Chapter 135 regarding the details of postpartum hemorrhage management. Grasp the base of each cervical incision or laceration to decrease the bleeding. If the distal angle is difficult to visualize, do not waste time attempting to locate it. Apply traction to the proximal edges of the incision or laceration with ring forceps. Alternatively, place 2-0 chromic, Dexon, or Vicryl sutures along the edges of the cervical incision or laceration that can be visualized. Place progressively proximal interrupted sutures until the base is completely visualized (**Figure 134-9B**). Apply traction to the sutures to better visualize the cervical incision or laceration.

COMPLICATIONS

Maternal complications associated with the performance of a vaginal breech delivery include lacerations (e.g., cervical, vaginal, and/or perineal), episiotomy extension, infection, postpartum hemorrhage, and hematomas (e.g., vaginal or pelvic).

Neonatal complications include hypoxia, anoxia (i.e., perinatal asphyxia), umbilical cord prolapse, fractures (e.g., cranial, femoral, and clavicular), cerebral hemorrhage, cephalohematomas, lacerations, brachial nerve palsy, cerebral palsy, spinal cord injuries from head hyperextension, arrest of the after-coming head, and death[1,2,7,8,10,20–25] Recent studies suggest that the occurrence of these complications may be greatly influenced by the urgency of the delivery rather than solely the method of delivery.[2] Thus, an adequately prepared Emergency Physician may not be able to prevent these complications but will less likely contribute to them.

There are complications that are unique to the breech presentation. Head entrapment is a potentially serious complication of breech delivery. The head is often the largest part of the fetus. There is no time for molding of the aftercoming breech head. If the fetal head does not deliver easily after delivery of the torso, umbilical cord compressions can contribute to fetal hypoxia, acidosis, and death. Attempts to expedite delivery can result in maternal and fetal trauma. The risk of head entrapment is especially high in the preterm infant before 30 weeks as the head is large in relation to the body.[16]

Nonfrank breech presentation has an increased incidence of umbilical cord prolapse as the presenting part may not completely occlude the cervix. The risks of umbilical cord prolapse and prematurity associated with the breech presentation are listed in **Table 134-1**.

SUMMARY

Perinatal survival is similar for the delivery of a breech infant vaginally or by cesarean section, although controversy still exists. Increased morbidity and mortality may be seen with estimated fetal weights of less than 1500 g or greater than 4000 g, single or double footling presentation, a diminished maternal pelvis, cephalic hyperextension, or in the hands of an inexperienced provider. Cesarean section is preferable in these instances if available. The Emergency Physician managing an imminent breech delivery should be well aware of not only the potential complications but also the relative indications for cesarean delivery and the techniques and tools for vaginal delivery in order to lessen the inherent risks to both patients.

135 Postpartum Hemorrhage Management

Leah W. Antoniewicz

INTRODUCTION

Postpartum hemorrhage, or excessive blood loss following delivery, is the leading cause of maternal death worldwide. It is traditionally defined as blood loss greater than 500 mL after vaginal delivery and 1000 mL after a cesarean section.[1] This is impractical because the normal blood loss is believed to be 300 to 500 mL following a vaginal delivery and 900 to 1200 mL following a cesarean section.[2] It has also been defined as blood loss that results in a decrease in

TABLE 135-1 Anatomic Sites of Postpartum Hemorrhage

Anus
Broad ligament
Cervix
Contractile tissue (previous uterine incision)
Episiotomy incisions
Lower urinary tract (periurethral area, urethra, bladder)
Noncontractile/poorly contractile tissue (lower uterine segment)
Perineum (perineal body, rectum)
Placental implantation site
Rectum
Tissue tears
Vagina (fornices, hymen, anomalous septa, side walls)

TABLE 135-2 Etiologic Associations for Postpartum Hemorrhage

Altered maternal anatomy	Operative delivery
Altered uterine contractility	Pitocin use, prolonged
Asian ethnicity	Placental abruption
Cesarean section dehiscence or rupture	Placenta previa
Chorioamnionitis	Postpartum hemorrhage history
Coagulopathy	Precipitous delivery
Compound delivery	Preeclampsia
Disseminated intravascular coagulation	Prolonged or tumultuous labor
Dührssen's incisions	Reproductive tract anomalies
Endometritis	Retained placental fragments
Episiotomy	Shoulder dystocia
Fetal scalp electrode injury	Tissue lacerations
General anesthesia	Tocolytic use
Grand multiparity	Trauma
Hispanic ethnicity	Uterine anomalies
Infection	Uterine atony
Intrauterine pressure catheter injury	Uterine inversion
Myomectomy dehiscence or rupture	Uterine leiomyomata
Occiput posterior delivery	Uterine pressure monitor injury
	Uterine rupture
	Von Willebrand's coagulopathy

the hematocrit of greater than 10 points between admission and the postpartum period, which corresponds to the 97th percentile of vaginal and 92nd percentile of cesarean deliveries.[1,2] A clinically useful definition is excessive bleeding that results in signs and/or symptoms of hypovolemia (e.g., tachycardia, hypotension, oliguria, dizziness, palpitations, syncope, and/or shortness of breath), which corresponds to a 10% or more loss in total blood volume.[3] Postpartum hemorrhage can occur at sites within or external to the genitourinary tract (**Table 135-1**).

The incidence of postpartum hemorrhage ranges from 4% to 6% of pregnancies in the United States.[3] Primary postpartum hemorrhage accounts for greater than 90% of all cases and occurs within 24 hours of delivery. It is most commonly the result of excessive bleeding from the placental implantation site (uterine atony) or trauma to the genital tract. It can be associated with a considerable drop in hematocrit and significant maternal complications. Secondary postpartum hemorrhage occurs more than 24 hours after delivery and up to 12 weeks postpartum. It is usually the result of excessive bleeding from the placental implantation site or retained products of conception, but can also be caused by an infection or coagulation defects.[3,6] This chapter reviews the pathophysiology of early postpartum hemorrhage, discusses the diagnosis and assessment of postpartum hemorrhage, and concludes with strategies for treatment.

ANATOMY AND PATHOPHYSIOLOGY

The most common causes of postpartum hemorrhage are uterine atony (70% to 90%), genital tract trauma (5% to 8%), retained products of conception (3% to 5%), and hematologic or coagulopathic abnormalities (<2%). Uterine inversion is a rare cause of postpartum hemorrhage. Risk factors for uterine atony include a prolonged third stage of labor, induced or augmented labor, high parity, an overdistended uterus, use of uterine relaxing agents, chorioamnionitis, some types of anesthesia, and previous postpartum hemorrhage.[1] Genital tract injuries include vaginal or cervical lacerations, episiotomies, vulvar or vaginal hematomas, and uterine rupture. Retention of all or part of the placenta interferes with uterine contraction, resulting in continued bleeding from the implantation site. Hematologic abnormalities include von Willebrand's disease, disseminated intravascular coagulation, and other less common inherited, congenital, or acquired disorders.

In a normal pregnancy, the plasma volume increases by approximately 40% and the red cell mass by 25% resulting in a hypervolemia of about 1500 to 2000 mL.[3,5] This compensates for typical blood losses. Visual estimates of blood loss are inaccurate, especially if blood is mixed with amniotic fluid. **Weigh all pads for an accurate assessment (1 g = 1 mL of blood).** The signs and symptoms of postpartum hemorrhage include measurable blood loss greater than 500 mL, tachycardia, hypotension, oliguria, syncope, pallor, diaphoresis, palpitations, dizziness, shortness of breath, and fatigue. Concealed hemorrhage from a vaginal hematoma, uterine rupture, or broad ligament hematoma must be suspected if the patient is symptomatic in the absence of obvious blood loss.

Patients at risk for postpartum hemorrhage require blood typed and held on admission. Leading risk factors associated with early postpartum hemorrhage in vaginal birth include prolonged third stage of labor, preeclampsia, mediolateral episiotomy, previous postpartum hemorrhage, multiple gestations, arrest of descent, and soft tissue lacerations.[1] Other risk factors are listed in **Table 135-2**. Surgical deliveries, as compared with vaginal deliveries, are often associated with increased blood loss. Inhalation anesthesia, especially with halogenated agents, increases the risk for postpartum hemorrhage and should be used sparingly in high-risk cases.[5,7] Other risk factors for postpartum hemorrhage in cesarean deliveries include chorioamnionitis, preeclampsia, protracted active phase of labor, and arrest of descent.[2]

INDICATIONS

All postpartum hemorrhage must be controlled as soon as possible to prevent maternal morbidity and mortality. The two foremost causes of postpartum hemorrhage are uterine atony and lower genital tract lacerations. Such lacerations and injuries are most common with difficult deliveries, especially operative vaginal deliveries, and with the use of an episiotomy. Carefully examine the vagina and cervix for injury immediately following delivery of the infant and placenta. If present, these factors should be noted and the possibility of postpartum hemorrhage anticipated.

CONTRAINDICATIONS

There are no absolute contraindications to the management of postpartum hemorrhage. Therapies for postpartum hemorrhage, specifically drug therapy for uterine atony, may have significant side

effects. Avoid undiluted rapid IV infusions of oxytocin which can cause hypotension. Ergots, such as methylergonovine, are potent vasoconstrictors and should be given intramuscularly. They are contraindicated in the presence of cardiac disorders, coronary artery disease, hypertensive disorders, preeclampsia, scleroderma, and Raynaud's phenomenon. Prostaglandin F (PGF) is contraindicated in patients with active asthma as it can incite severe bronchospasm in sensitive individuals.[4] It may also result in vasoconstriction of the pulmonary bed.[4] The side effects include diarrhea, fever, and tachycardia. PGE_2 (Prostin) should be avoided in hypotensive patients. Human recombinant factor VIIa is a new, expensive treatment for life-threatening hemorrhage but can cause subsequent thromboembolism.[8]

EQUIPMENT

- Sterile gown and gloves
- Face mask with eye shield or goggles
- Cap
- Povidone iodine or chlorhexidine solution
- Foley catheter
- Gauze sponges
- Sponge-tipped applicators (large)
- Sterile delivery drapes
- Alcohol swabs
- 16 to 18 gauge needle
- 10 mL syringe
- 22 to 25 gauge epidural needle for injection
- Weighted vaginal speculum or Sims retractor
- Two right angle (Heaney) retractors
- Four ring forceps
- Straight Mayo scissors or sterile scalpel
- 2-0 or 3-0 suture: polyglactin (Vicryl) or chromic gut
- SOS Bakri tamponade balloon
- Sengstaken–Blakemore tube
- Three 30 mL bulb Foley catheters
- Packing forceps

Medications

- Local anesthetic solution (lidocaine, bupivacaine, or mepivacaine)
- Oxytocin (Pitocin)
- Methylergonovine maleate (Methergine)
- 15-methyl $PGF_{2\alpha}$ (Hemabate, Carboprost)
- Misoprostol or PGE_1 (Cytotec)
- Dinoprostone or PGE_2 (Prostin)
- Factor VIIa (NovoSeven)
- 4-inch gauze soaked with 5000 U of thrombin in 5 mL of saline

PATIENT PREPARATION

The initial management must be aimed at stabilizing the mother and identifying the bleeding source. Apply bimanual compression (**Figure 135-1**), which will control most hemorrhage, and obtain help. Establish intravenous access at two sites with 16 to 18 gauge angiocatheters. Type and cross match the patient for any required blood components if not done previously. Place a Foley catheter to monitor urine output and to allow the uterus to contract. Regulate fluid intake carefully.

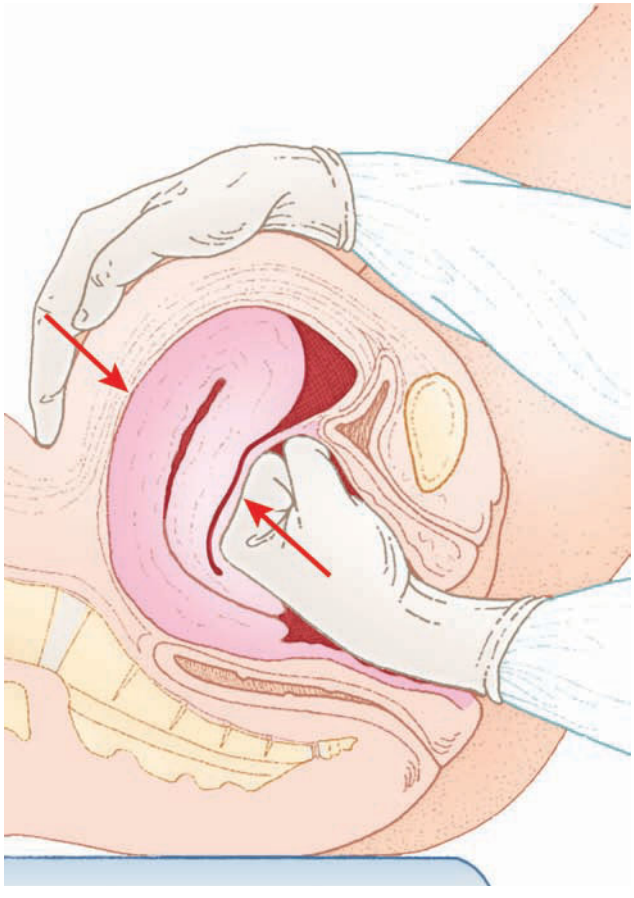

FIGURE 135-1. Bimanual uterine compression for uterine atony.

Identification of the origin or site of bleeding is critical. Uterine hypotonia is the most frequent source of hemorrhage. Therefore, uterotonics are usually administered concurrently with a complete examination of the uterus. Palpation will often exhibit a boggy, soft, and spongy uterus that may be increasing in size due to the accumulation of clots and blood within the endometrial cavity. These must be cleared to allow for adequate uterine contractions. Continued bleeding from the endometrial cavity through the cervical os is always present. A well-contracted uterus does not bleed significantly in the absence of a severe coagulopathy. Examination of the uterus is performed by palpation of the fundus with the nondominant hand and manual exploration of the uterine cavity with the other. Ultrasound may be used to ascertain the presence of placental tissue or clots that may require manual removal and/or curettage.

Continued hemorrhage with a firm uterus indicates bleeding from another source such as the lower uterine segment, the cervix, or the vagina. **Examine all areas carefully, even after hemorrhage is noted at one site, as there may be more than one source of hemorrhage.** Begin at the most distal aspects of the genital tract and work proximally.

TECHNIQUES

UTERINE ATONY

Oxytocin and fundal (transabdominal) massage should be initiated just after delivery of the placenta, which usually results in a firm, contracted (rock-like) fundus. However, the uterus may never become firm or may relax again.

Uterine atony is identified by palpating a soft and boggy uterus. Begin transabdominal uterine massage to promote uterine muscle contractions. Use one or two hands to palpate the uterus through the abdominal wall and rhythmically press downward in a circular motion. Massage in a firm but gentle manner, without pushing the uterus through the birth canal (inversion). **Avoid overly vigorous massage, as this can injure the vasculature of the broad ligament.**[5]

Initiate an oxytocin infusion at the same time as fundal massage. Inject 40 units of oxytocin into 1 L of intravenous sterile normal saline. Allow this solution to infuse over 10 minutes. Alternatively, administer 10 U of oxytocin intramuscularly. Repeat the oxytocin dose if atony persists.

Continued bleeding requires the initiation of bimanual uterine compression. Massage the posterior aspect of the uterus with the abdominal hand and the anterior aspect of the uterus through the vagina with the other hand clenched into a fist (**Figure 135-1**).[5] Use the intravaginal hand to massage the uterus against the external pressure applied by the abdominal hand. This allows for more effective uterine massage. Perform manual uterine exploration if the massage fails to control the hemorrhage. Manual uterine exploration can localize and extract any placental fragments remaining within the uterus.

Begin second-line medications to contract the uterus if bimanual massage is ineffective. **Consult an Obstetrician prior to administering any of these medications.** In the nonhypertensive patient, administer 0.2 mg of methylergonovine (Methergine) intramuscularly. This is an ergot derivative that causes uterine contraction. The dose may be repeated every 2 to 4 hours. Prostaglandin F-2 (Hemabate) is a potent stimulator of uterine contraction.[9] Administer 250 µg intramuscularly or transabdominally into the uterine musculature every 15 to 90 minutes to a maximum total dose of 2 mg. Misoprostol (Cytotec) has been widely used and is inexpensive, safe to use in patients with hypertension, and safe to use in patients with asthma. Administer 800 to 1000 µg (in 100 µg tablets) rectally. This dose may be repeated every 4 to 6 hours. Monitor the patient's temperature frequently as pyrexia can occur. Dinoprostone (Prostin) 20 mg rectal suppository is preferred over the intravaginal route as continued bleeding may expel the suppository. This may be repeated every 2 hours. Consider using 16.7 to 200 µg/kg of factor VIIa concentrate (NovoSeven) intravenously. This agent has the potential to cause intravascular clot formation with subsequent end organ damage.

Sustained bleeding requires an Obstetrician for curettage or other operative management. A discussion of these techniques is beyond the scope of this chapter. Tamponade the uterus while waiting as described below. Alternatively, consult an Interventional Radiologist, if available, to consider uterine artery embolization.

BALLOON TAMPONADE

The SOS Bakri balloon was designed to tamponade the uterus for postpartum bleeding.[10] Gently grasp the balloon with a ringed forceps. Insert it into the uterus transcervically. Hold the tubing in place at the cervical os to ensure the balloon remains above the cervix. Instill 300 to 500 mL of sterile saline to inflate the balloon. Clamp the tubing. Apply gentle traction. Secure the tube to the patient's thigh or attach a 500 mL saline bag to the tubing as a weight. Blood will drain from sites proximal to the tube. If bleeding is excessive, tamponade has failed.

If a Bakri balloon is not available, use a Sengstaken–Blakemore tube. These are often available in the Emergency Department. Insert the Sengstaken–Blakemore tube into the uterine cavity. Inflate the gastric balloon with 250 mL of sterile saline. Apply slight traction and secure the tube as described above. Flush the lumen of the Sengstaken–Blakemore tube with 10 mL of sterile saline to clear any clots or blood collected behind the balloon.

If neither of these devices is available, use Foley catheters with a 30 mL balloon. Gently grasp the distal end of the Foley catheter with ring forceps. Insert it completely into the uterus. Securely hold the catheter in place. Instruct an assistant to instill 50 to 60 mL of sterile saline into the balloon and clamp the tubing. Repeat this procedure with up to two more Foley catheters to completely fill the endometrial cavity and tamponade the hemorrhage.

UTERINE PACKING

If none of the previously mentioned devices are available or if they fail, consider packing the uterus. Tightly pack the uterus, starting at the fundus and working outwards, with 4-inch wide gauze roll (e.g., Kerlix) soaked in 5 mL sterile saline and 5000 units of thrombin. Administer intravenous broad spectrum antibiotics if the uterus is packed with gauze to prevent a subsequent toxic shock syndrome. Carefully monitor hematocrit, urine output, and uterine size. Blood may collect behind in the uterus with all forms of tamponade.

RETAINED PLACENTA

Postpartum hemorrhage, whether primary or secondary, may be caused by retained placental tissue within the uterine cavity. The retained placental tissue may be completely attached, partially separated, or completely separated from the uterine wall. Placental fragments completely attached to the uterine wall may not be removable manually and may require a curettage or laparotomy. Completely or partially separated placental fragments may remain due to a closed cervix entrapping them or inadequate uterine contractions. Manual extraction will remove the retained placental fragments. **Administer adequate anesthesia. A uterine relaxant may be utilized to relax the lower uterine segment in the absence of uterine atony. This must be performed using strict aseptic technique.**

Insert a sterile gloved hand through the open cervix and into the uterine cavity (**Figure 135-2**). Place the other hand on the abdominal wall and over the fundus of the uterus. Gently and carefully sweep the fingers around the circumference of the uterus to determine if any fragments of placenta remain. Identify the edge of the fragment if it has not separated from the uterine wall. Gently place the fingertips under the edge of the fragment. Gently remove any placental fragments from the uterus by alternating abducting, adducting, and advancing the fingers in a scissors-like motion until the entire fragment is separated from the uterus.[8] Grasp and gently remove the placental fragments when separated from the uterine wall. **Ensure that the entire placenta is removed. Reinsert a hand into the uterine cavity and palpate for any remaining placental fragments. Examine the placenta carefully to make sure that no cotyledons are missing.**

Determine if any placental membranes are retained. Reinsert the gloved hand covered with a gauze sponge (**Figure 135-3**). Wipe the uterine walls with the sponge to collect any retained membranes. Remove the gauze sponge with any adherent membranes.

Identify the edge of the placenta if it has not separated from the uterine wall. Gently place the fingertips under the edge of the placenta, forming a line of cleavage between the uterine wall and the placenta. Alternately abduct, adduct, and advance the fingers in a scissors-like motion until the entire placenta is separated from the fundus (**Figure 135-2**).[8] Gently remove the placenta from the uterine cavity. **Make sure that the entire placenta is removed. Reinsert a hand into the uterine cavity and palpate for any remaining placental fragments. Examine the placenta carefully to make sure that no cotyledons are missing.** Initiate intravenous oxytocin following removal of the placenta.

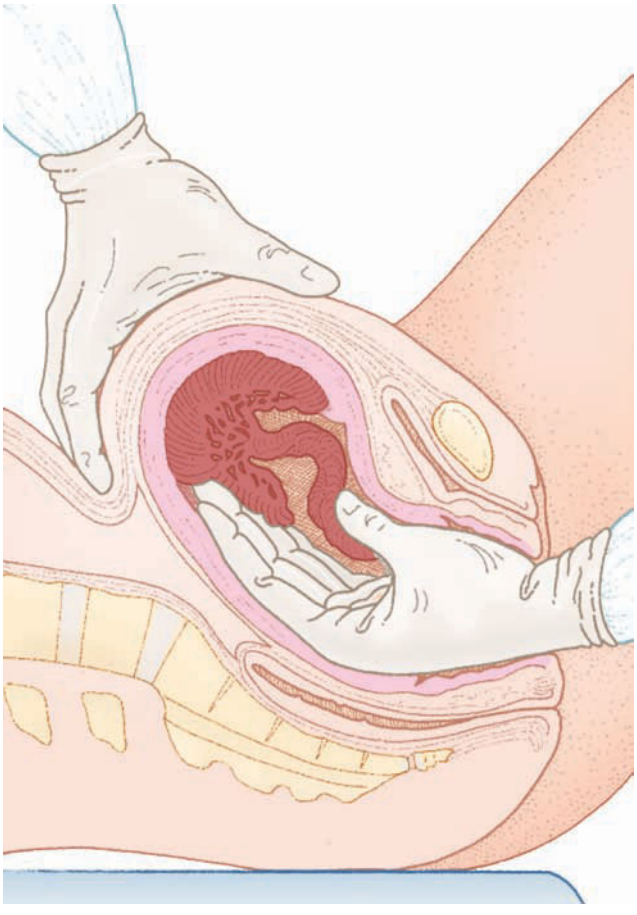

FIGURE 135-2. Manual removal of the placenta. The fingers are abducted, adducted, and advanced continually (in a scissor-like motion) in this sequence of movements until the placenta is completely detached.

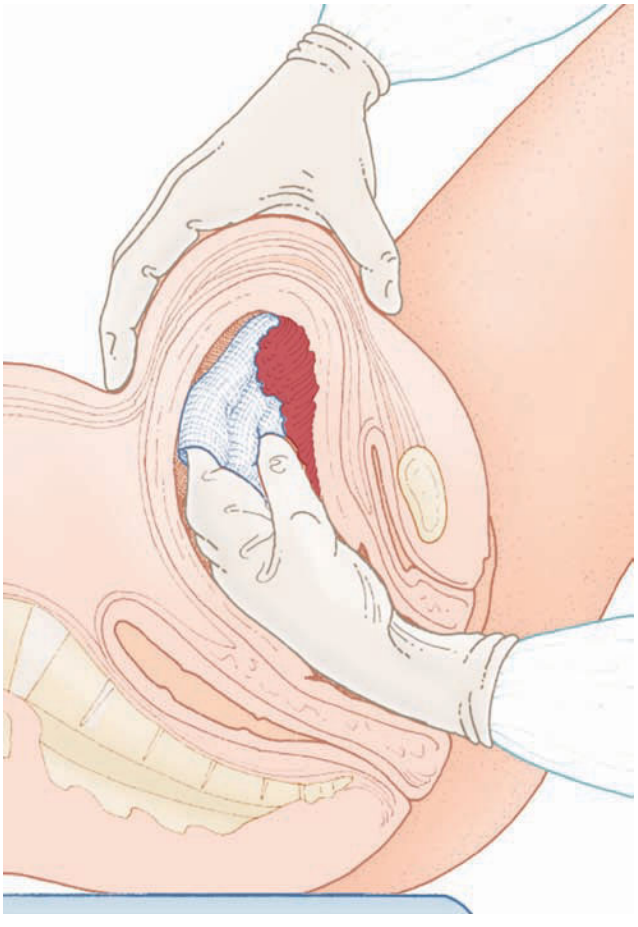

FIGURE 135-3. Manual removal of retained placental membranes.

The placenta is likely embedded into the wall of the uterus if it does not manually separate. This is known as placenta accreta, percreta, or increta depending on the degree of myometrial penetration. Consult an Obstetrician as a laparotomy, hysterotomy, and possibly a hysterectomy will be required.

GENITAL TRACT ABNORMALITIES

Bleeding from the lower uterine segment, cervix, or upper vagina is difficult to diagnose and manage. The anatomic locations are awkward and difficult to visualize. Excessive bleeding makes visualization even more problematic. It may be almost impossible to see a small laceration or an individual bleeding vessel. **Do not attempt to repair a laceration that cannot be completely visualized as this could result in damage to other structures.** The uterotonic medications, such as oxytocin and the prostaglandins, are less effective due to the relative paucity of contractile muscle in these tissues. Consider packing the uterus with gauze or a vaginal pack if available. Management of excessive bleeding from this area may require a laparotomy with uterine artery embolization or a hysterectomy. Discussion of these techniques is beyond the scope of this chapter.

LACERATION REPAIR

All lacerations must be repaired. Always make sure there is adequate exposure and visualization of the laceration. Insert a Foley catheter if the laceration is in proximity to the urethra. This ensures urethral patency and helps preclude inclusion when placing sutures. Scrub the perineum with povidone iodine or chlorhexidine solution. Apply sterile drapes beneath the patient's buttocks, on the legs, and on the abdomen to prevent contamination from nonsterile areas. Provide anesthesia with the injection of local anesthetic solution directly into the laceration or with a nerve block. Refer to Chapter 132 for details regarding perineal nerve blocks.

Thorough knowledge of the anatomy and awareness of where sutures are being placed is necessary to avoid perforation of any proximate viscera. Always use absorbable suture. Refer to Chapter 132 for complete details regarding the repair of an episiotomy. A brief description of the repair procedure is provided below.

FIRST-DEGREE LACERATIONS

First-degree lacerations involve the fourchette, the perineal skin, and/or the vaginal mucous membrane. They spare the underlying fascia and muscle. If the lacerations are small and hemostatic, they do not need to be repaired. Use continuous (running) 2-0 or 3-0 polyglactin (Vicryl) suture to close the vaginal mucosa and submucosa. Chromic gut suture is an alternative but causes more postprocedural pain until it is absorbed. Interrupted sutures may better approximate the laceration if it is very irregular. Approximate the cut margins of the hymenal ring with a stitch. Repair skin lacerations with subcuticular 3-0 sutures as they cause less perineal pain.[5] An alternative is to place interrupted 3-0 sutures.[5]

SECOND-DEGREE LACERATIONS

Second-degree lacerations involve the perineal skin, vaginal mucous membrane, subcutaneous tissue, fascia, and muscles of the perineum but not the anal sphincter muscle. Repair is essentially the same as for an episiotomy but complicated by the irregularity of the laceration. Begin as in a first-degree laceration by repairing the vaginal mucosa and submucosa. Do not place the sutures too deep as to avoid injuring the ureters above the vaginal fornices. Approximate the hymenal ring. Place interrupted 2-0 or 3-0 Vicryl or chromic gut sutures to close the fascia and muscles of the lacerated perineum. Carry a continuous (running) suture downward to unite the superficial fascia and then upward to close the subcutaneous tissue. Close the skin with a running subcuticular stitch. Alternatively, the subcutaneous tissue and skin may be closed together with interrupted 3-0 chromic sutures to minimize the amount of buried suture in the superficial perineal layers.[5]

THIRD-DEGREE LACERATIONS

Third-degree lacerations involve a second-degree laceration that extends into the anal sphincter but not the rectal mucosa. Isolate, approximate, and suture together the cut ends of the anal sphincter muscle with interrupted 2-0 Vicryl sutures. The remainder of the repair is the same as that for second-degree lacerations.[5]

FOURTH-DEGREE LACERATIONS

Fourth-degree lacerations extend through the rectal mucosa to expose the rectal lumen. Approximate the torn rectal mucosa with running or interrupted 3-0 or 4-0 chromic gut sutures placed approximately 0.5 cm apart. Cover this muscular layer with a layer of fascia. Proceed as with the repair of third-degree lacerations.[5]

CERVICAL LACERATIONS

Gently grasp each side of the cervical laceration with ringed forceps. Start at the apex of the laceration using 2-0 chromic gut suture and close the laceration in a running pattern. **Do not suture closed the endocervical canal.** If the apex cannot be visualized, start at the highest point that can be visualized and place the first stitch as a single interrupted stitch. Use the suture to apply gentle traction to identify the upper part of the laceration. Place interrupted 2-0 chromic gut sutures to close the apex. Use a running stitch to close the lower part of the laceration.

ASSESSMENT

Thoroughly examine the patient to ensure the cessation of bleeding. **Any additional bleeding sites must be found and repaired.** Carefully monitor the patient's vital signs and urinary output. Manage any hypotension with fluid boluses and packed red blood cells as indicated. Follow serial complete blood counts if the patient has lost a significant amount of blood. Persistent hypotension, tachycardia, or a hematocrit less than 21% may require a transfusion. Hemodynamically stable patients may be expectantly managed.

AFTERCARE

The aftercare for postpartum hemorrhage is targeted toward the etiology of the bleeding episode. Warm sitz baths alternated with ice packs applied to the perineum three to four times a day will decrease inflammation and the risk of infection in patients with lacerations or episiotomies. Stool softeners will decrease the pain of defecation and the risk of wound dehiscence, especially with third- or fourth-degree lacerations. A high-fiber, low-residue diet may be helpful. Prescribe oral analgesics for pain relief. Nonsteroidal anti-inflammatory drugs or acetaminophen provide adequate analgesia for most patients. Narcotic analgesics such as hydrocodone or acetaminophen with codeine may be necessary initially. Avoid formulations that increase constipation in patients with third- or fourth-degree lacerations.

Follow complete blood count values until the patient is asymptomatic and stable. Consider a transfusion if the patient's hematocrit is less than 25, the patient is symptomatic from anemia, or is hemodynamically unstable. Prescribe 325 mg of iron sulfate orally twice daily.

Follow-up therapy for uterine atony often includes the use of oxytocin (20 to 40 U/L of intravenous fluid) for 12 to 24 hours. An alternative is oral Methergine. Initiate therapy after consultation with an Obstetrician.

COMPLICATIONS

Maternal complications resulting from postpartum hemorrhage include shock, acute renal failure, acute respiratory distress syndrome, the need for blood transfusion, a consumptive or dilutional coagulopathy, the need for surgical intervention (dilatation and curettage or laparotomy) and its associated complications, extreme fatigue, postpartum endometritis, and Sheehan's syndrome. Complications associated with pharmacologic therapy can be avoided by carefully selecting the appropriate patient for each agent (see "Contraindications," above).

SUMMARY

Postpartum hemorrhage is a serious and potentially lethal condition. Early identification of risk factors and a prompt response to the early signs and symptoms of postpartum bleeding will decrease the morbidity and mortality of this situation. Always consult an Obstetrician immediately if the patient experiences postpartum hemorrhage.

136 Perimortem Cesarean Section

Silvia Linares

INTRODUCTION

The term "perimortem cesarean section" was introduced in 1986 to describe a cesarean section done at time of cardiopulmonary resuscitation and within the first 4 minutes if resuscitative efforts were not successful.[1] The goal of this procedure is to improve survival for the fetus, and sometimes provide a better chance for the mother to be resuscitated.[2,3]

The incidence of cardiac arrest during pregnancy is estimated to be about 1 in 30,000 pregnancies.[4] According to a review of reported perimortem cesarean deliveries from 1985 to 2004, the most frequent causes are trauma, cardiogenic, emboli (e.g., amniotic fluid and air), magnesium overdose, sepsis, anesthesia, eclampsia, spontaneous uterine rupture, and intracranial hemorrhage.[2]

Trauma is the leading cause of death in women of reproductive age and accounts for 25% to 50% of maternal morbidity. Major maternal injury is associated with a 45% to 50% fetal loss rate. **The primary goal in the management of the severely injured pregnant patient is maternal assessment and stabilization. Prompt**

attention to the needs of the gravid patient can save the life of both the fetus and the mother. Nonetheless, there are occasions when emergent cesarean delivery of the fetus is necessary to save the fetus, and sometimes, the mother.

This procedure is best performed by a qualified Surgeon in the Operating Room. However, there are circumstances that may necessitate the performance of this procedure in the Emergency Department. These include the possibility of uterine rupture, placental abruption, fetal distress, and imminent maternal demise. The perimortem cesarean section is a key procedure that all Emergency Physicians need to be able to perform in the rare instance it is required.

There are several simple principles to keep in mind. Quickly establish that the mother is deceased or that no further intervention is possible. Quickly open the abdominal wall and uterus with vertical incisions. The use of strict aseptic technique is not required and only wastes valuable time. Deliver the fetus and begin resuscitation. Manually remove the placenta. Close the uterus and abdominal wall with running sutures.

ANATOMY AND PATHOPHYSIOLOGY

MATERNAL PHYSIOLOGY

Important maternal physiologic changes during pregnancy should be considered in the event of a cardiorespiratory arrest. Pregnancy changes almost all maternal body systems. Cardiac output, blood volume, and heart rate all increase. Pulmonary and systemic vascular resistance decreases. Uteroplacental blood flow increases, with the uterus receiving up to 30% of the cardiac output during pregnancy. Aortocaval compression during the second half of pregnancy can result in decreased venous return to the heart, decreased cardiac output, and systemic hypotension. These changes complicate the resuscitation efforts. The pregnant woman is predisposed to a more rapid decrease in arterial and venous oxygen tension during episodes of hypoxia. Gastrointestinal changes include decreased motility, relaxation of the esophageal sphincter, and thus a predisposition to aspiration of gastric contents.[3–6]

In general, the same algorithms used for the nonpregnant patient should be used for the pregnant patient during a cardiorespiratory arrest. There are some modifications to keep in mind.[5] The stroke volume of a term pregnant patient lying supine is only 30% of normal. Lateral displacement of the uterus will increase the stroke volume and cardiac output by at least 25%.[7] Pregnancy increases oxygen requirements and the risk of aspiration. Early intubation to protect airway is indicated. Be cautious in using of sodium bicarbonate to reverse metabolic acidosis. Rapid correction of maternal, but not fetal, acidosis could lead to reduced compensatory hyperventilation and normalization of fetal $PaCO_2$ with worsening of the fetal acidosis.[4]

The performance of adequate CPR in the gravid patient at or near term is extremely difficult. Adequate CPR produces a cardiac output equivalent to 30% of normal under ideal circumstances. The enlarged uterus lies anterior to the inferior vena cava and suppresses venous return in the gravid patient. **Place a wedge under the patient's right flank and hip to position them in 15° of left lateral tilt to adequately relieve the obstruction of the inferior vena cava by the uterus.** Give early consideration to performing a perimortem cesarean delivery.

Evacuation of the uterus by cesarean section may save the fetus and, by enabling adequate maternal resuscitation, save the mother as well. The pregnant patient has a decreased tolerance for anoxic brain injury. The fetus can tolerate anoxic injury slightly longer than the mother.

EVALUATION FOR PERIMORTEM CESAREAN SECTION

Quickly determine the gestational age using ultrasonography, the last known menstrual period, the history of term gestation by family members, or fundal height. A quick rule to remember is if you can place at least four fingers above the umbilicus to the top of the fundus, the gestational age is likely to be equal to or more than 24 weeks.[2] Twenty-four weeks is also the beginning of aortocaval compression by the uterus.[7] Nevertheless, this estimate can be distorted by overweight patients, abdominal distention, and a history of multiple pregnancies. Unfortunately, no other quick rule has been yet described.

Perform ultrasonography only if the unit is immediately available and if experienced in obstetric ultrasound. Note the time of the maternal arrest. Immediately consider performing a perimortem cesarean section in the resuscitation of a pregnant patient with an estimated gestational age of 24 weeks or greater and with a cardiorespiratory arrest that has not responded to aggressive resuscitation within 4 minutes from onset.

The single most important prognostic factor for neonatal outcome is the time from maternal arrest to delivery. Delivery of the fetus can also maximize maternal resuscitation efforts and minimize the risk of maternal brain injury. Delay the initiation of vasopressor agents until after adequate volume replacement. However, they should not be withheld if needed to resuscitate the patient.

INDICATIONS

The major indication for performing a perimortem cesarean section is to optimize maternal cardiopulmonary resuscitation. The rescue of a viable fetus greater than 24 weeks gestation is an important consideration, but such rescue is always secondary to the safety and life of the mother. Consider performing a postmortem cesarean section if CPR does not resuscitate the mother within 4 minutes of the arrest. Waiting for the Obstetrical and Pediatric teams is contraindicated.[2,7]

CONTRAINDICATIONS

There are few contraindications to performing a perimortem cesarean delivery. The best fetal outcomes are reported when cesarean delivery occurs within 5 minutes of maternal arrest. However, perimortem cesarean section should be considered if the time from the maternal arrest to delivery would be no greater than 25 minutes. It is contraindicated if the mother has a serious brain injury but is otherwise hemodynamically stable and the fetus shows no signs of distress. Other contraindications to a perimortem cesarean delivery are the inability to adequately resuscitate the infant after delivery or extreme fetal prematurity/immaturity.

Attempt to obtain consent for the procedure. However, there is no documentation of physician liability in these situations. **Do not delay treatment pending consent.** The unanimous consensus in the medical literature and of legal authorities is that a civil suit for performing a perimortem cesarean delivery, regardless of the outcome, would not result in a judgment against the Emergency Physician.

EQUIPMENT

- 10 towel clips
- 16 Kelly clamps
- 16 hemostats
- 10 Peon or Pennington clamps
- Eight Allis forceps
- Six Babcock forceps

- Six ring forceps
- Six straight Kocher clamps
- #10 surgical scalpel blade and handle
- #15 surgical scalpel blade and handle
- Straight Mayo scissors
- Curved Mayo scissors
- Metzenbaum scissors
- Bandage scissors
- Two suture scissors
- Two Adson forceps, or other forceps with teeth
- Two Russian forceps, 5 1/2 inches and 8 inches
- Dressing forceps
- Bladder retractor
- Two medium Richardson retractors
- Two small Richardson retractors
- Two malleable retractors
- Two Army–Navy retractors
- Needle drivers, 8 inches and 6 inches long
- Two suction tips
- Suction tubing set(s)
- Wall suction
- Electrocautery unit with disposable tips
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Sterile gloves
- Two skin staplers
- Three packs 0 chromic suture with CTX taper needle
- One pack 2-0 chromic suture with taper SH needle
- Two packs of 1-0 Vicryl suture with a CT taper needle
- Chromic, Polysorb, or Vicryl suture (2-0 or 1-0)
- Nylon suture, 3-0
- Bulb syringe
- Clean towels or blanket for baby
- Umbilical cord clamp
- Sterile scissors to trim umbilical cord
- Infant warmer
- Neonatal resuscitation equipment

Ideally, all of the equipment should be prepackaged in a sterile cesarean section instrument tray prepared by the hospital. A prepackaged sterile instrument tray is commercially produced but may not be available as this procedure is rarely performed in the Emergency Department. A standard thoracotomy tray or tube thoracostomy tray will contain all the required equipment except for the bulb syringe and umbilical cord clamp.

PATIENT PREPARATION

Time is of the essence. Establishing IV access and endotracheal intubation takes several minutes. Thus, it is very important to activate a protocol for an emergency cesarean section as soon as a cardiorespiratory arrest occurs in a pregnant woman.[6,7] Every attempt should be made to contact an Obstetrician and Neonatologist if a perimortem cesarean section is anticipated. Consult a General Surgeon if an Obstetrician is not available. Notify the neonatal resuscitation team and Anesthesia (Physician or Nurse Anesthetist) of the impending procedure. The procedure should not be delayed in an attempt to obtain consent.[1,6,8] The medicolegal risks are few since the Emergency Physician is acting under the principle of beneficence.

Administer adequate anesthesia if the patient is awake and aware of their surroundings. General or epidural/spinal anesthesia is preferred as provided by a qualified Anesthesiologist or Nurse Anesthetist. However, local infiltration of anesthetic solution may be performed in conjunction with procedural sedation. The deceased patient requires no anesthesia.

Surgical preparation in an emergency is minimal.[1,8,9] Perform a minimal shave of the lower abdomen and pubic region if time permits. Prepare the abdomen with povidone iodine or chlorhexidine solution. Place a Foley catheter to continuously drain the bladder and to decrease the risk of inadvertent entry into the bladder during the procedure. Perform an appropriate surgical scrub if time allows. Apply relevant surgical clothing and covers (i.e., a hat, mask, booties, sterile gloves, and a sterile gown). Apply sterile surgical drapes over the patient to isolate a surgical field.

The patient will be clinically deceased in most cases if this procedure is performed in the Emergency Department. Patient preparation is not necessary and wastes valuable time when trying to salvage the fetus. The Emergency Physician should follow body fluid precautions (hat, mask, sterile gloves, boots, and sterile gown). Administer broad-spectrum intravenous antibiotics if the mother survives the procedure. Continue cardiopulmonary resuscitation throughout the preparation and procedure until the fetus is delivered.

TECHNIQUE

The "classical" technique of cesarean delivery is the most appropriate and is described in this section. It provides better exposure, easy access, and a larger opening for the delivery. Identify the patient's umbilicus and pubic symphysis. Make a vertical midline skin incision with a #10 scalpel blade beginning 1 cm below the umbilicus and extending caudally to 2 to 3 cm above the pubic symphysis (**Figure 136-1A**). This incision is long enough to deliver a full-term infant.[7,8,10] Ignore any subcutaneous bleeding unless it is arterial. Clamp the bleeding artery or use an electrocautery unit, if available, to coagulate the vessel.

Extend the incision through the subcutaneous fat to the rectus sheath (**Figure 136-1B**). **Do not be overzealous and cut through the rectus sheath, peritoneum, uterus, abdominal organs, or bladder.** Grasp and elevate the rectus sheath using a toothed forceps (**Figure 136-1C**). Make an incision in the rectus sheath with a Mayo scissors. Extend the rectus sheath incision superiorly and inferiorly with the Mayo scissors (**Figure 136-1C**). **Be cautious not to cut any abdominal or pelvic organs.**

Expose the uterus (**Figure 136-2**). The underlying peritoneal membrane (peritoneum) should be visible (**Figure 136-2A**). It may occasionally be attached to the rectus sheath and opened simultaneously. Insert retractors to fully expose the peritoneal membrane (**Figure 136-2A**). Grasp and elevate the peritoneal membrane with a toothed forceps. Incise the peritoneal membrane with a Mayo or Metzenbaum scissors in a manner similar to that used to open the rectus sheath (**Figure 136-2A**).[10]

Make reasonable attempts to protect the bowel and bladder from injury. Elevate the bowel off the field and cover it with a saline-soaked towel. Place a bladder retractor over the pubic symphysis to retract the rectus sheath and bladder (**Figure 136-3A**).[10] This will allow visualization of the uterus and prevent injury to the bladder. Alternatively, grasp and elevate the bladder from the pelvis with a saline-soaked gauze or towel (**Figure 136-2B**).

Identify the position of the fetal head by palpating the uterus. Make a 2 to 4 cm midline vertical incision in the uterus

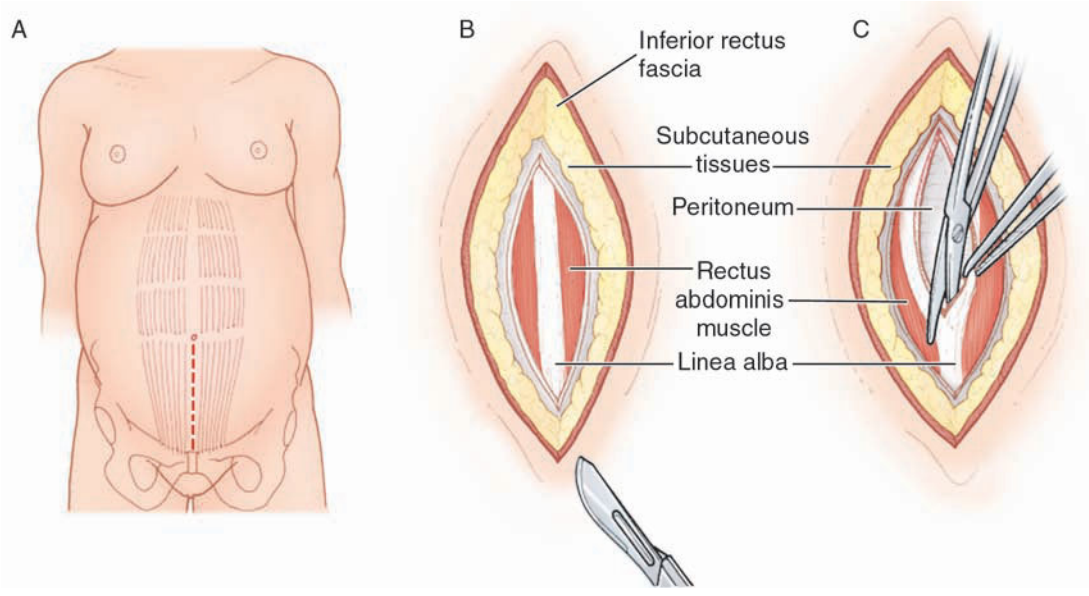

FIGURE 136-1. Accessing the peritoneal cavity. **A.** Make a midline skin incision from just below the umbilicus to just above the pubic symphysis. **B.** Extend the incision through the subcutaneous tissues and down to the linea alba. **C.** Grasp and elevate the rectus abdominis muscle while opening the linea alba with a Mayo scissors.

(**Figure 136-3A**). The amniotic sac will bulge through the incision if the membranes are intact. **Place a finger into the uterine incision and aimed vertically (Figure 136-3B). Insert one blade of a bandage or Mayo scissors between the finger and the uterine wall (Figure 136-3B).** The finger will protect the fetus from the scissors. The other blade of the scissors should be outside the uterus. Extend the vertical uterine incision fundally, superior and away from the bladder (**Figure 136-3B**). The finger inside the uterus will protect the fetus from injury when opening the uterine wall. Repeat this procedure to open the uterine wall inferiorly (**Figure 136-3C**).

Rupture the amniotic membranes with a clamp or other blunt instrument. The placenta will often be embedded in the anterior wall of the uterus. It is imperative to expedite the delivery of the fetus by cutting through the placenta. Carefully transect the placenta if it is anterior to the fetus. There is an urgency to deliver the fetus and clamp the umbilical cord to prevent significant fetal hemorrhage. Insert a hand between the pubic symphysis and the fetal occiput if the fetus is in a cephalic presentation (**Figure 136-4A**). Advance the hand to the base of the occiput. Gently flex the fetal head with your fingers and palm (**Figure 136-4A**). Apply gentle anteriorly and superiorly directed traction to elevate and deliver the head (**Figure 136-4B**). Deliver the entire fetal head (**Figure 136-4C**). Suction the mouth and nose with a bulb syringe (**Figure 136-4D**).[10] Deliver the shoulders in a manner similar to that of a vaginal delivery (**Figure 136-4E**). Apply gentle upward traction on the head while an assistant applies pressure on the uterine fundus. First deliver the anterior shoulder. Deliver the other shoulder followed by the torso and lower extremities. Once the shoulders are delivered, the remainder of the fetus readily follows.

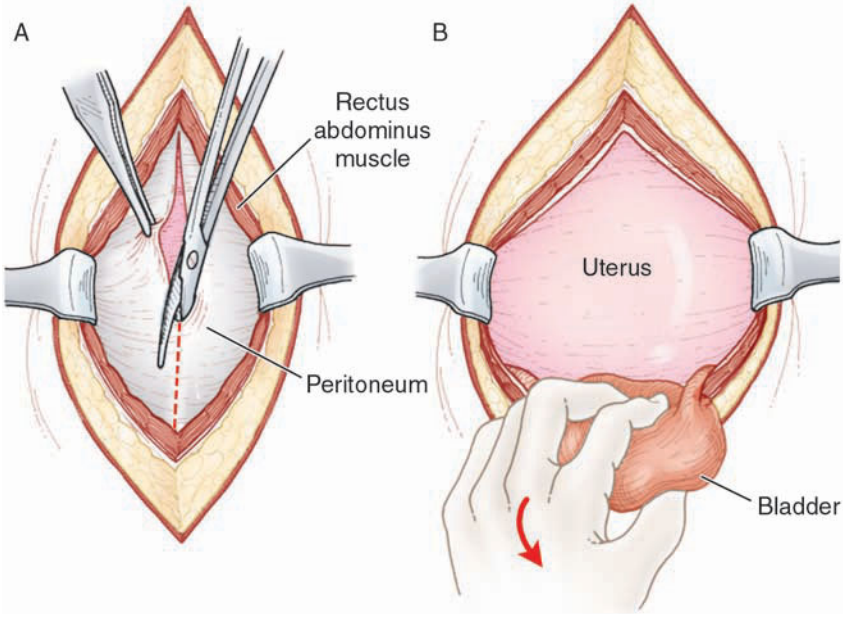

FIGURE 136-2. Exposure of the uterus. **A.** Apply retractors to hold the abdominal wall open. Grasp, elevate, and incise the peritoneal membrane in the midline. **B.** Grasp and elevate the bladder out of the pelvis.

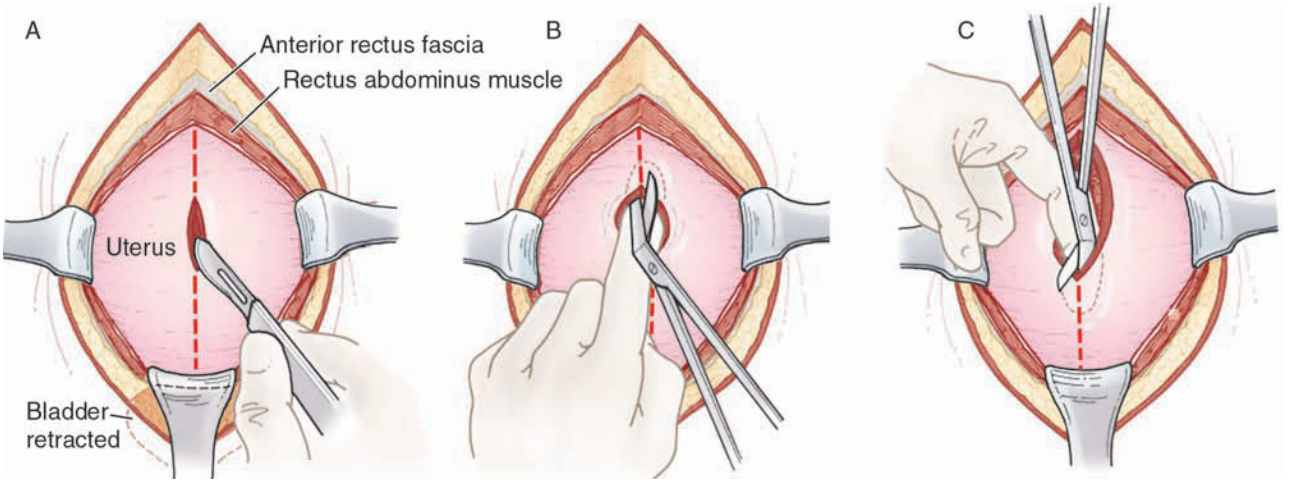

FIGURE 136-3. The vertical uterine incision. **A.** Make a 2 to 4 cm midline vertical incision with a scalpel blade. **B.** Place a finger into the incision to protect the fetus. Extend the uterine wall incision superiorly. **C.** Extension of the uterine wall incision inferiorly.

If the fetus is in a breech presentation or transverse lie, the feet first delivery is easiest. During the delivery, grasp the fetus by the pelvic bones and not by the abdomen to protect the delicate viscera.[8,10]

Clamp the umbilical cord with a hemostat or umbilical cord clamp approximately 10 to 15 cm from the fetus. Attach a second hemostat or clamp 2 to 3 cm distal to the first. Cut the umbilical cord between the clamps with a Mayo scissors. Hand the neonate

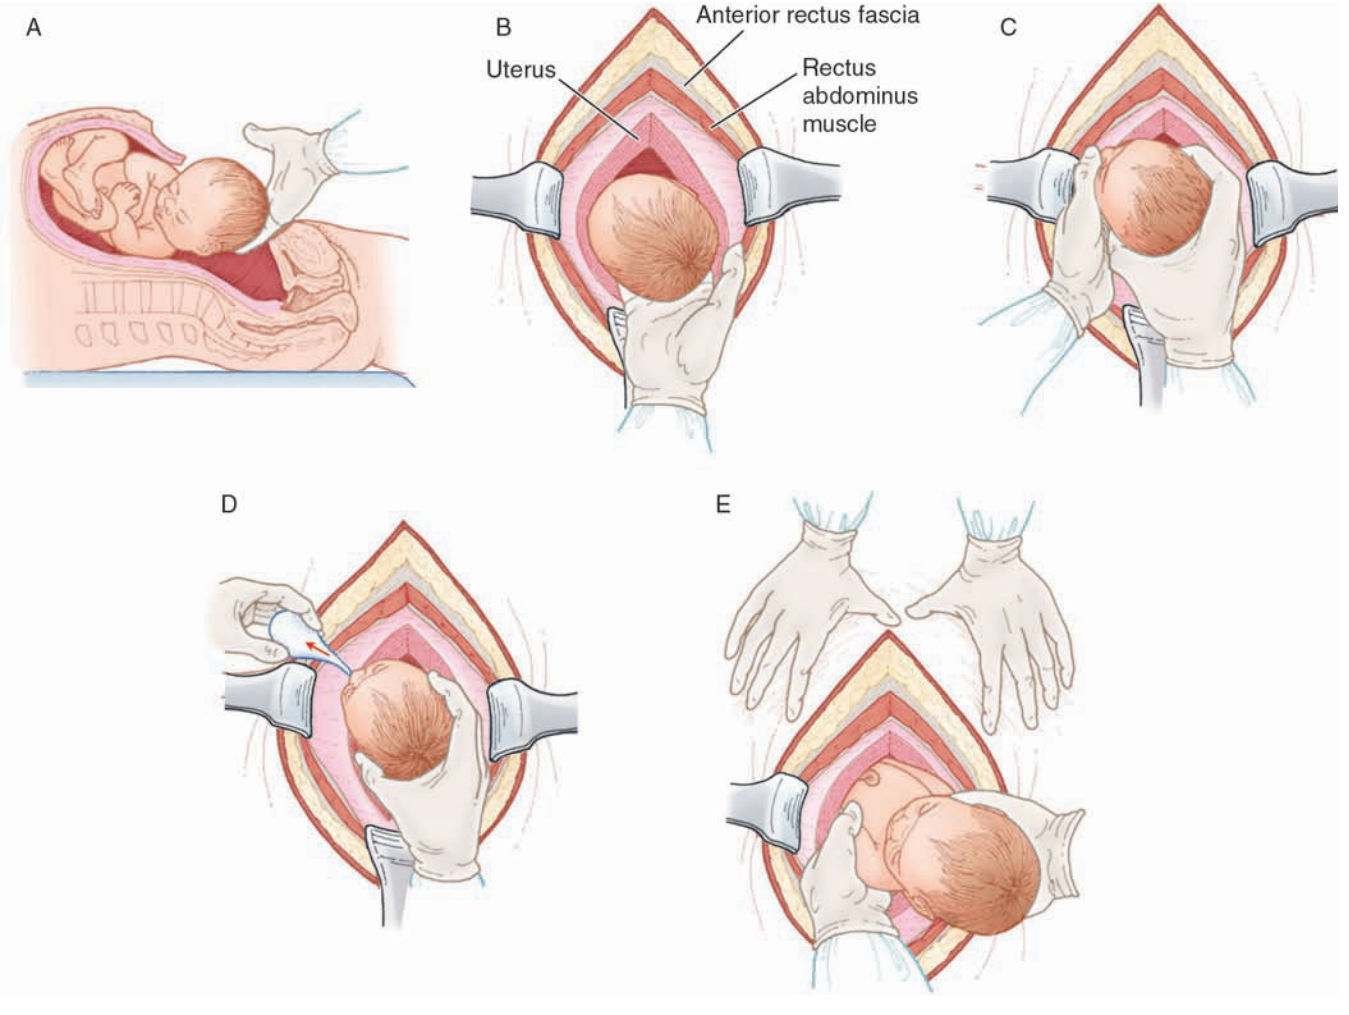

FIGURE 136-4. Delivery of the infant. **A.** Midsagittal section through the abdomen and pelvis. A hand is inserted between the pubic symphysis and the fetal head. **B.** Flex the fetal head while applying anterior and superior traction. **C.** Delivery of the entire fetal head. **D.** Suction the mouth and nose. **E.** Deliver the fetus while an assistant applies pressure to the uterine fundus.

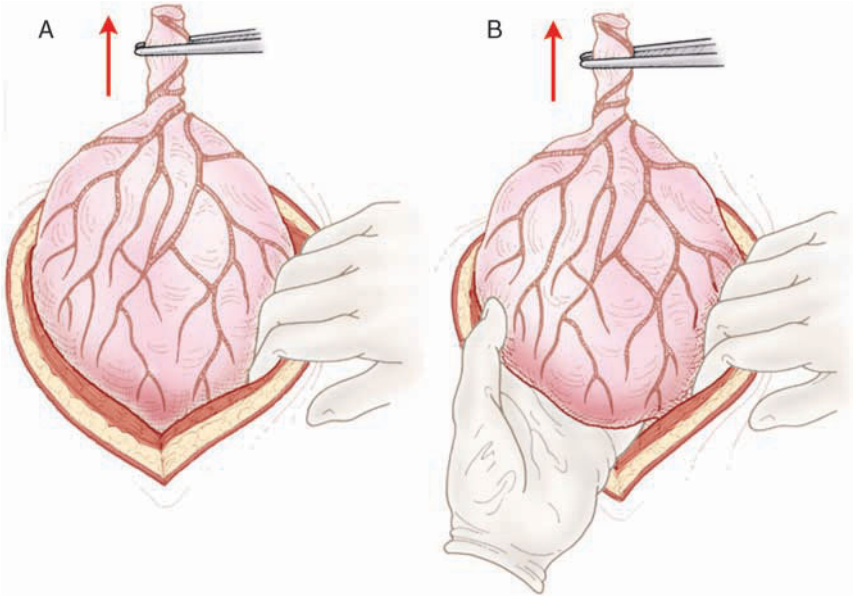

FIGURE 136-5. Delivery of the placenta. **A.** Apply gentle upward traction on the umbilical cord while holding the uterine wall open. **B.** Insert a hand between the placenta and the uterine wall to separate the placenta from the uterus.

to waiting personnel for resuscitation.[8,10] Resuscitate the neonate yourself if additional help is not available.

AFTERCARE

Palpate inside the uterus for another fetus to rule out an unknown twin pregnancy. Deliver the placenta if the patient is still alive or if they regain vital signs (**Figure 136-5**). Begin an oxytocin infusion of 20 units in 1 L of normal saline at a rate of 10 mL/min to help the uterus contract.[10] Apply gentle upward traction on the umbilical cord while holding the uterine wall open (**Figure 136-5A**). Insert the other hand between the placenta and uterine wall (**Figure 136-5B**). Apply gentle pressure to separate the placenta from the uterus.

Close the patient if they are still alive or if they regain vital signs (**Figure 136-6**). Apply ring forceps to the uterine incision. Close the uterus in two layers with 0 or 1-0 absorbable chromic gut, Polysorb, or Vicryl suture. Close the first layer in a running locked fashion (**Figure 136-6A**). This will provide hemostasis. A second running layer is necessary to ensure hemostasis and reapproximate the uterine wall. Closure of the serosa of the uterus (**Figure 136-6B**) and the peritoneal membrane (**Figure 136-6C**) is recommended but not required. Close the serosa and peritoneum with running 2-0 absorbable chromic gut, Polysorb, or Vicryl suture. Identify and grasp the cut ends of the rectus sheath with hemostats. Close the rectus sheath in a running pattern with 2-0 Vicryl suture (**Figure 136-6D**). Close the skin with running 3-0 nylon (**Figure 136-6E**) or staples for speed.[7,8,10]

The only closure required if the mother will not survive is a minimal closure of the skin. Use either a running baseball stitch or skin staples.

COMPLICATIONS

The major associated complications of the procedure include maternal sepsis, maternal visceral injury, maternal hemorrhage, and fetal injury secondary to delivery. The possible benefits of maternal and/or fetal survival far outweigh these considerations.[1]

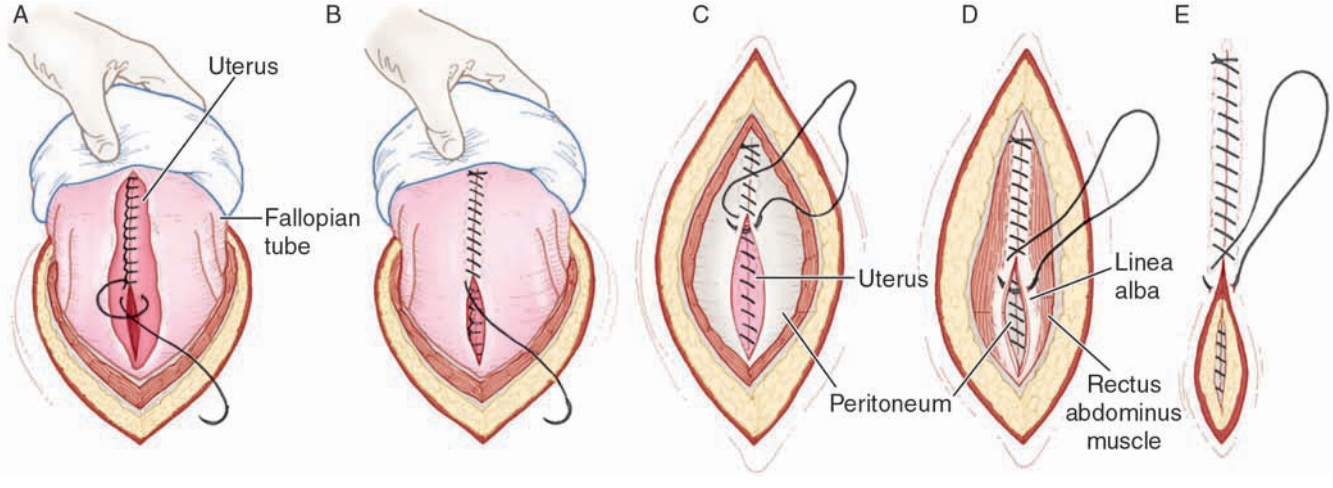

FIGURE 136-6. Closure of the incisions. **A.** Running locked closure of the uterine wall. **B.** Closure of the serosa of the uterus. **C.** Running closure of the peritoneal membrane. **D.** Running closure of the rectus sheath. **E.** Running closure of the skin.

SUMMARY

The perimortem cesarean section is a valuable procedure that should be considered in any maternal arrest with an estimated fetal gestational age of greater than 24 weeks. The procedure will bring a great deal of stress and fast decision making is required. It provides the fetus with a chance for survival in the face of maternal death. In addition to potentially saving the life of the infant, emergent delivery might also aid in the resuscitation of the mother. The medicolegal risks are few. It should ideally be performed within 5 minutes of maternal arrest, as this gives the greatest potential for successful fetal, and possibly maternal, resuscitation.

137 Symphysiotomy

Ikem Ajaelo

INTRODUCTION

Symphysiotomy is the artificial division and separation of the pubic symphysis in order to facilitate vaginal delivery. This is not to be confused with a pubiotomy, or the severance of the pubic bone a few centimeters lateral to the symphysis, for the same purpose. First performed in the seventeenth century, it is indicated in cases of cephalopelvic disproportion and may be a life-saving alternative to cesarean delivery.[1] The reported success rate of this procedure is approximately 80% when performed appropriately.[2]

The procedure itself is well described and can be accomplished under local anesthesia.[2] Early reports of urologic and orthopedic complications led to its decline and lack of acceptance in modern obstetrical practice despite initial successes.[3] Presently, a symphysiotomy is performed quite regularly and successfully in rural areas of the world where medical resources are not as abundant as in developed countries.[4]

Indications for a symphysiotomy include breech delivery, cephalopelvic disproportion, and for the relief of shoulder dystocia.[1,5,6] Each of these conditions poses significant potential risks to mother and child, even under optimal conditions. Emergency Physicians should be familiar with the indications and technique of symphysiotomy as expeditious delivery is vital in these scenarios.

ANATOMY AND PATHOPHYSIOLOGY

The pelvis is composed of four bones: the sacrum, the coccyx, and the two innominate bones. Each innominate bone is made up of the fused ischium, ilium, and pubis. The innominate bones are connected at the sacrum by the sacroiliac ligaments and at the pubic symphysis by the superior and arcuate pubic ligaments.[7] Together they determine the size and shape of the pelvis. The fetus assumes positions during labor that are primarily determined by the conformation of the mother's pelvis.[8]

The pelvis is divided into a true pelvis and a false pelvis. They are separated by the linea terminalis, an anatomic boundary formed by the pelvic brim (superior pelvic aperture). The true pelvis lies below the linea terminalis and is the more relevant portion in delivery.[9] Dense ligaments hold the walls of the true pelvis together. The posterior wall is the anterior surface of the sacrum and coccyx. The lateral boundaries are formed by the inner surface of the ischial bones as well as the sacrosciatic notches and ligaments. The ischial spines can be readily palpated during the vaginal or rectal examination. They serve as important landmarks in determining to which level the presenting part has descended into the true pelvis. The true pelvis is bounded anteriorly by the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramina.

The ligaments of the pubic symphysis and the sacroiliac ligaments allow mobility and contribute to the increase in pelvic diameter during pregnancy.[8] The sacral nerves, the coccygeal nerves, and the pelvic portion of the autonomic nervous system innervate the pelvis. The important pudendal nerve arises from the sacral plexus and accompanies the internal pudendal artery. It enters the perineal region via the lesser sciatic foramen and around the sacrospinous ligament to supply the muscles of the perineum.[7] Anesthesia to the perineal region can be accomplished by performing a pudendal nerve block.

INDICATIONS

Symphysiotomy is indicated in any difficult delivery in the presence of fetal distress, when labor is obstructed, and when an Obstetrician is not immediately available. It has traditionally been reserved for complicated breech deliveries or cases of cephalopelvic disproportion in which the fetal head is presenting vertex and at least one-third of the fetal head has entered the pelvic brim and cervical dilatation is no more than 7 cm.[1] Symphysiotomy has been advocated more recently for the relief of intractable shoulder dystocia.[5,6]

CONTRAINDICATIONS

There are no absolute contraindications to performing a symphysiotomy. Some authors have recommended limiting symphysiotomy to mothers weighing between 50 to 80 kg and a fetus with an estimated mass of 2700 to 3700 g.[10,16] Other relative contraindications include the presence of maternal spinal deformities, hip deformities, pelvic deformities, and gross obesity.[10] Symphysiotomy has been performed after a prior cesarean section without added complications despite concerns regarding the safety of symphysiotomy in the presence of a previous cesarean scar.[10]

EQUIPMENT

- Local anesthetic solution
- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask and cap
- Urethral catheter set
- Sterile drapes
- #10 scalpel blade on a handle
- Mayo scissors
- Finger guard
- Hemostats
- Sterile gloves
- Neonatal resuscitation equipment
- Infant warmer

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. Obtain an informed consent to perform this procedure if time allows. Place the patient in the lithotomy position with the thighs separated no more than 90°. This position is necessary to prevent undue strain on the sacroiliac joints. Two assistants should be available to maintain proper maternal leg positioning. Insert a Foley catheter into the bladder (Chapter 142).

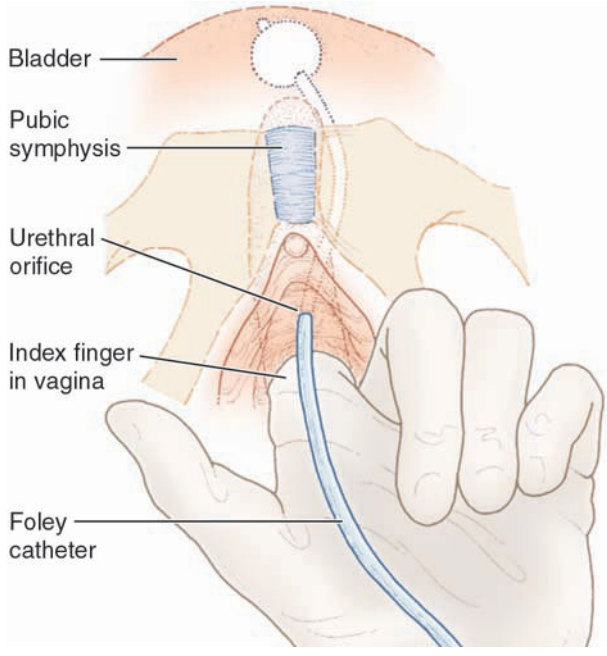

FIGURE 137-1. Frontal view demonstrating the operator's nondominant index finger inserted into the vagina and pushing anteriorly to palpate the pubic symphysis.

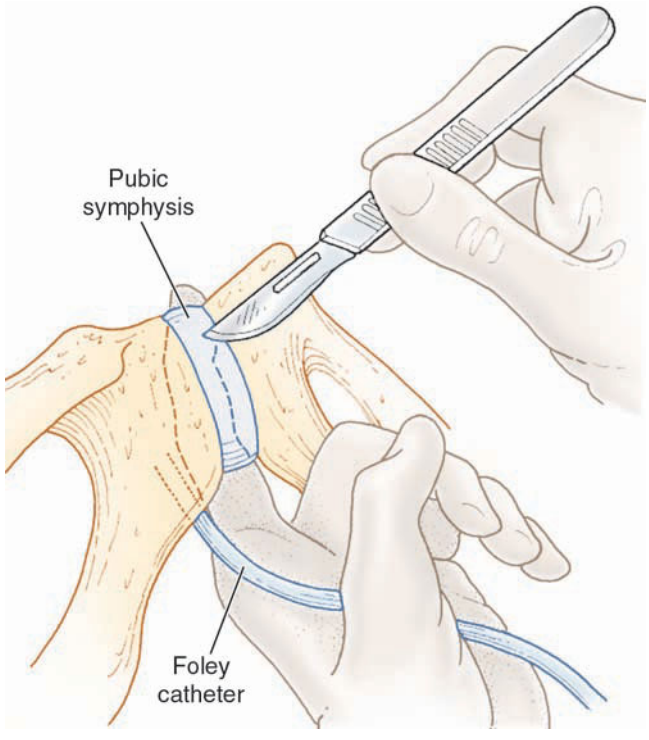

FIGURE 137-2. Skeletal outline demonstrating the position of the scalpel blade in relation to the pubic symphysis.

Prepare the surgical area. Shaving the mons pubis is optional. Apply povidone iodine or chlorhexidine solution onto the skin overlying the pubic symphysis and surrounding area and allow this to dry. The Emergency Physician must perform this procedure using aseptic technique. This includes wearing sterile gloves, a sterile gown, a cap, and a face mask. Apply sterile drapes to form a sterile field. Infiltrate the anterior and inferior aspects of the pubic symphysis and the surrounding skin with 5 to 10 mL of local anesthetic solution to anesthetize the pubic symphysis. Leaving the needle in place may be useful in identifying the pubic symphysis joint. Equipment for infant resuscitation should be readily available, as with all deliveries. Notify the neonatal resuscitation team and a Neonatologist of the impending procedure and delivery.

TECHNIQUE

Place the nondominant index finger into the vagina and against the posterior aspect of the pubic symphysis (**Figure 137-1**). Advance the finger approximately 2 to 3 cm beyond the superior aspect of the pubic symphysis to displace the bladder and urethra. **Do not move this finger until the procedure is complete.**

Grasp the scalpel in the dominant hand with the cutting edge of the blade facing you (**Figure 137-2**). **The scalpel blade must be kept in a strict midsagittal plane and perpendicular to the skin overlying the pubic symphysis.** Resting the hypothenar eminence of the dominant hand against the patient's pubic ramus will help maintain fine control of hand and finger movements.[2]

Make a midline stab incision 1 cm below the upper edge of the pubic symphysis (**Figure 137-3**). **Very little resistance should be met as the scalpel blade pierces the hyaline cartilage of the pubic symphysis if the scalpel is in the midline.** Carefully and slowly advance the scalpel blade until the tip is just felt through the anterior vaginal wall. Resistance is usually a result of lateral deviation of the scalpel blade against the pubic bones. Withdraw the scalpel blade 2 to 3 mm and re-advance it in the midline. **Use extreme caution so that the scalpel does not lacerate the vagina, the urethra, or the finger.**

Lower the handle of the scalpel blade cephalad, toward the abdomen, using the upper portion of the pubic symphysis as a fulcrum. Cut through the lower half of the pubic symphysis, dividing the cartilage and associated ligaments. Remove the scalpel blade and reinsert it with the cutting edge in the opposite direction and facing the cephalad. Repeat the same maneuver but with the scalpel handle lowered caudally to divide the upper portion of the pubic symphysis, thereby completing the separation.

Use the nondominant index finger to confirm complete separation of the pubic symphysis. **The symphysiotomy is complete when the index finger pressing through the vaginal wall can fit into the space between the pubic symphysis.** Reinsert the scalpel to complete the division if any ligaments or cartilage remains. The entire procedure should take 2 to 3 minutes. A variation of the above technique involves simply dividing the pubic symphysis in a single step by a repeated slow stabbing motion.

Once the symphysiotomy is completed, delivery of the infant should follow. Delivery of the infant usually requires more downward traction than is usually necessary.

AFTERCARE

Deliver the placenta and control any postpartum hemorrhage. Carefully return the mother to the supine position with the thighs in normal anatomic position. Close the skin and subcutaneous tissue with simple interrupted 4-0 nylon sutures. Some authors have recommended binding the knees for 12 to 48 hours to prevent inadvertent abduction or external rotation of the hips.[11] Admit the patient to the hospital for observation and monitoring of any potential complications. Leave the Foley catheter in place until any bleeding resolves or the patient begins to walk. Patients may begin ambulation with assistance between the second and fifth days. They should be warned against any unusual straining or heavy lifting.

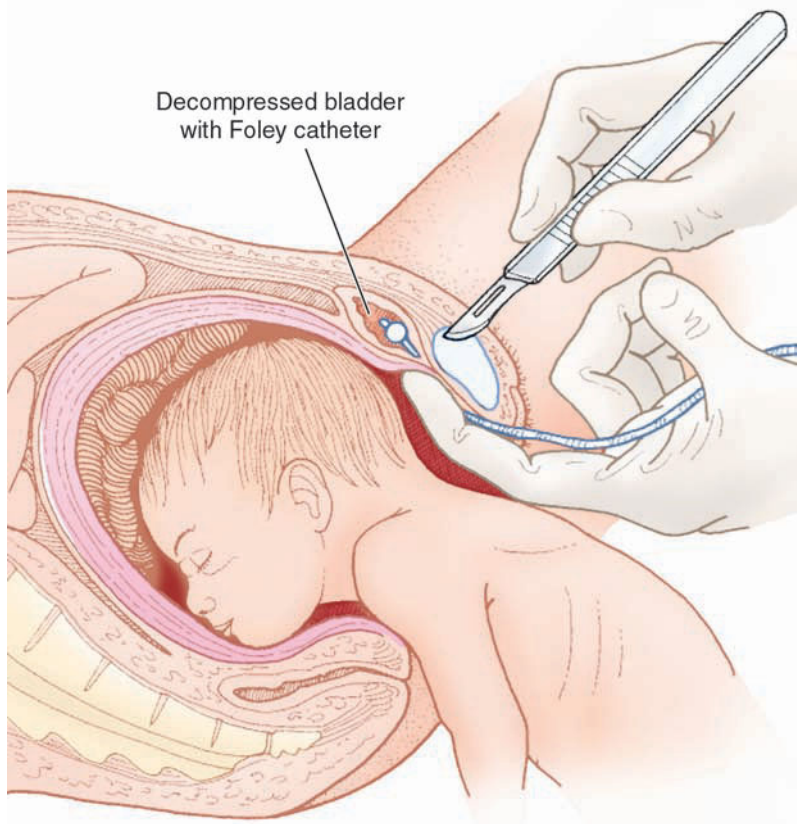

FIGURE 137-3. Sagittal view of a symphysiotomy using the scalpel blade to divide the pubic symphysis.

COMPLICATIONS

Experience and careful case selection appear to be the most important factors in determining outcome and morbidity associated with this procedure.[2] While symphysiotomies do not cause maternal death, immediate complications include bladder lacerations, urethral lacerations, subcutaneous bleeding, and urinary incontinence.[10,11] Some patients develop gait instability immediately after the operation that tends to be transient and does not appear to affect subsequent pelvic stability.[13]

Lacerations to the Emergency Physician's fingers are a significant concern.[12,15] Prevent lacerations by using the utmost of care and slowly transect the cartilage and ligaments of the pubic symphysis. The nondominant hand should be double-gloved at a minimum.[12] The use of a Kevlar glove that is resistant to scalpel injury may also be used.[15] A third option is to apply a malleable splint over the palmar aspect of the index finger before double gloving.[12]

Long-term complications include, but are not limited to, stress urinary incontinence, recurrent urinary tract infections, sepsis, and vesicovaginal fistulas.[14] Vaginal fistulas are frequently due to nonplacement of a Foley catheter during the procedure.[3] This important step should never be omitted. The effect of a symphysiotomy on subsequent pregnancies has not been studied in detail. However, the limited data available suggest that a symphysiotomy permanently enlarges the pelvis so that subsequent vaginal deliveries are in fact easier.[13]

SUMMARY

In developed countries, modern surgical techniques and obstetrical advances have diminished the practice of symphysiotomy. However, it still remains a simple and safe method to overcome the common and lethal problems of cephalopelvic disproportion, shoulder dystocia, and breech deliveries. Complications are uncommon when performed correctly. Emergency Physicians can master this procedure.[12] A symphysiotomy is a viable and potentially lifesaving option for those who may be working outside the confines of a well staffed and equipped hospital.

138 Bartholin Gland Abscess or Cyst Incision and Drainage

Charlie C. Kilpatrick

INTRODUCTION

Bartholin gland cysts and abscesses are common problems for women of reproductive age, with an incidence of 2% in this population.[1–3] A Bartholin gland and its duct may enlarge to form a Bartholin cyst or become infected and form a Bartholin abscess. A number of different techniques have been developed for the treatment of both cysts and abscesses.

ANATOMY AND PATHOPHYSIOLOGY

The Bartholin glands are named after Caspar Bartholin, a Danish anatomist.[1,4] They are located on each side of the vulvar vestibule beneath the fascia, posterolaterally to the vaginal orifice, and at the 4 and 8 o'clock positions.[5,6] The glands are approximately 1 cm in diameter, the size of a pea, and drain through a duct approximately 2.5 cm in length. The ducts of the glands open into the vulvar vestibule at the 5 and 7 o'clock positions, existing between the hymenal ring and the labia minora. The cells of the gland produce mucin which is secreted during sexual excitement and contributes

to vaginal lubrication.[4,7] The Bartholin glands are not normally palpable. The gland has an extensive blood supply from branches of the internal pudendal artery. The neural supply is provided from branches of the pudendal nerve.

A cyst of the Bartholin gland may develop most often secondary to obstruction of the duct. This leads to ductal dilation and cyst formation. Noninfectious etiologies of cyst formation include inspissated gland secretions, trauma, tumor of the vulva, or scarring of the duct from repeated bouts of cyst formation.[3] Cysts may grow as large as 1 to 3 cm. Bartholin cysts present as painless unilateral swellings in the labial area. A patient will become symptomatic if they become large enough or infected. Infected cysts contain purulent material and are known as a Bartholin's abscess; although it is more akin to a pseudoabscess unless the surrounding tissue appears erythematous, tender, and inflamed.[3] A Bartholin cyst may present with pain, dyspareunia, pressure, difficulty with walking, or may be completely asymptomatic.[4,7–11] The diagnosis is made on visual inspection of the vulva. Common signs are a mass near the inferior labia minora, drainage, and erythema.

Primary carcinoma of the Bartholin gland is a rare occurrence, but should be considered in the differential diagnosis. Most cancers occurring in the Bartholin gland are metastatic primary vulvar cancers. They can present as a Bartholin gland cyst when the vulvar cancer obstructs the ductal outflow of the gland. Adenocarcinoma (40%), squamous cell carcinoma (40%), adenoid cystic carcinoma (15%), and transitional cell carcinoma (5%) of the Bartholin gland have all been documented.[6,12–15] Carcinoma can easily mimic a Bartholin gland cyst or abscess.

The majority of Bartholin gland cysts appear to be sterile or contain bacteria common to the vaginal flora.[16] Studies of Bartholin gland abscesses have shown no bacterial growth in 7%, 10%, and 30% of specimens cultured.[16–18] The causative organisms are multiple in the cultures that do grow bacteria. The most prevalent organisms isolated are anaerobes, with *Bacteroides* and *Peptostreptococcus* being the most common species.[17] The remainder of the cultures demonstrated either aerobic/facultative isolates with *Escherichia coli* being the most common species or a mixture of both aerobic and anaerobic organisms. *Neisseria gonorrhea* and *Chlamydia trachomatis* have also been implicated as causative agents and have been isolated in 8% to 16% of cultures.[16,19]

INDICATIONS

Small and asymptomatic cysts in women less than 40 years of age can be managed expectantly. All others should be treated. Any cyst that becomes large and symptomatic (i.e., painful, interfering with physical or sexual activity) should be treated. Any cyst that appears tender, red, hot, or cellulitic represents a Bartholin abscess and requires treatment.

CONTRAINDICATIONS

There is some controversy about the treatment of Bartholin cysts and abscesses in women over the age of 40. Previously, the recommendation was to excise the gland in women over the age of 40, for concern of the possibility of carcinoma. Carcinoma of the Bartholin gland is rare, comprising less than 1% of female genital tract neoplasms.[11] It is felt that women over the age of 40 are at an increased risk for having carcinoma of the Bartholin gland, Bartholin duct, or adjacent structures; and thus all of these should be properly biopsied or completely excised and sent for pathologic evaluation.[1,6,7,12–14] Another study reported an incidence of Bartholin gland cancer in postmenopausal women of 0.114 per 100,000 women and suggests that selective biopsy be performed to reduce the number of total excisions.[15] Given the rarity of malignancies in this area, this view has been challenged in the recent literature. Currently, drainage and selective biopsy seems to be a reasonable alternative.[7] In general, these women should be referred to a Gynecologist for diagnosis and further treatment.

Patients who have had multiple recurrences and previous treatments are best served with a referral to their Gynecologist for more definitive measures.

Consider draining Bartholin abscesses that are large or extremely tender in the Operating Room. Other indications for drainage in the Operating Room include patients with a contraindication to procedural sedation, those that cannot be adequately anesthetized using procedural sedation and local anesthetics, and those who cannot be safely sedated in the Emergency Department.

EQUIPMENT

Simple Incision and Drainage

- Povidone iodine or chlorhexidine solution
- Gloves and gown
- Face mask with an eye shield or goggles
- Drapes
- Lidocaine, 1% to 2%
- 3 mL syringe
- 18 gauge needle
- 25 gauge needle
- 2 × 2 gauze squares
- 4 × 4 gauze squares
- #11 scalpel blade and scalpel handle
- Culture medium for routine bacteria, gonorrhea, and chlamydia
- Hemostat
- Small wick, 2 inches long

Incision and Insertion of a Word Catheter

- Equipment for simple incision and drainage
- Word catheter
- 5 mL sterile saline or water

Marsupialization

- Equipment for simple incision and drainage
- Two small retractors
- Specimen container for excised tissue
- Silver nitrate sticks or electrocautery
- Vicryl, 3-0 or 4-0 on cutting needle
- Scissors
- Small toothed forceps

Window Operation

- Same as equipment for marsupialization

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. Obtain a signed consent for the procedure. Some Emergency Physicians may omit the signed consent and place in the procedure note a statement saying: "the risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure."

Place the patient in the lithotomy position. Apply povidone iodine or chlorhexidine solution to the labia and allow it to dry. The surface of the vagina must be anesthetized as the procedure is extremely painful. The use of ice packs, topical refrigerant spray (Chapter 124), parenteral sedation, parenteral analgesics, or procedural sedation (Chapter 129) should be considered for patient comfort prior to infiltrating local anesthetic solution. Infiltrate 0.25 to 1.0 mL of local anesthetic solution subcutaneously under the mucosal surface of the labia minora for simple incision and drainage, with or without the use of a Word catheter. When injecting local anesthetics, ensure that you do not inject purulent material after aspiration as this can cause extensive inflammation. Infiltrate 2 to 3 mL of local anesthetic solution if a marsupialization will be performed.

The Emergency Physician should be wearing a gown, gloves, and a face mask with an eye shield or goggles. The cyst contents are usually under pressure and can spray out. A face mask and eye protection will prevent a mucous membrane exposure if the contents spray out of the incision. The gown will protect clothing from contamination.

TECHNIQUES

A number of different treatments and procedures have been developed to manage a Bartholin cyst or abscess. These are largely influenced by its size, patient symptoms, the age of the patient, the suspected etiology, and any previous treatment in the same patient. The techniques include simple incision and drainage, incision and insertion of a Word catheter, marsupialization, a window operation, and complete excision.

SIMPLE INCISION AND DRAINAGE

The standard treatment for most abscesses is simple incision and drainage.[7,9,10,20,21] Simple incision and drainage of a Bartholin cyst or abscess provides immediate pain relief but is often complicated by chronic recurrences. This technique is not recommended but described for the sake of completeness.

Spread open the labia to visualize the area (**Figure 138-1**). Make a 1 cm vertical incision on the mucosal surface of the labia minora in the vaginal vestibule. It should be parallel to the border of the hymenal ring, between the hymen and labia minora (**Figure 138-1**). **The incision should ideally be external to the hymenal ring, if possible, and in the area where the duct normally exits.** Extend the incision into the abscess/cyst cavity. **Do not make incisions along the skin surface of the labia minora.** Skin incisions can lead to the formation of a fistula tract, more postprocedural pain, and are fraught with complications. Culture the contents of the sac. Manually express the contents of the sac. Insert a hemostat and break any adhesions. Place a small wick within the cavity and exiting the incision to allow for complete drainage and prevent premature closure of the skin incision.

INCISION AND INSERTION OF A WORD CATHETER

Dr. B. Word first described this procedure in 1964.[4] It is a relatively simple procedure that can be accomplished in the Emergency Department.[4,7,9,10,22] The catheter is approximately 5 cm long and made of soft pliable latex with a 10 French tip. The tip contains a balloon that inflates up to a volume of 5 mL (**Figure 138-2**). These catheters cost approximately $15 each (Berkeley Medevices Inc., Berkeley, California).

Verify that the patient is not allergic to latex.[8] Fill a 5 mL syringe armed with a 21 gauge needle with saline or water. Insert the needle into the self-sealing port on the distal end of the Word catheter. Inject 3 to 4 mL of the fluid to inflate the balloon. Observe the balloon for any leaks. If no leaks are visible, aspirate the fluid back into the syringe to deflate the balloon. Remove the needle from the self-sealing port.

Spread open the labia to completely visualize the area (**Figure 138-3A**). Make a 0.5 cm long puncture on the mucosal surface of the labia minora with a #11 scalpel blade into the cyst or abscess cavity (**Figure 138-3A**). **This puncture should ideally be located just outside the hymenal ring and where the duct normally drains into the vaginal vestibule, between the hymen and labia majora at the 5 or 7 o'clock position.** The incision should be just large enough to allow the passage of the Word catheter. Culture the contents of the sac. Manually express the contents of the sac. Insert a small hemostat and break any adhesions.

Insert the tip of the Word catheter deep within the cavity (**Figure 138-3B**). Inject 2 to 4 mL of sterile saline into the free end of the catheter to inflate the balloon (**Figure 138-3C**). **Pain upon inflation of the balloon or persistent pain after the procedure indicates overinflation of the balloon. Do not use air to inflate the balloon.** The catheter will stay in place because the inflated balloon is larger than the puncture incision. Tuck the free

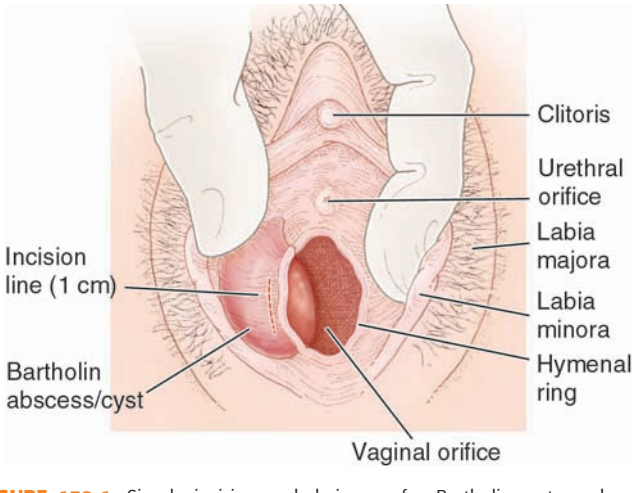

FIGURE 138-1. Simple incision and drainage of a Bartholin cyst or abscess. Spread open the labia to expose the area. The dotted line represents the incision line over the cyst or abscess.

FIGURE 138-2. The Word catheter. The plastic catheter has a port at its proximal end to insert a needle. The distal end contains a balloon that can be inflated.

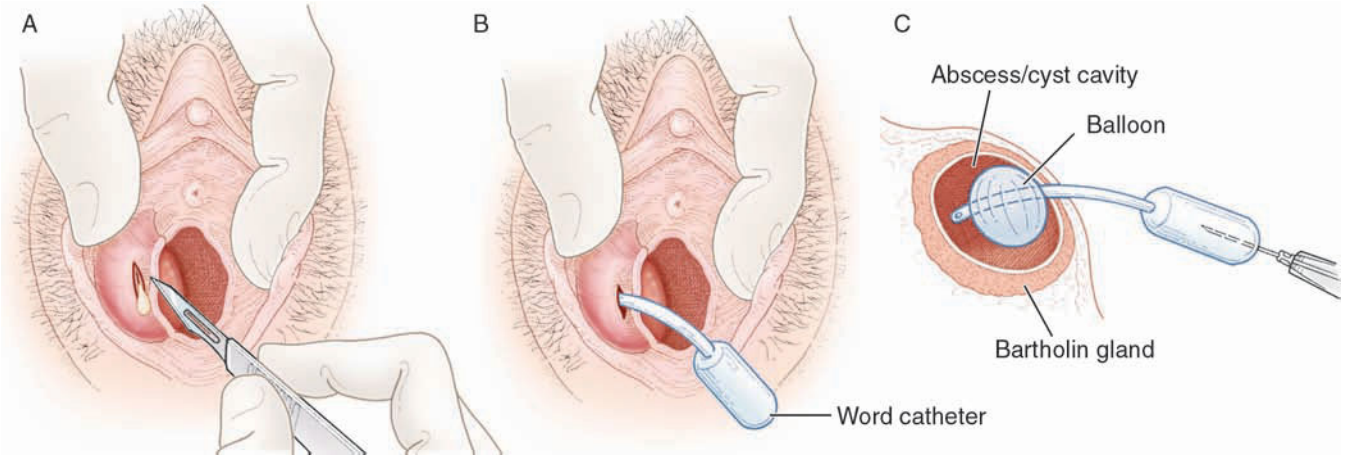

FIGURE 138-3. Incision and insertion of the Word catheter. **A.** Make a 0.5 cm long stab incision on the mucosal surface of the labia minora. **B.** The cavity has been evacuated and the Word catheter inserted. **C.** The balloon is inflated with saline.

end of the catheter within the vaginal canal. The Word catheter should ideally stay in place for up to 4 weeks. This allows the tract to become epithelialized and prevent a recurrence. The patient should abstain from sexual activity while the catheter is in place.

MARSUPIALIZATION

Marsupialization is an alternative treatment choice, initially described in 1950.[1,7,9,10,21,23–25] It is performed once and is curative in some case series greater than 90% of patients.[24,26] Advantages are that it can be done as an outpatient, is associated with little postoperative pain, has minimal postoperative scarring, and preserves the gland function.[8] Marsupialization can be easily and safely performed in the Emergency Department using local anesthesia. **Do not attempt to marsupialize a Bartholin abscess with an accompanying cellulitis.** Some Obstetricians prefer to perform this procedure in the Operating Room under general anesthesia.

Make an oval-shaped or elliptical incision approximately 1.5 cm long and 1 cm wide through the vestibular mucosa over the cyst/abscess and just outside the hymenal ring (**Figure 138-4A**). Remove this piece of mucosa to visualize the anterior wall of the cyst/abscess cavity. Insert a retractor to pull the skin edges open and better visualize the sac (**Figure 138-4B**). Make a similar incision through the anterior wall of the cyst/abscess cavity (**Figure 138-4B**). Most times the initial incision will pierce both the vaginal mucosa and cyst wall. Remove this piece of tissue leaving the cavity exposed. Culture the contents of the sac. Express the contents of the sac. Insert a small hemostat and break any adhesions.

Control any bleeding with electrocautery, silver nitrate application, or manual pressure. Closing the cavity with interrupted sutures, as a final option, will control the bleeding. Suture closure is only temporary for hemostasis as this pocket will become reinfected and require another procedure. Remove any sutures placed in 20 to 30 minutes. Identify the former bleeding site and treat it with electrocautery or silver nitrate to prevent rebleeding after the patient leaves the Emergency Department.

Evert the cyst/abscess wall. Approximate the wall of the cyst/abscess to the vestibular mucosa. Sew the wall of the cavity to the

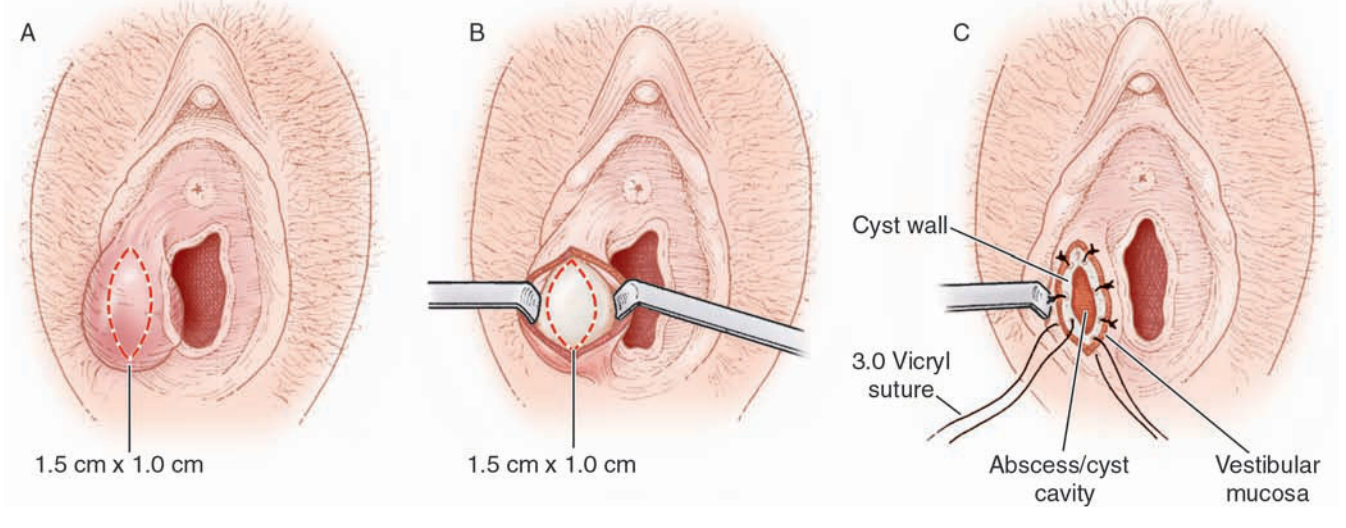

FIGURE 138-4. The marsupialization of a Bartholin cyst or abscess. **A.** An elliptical incision, 1.5 cm in length and 1.0 cm in width, is made through the vulvar mucosa and just outside the hymenal ring. The ellipse of mucosal tissue is then removed. **B.** An elliptical incision (*dotted line*) is then made through the anterior wall of the cyst or abscess. **C.** Approximation of the cyst or abscess wall to the vestibular mucosa with 3-0 or 4-0 interrupted Vicryl suture.

mucosa of the vaginal vestibule with interrupted 3-0 or 4-0 Vicryl sutures (**Figure 138-4C**). The orifice will reduce in size, epithelialize, and form a new duct in time. **Send all excised tissue to the Pathology Department to confirm the diagnosis and to rule out neoplasm.**

WINDOW OPERATION

This technique is almost identical to marsupialization.[27] It differs only in the size of the incision. One study claimed that this procedure had no long-term complications or recurrences, thus making it a more desirable technique.[27] However, the total patient population was small and the study has not been duplicated and republished. In essence, one follows the exact procedure for marsupialization with the exception of making a larger incision (2 to 3 cm long and 1.5 cm wide). At the completion of the procedure a wide opening is observed. The opening will be approximately one-half its original size at the 1 year follow-up. This much larger and radical incision is not recommended for the Emergency Physician.

COMPLETE EXCISION

This technique is reserved for the treatment of recurrent cysts and abscesses unresponsive to less invasive techniques.[7,9–12,15,21,27] It is also indicated in patients for whom carcinoma is suspected. Even though the function of the gland is to provide lubrication for sexual activity, in a well-estrogenized woman removal of the gland poses little clinical problem. In the past, excision of the Bartholin gland in all women over the age of 40 for fear of carcinoma was championed. This has been challenged given the low incidence of carcinoma of the Bartholin gland in favor of drainage and selective biopsy.[7] Significant bleeding may complicate dissection into this

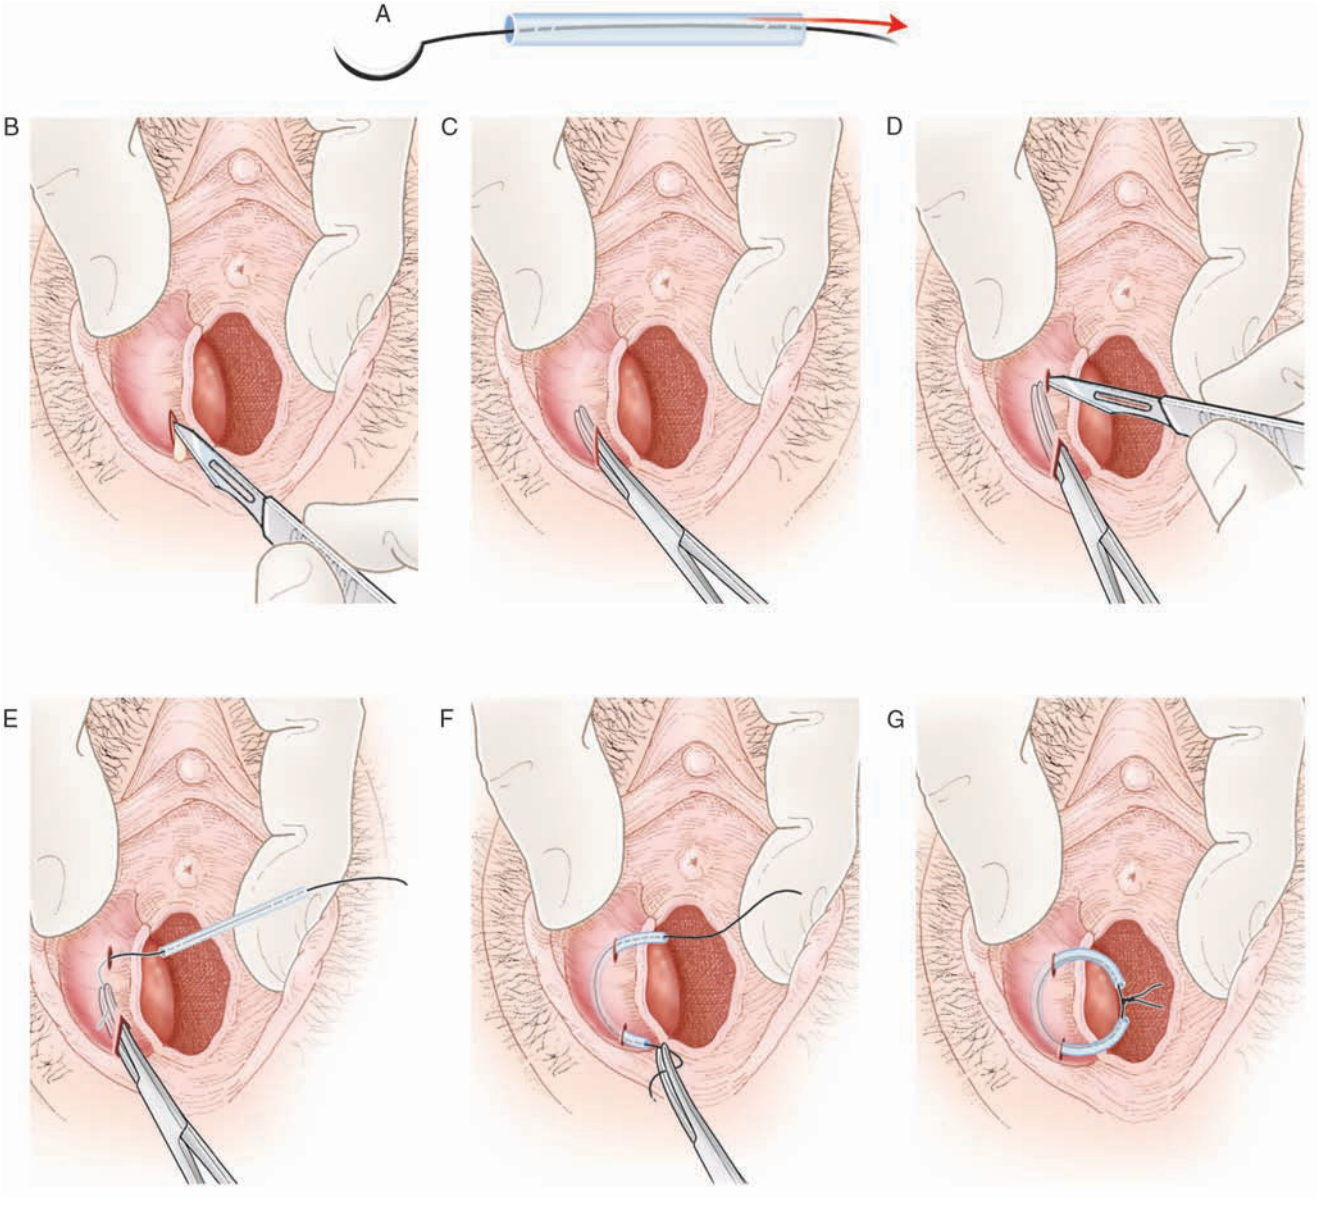

FIGURE 138-5. An alternative technique to incise and drain a Bartholin's cyst or abscess. **A.** A silk suture has been inserted through the tubing. **B.** A stab incision is made in the lower half of the abscess and outside the hymenal ring. **C.** A hemostat is inserted to break any loculations. **D.** The hemostat provides support as a second stab incision is made in the upper half of the abscess. **E.** One end of the silk suture is grasped with the hemostat. **F.** The suture and tubing are pulled out through the lower incision. **G.** The suture ends are tied to form a ring with the tubing.

area due to the underlying anastomosing venous plexus. If hemostasis is not achieved, a vulvar hematoma will result. Excision of the gland is often referred to as the "bloodiest little operation in gynecology." This procedure should only be performed by a Gynecologist in the controlled setting of an Operating Room under general anesthesia.

ALTERNATIVE TECHNIQUE

An alternative to the Word catheter has been described in the literature.[32,33] The advantages of this technique are that the materials are available in every Emergency Department, the device does not prematurely fall out as often happens with the Word catheter, and it is easily placed. Unfortunately, these reports had few patients. Larger studies comparing this technique to the Word catheter are required.

Prepare the equipment. Obtain a 5 to 7 cm long piece of tubing. Suggestions include cutting a piece from an 8 French T tube or a butterfly IV catheter.[32,33] Insert a strand of 2-0 silk suture, without a needle or the needle cut off, through the tubing (**Figure 138-5A**).

The procedure is quite similar to that previously described. Make a stab incision in the lower half of the abscess and outside the hymenal ring with a #11 scalpel blade (**Figure 138-5B**). Insert a hemostat and break any loculations (**Figure 138-5C**). With the hemostat in the abscess cavity for support, make a second stab incision in the upper half of the abscess (**Figure 138-5D**). Insert one end of the silk suture into the incision and grasp it with the hemostat (**Figure 138-5E**). Pull the suture and tubing out through the lower incision (**Figure 138-5F**). Tie the ends of the suture to form a ring with the tubing (**Figure 138-5G**). Place four to five knots in the suture. Cut off the excess suture.

AFTERCARE

All abscess and cyst contents should be cultured. The initiation of antibiotics can be delayed pending the culture results, at the discretion of the physician. Administer antibiotics if the abscess is accompanied by cellulitis. Keep in mind the prevalence of MRSA in soft tissue infections and specifically in labial abscesses when choosing antibiotics.[28,29]

All patients should begin sitz baths in 2 days. Prescribe appropriate oral analgesics. Nonsteroidal anti-inflammatory drugs will provide most patients with adequate analgesia. Some patients may require a brief course (1 to 3 days) of narcotic analgesics. Give written discharge instructions to each patient explaining the aftercare, the complications, and the actions to take if a complication does arise. All patients should abstain from sexual activity until the inflammation and pain resolves or until the Word catheter is removed.

COMPLICATIONS

The most common complication with the incision and drainage technique is frequent recurrence. The most common complication of Word catheter insertion is premature loss of the catheter resulting in early incision closure and recurrence. It can also be associated with significant discomfort if the catheter is inserted improperly. Marsupialization has few complications and a low recurrence rate. With any of these procedures, one can miss a carcinoma of the Bartholin duct or Bartholin gland if a biopsy or excision is not performed. Bleeding and progressive infection, including sepsis and toxic shock syndrome, are rare but possible complications.[30,31]

The immunocompromised patient (e.g., diabetic, steroid dependent, or HIV positive) needs particular attention paid to cleanliness during and after the procedure. If the abscess is accompanied by cellulitis and/or involves the labia majora, consider inpatient management and gynecologic consultation. Initial IV antibiotics should cover MRSA. A large Bartholin/labial abscess in a diabetic patient requires close surveillance and a high suspicion for necrotizing fasciitis. Daily follow-up visits are recommended for these patients during the initial postprocedural period. Early hospitalization and administration of intravenous antibiotics are warranted if there is any sign of progressive infection.

SUMMARY

Bartholin cysts and abscesses will be encountered by the Emergency Physician and can easily be treated. They present as a painful unilateral swelling of the inferior aspect of the labia. There are many treatments option. Culture all cyst or abscess contents. Send any tissue removed to the Pathology Department to rule out carcinoma. Refer patients with previously treated cysts or abscesses, those suspicious for carcinoma, and those over the age of 40 to a Gynecologist for definitive care. Give all patients written discharge instructions at the end of the procedure. All immunocompromised patients require very careful follow-up.

139 Sexual Assault Examination

Ann I. Schutt-Ainé and Audra E. Timmins

INTRODUCTION

The exact legal definition of sexual assault varies from state to state. Sexual assault is defined as forced sexual contact without consent. Nonconsensual sexual contact involves a continuum ranging from unwanted touching and fondling of sex organs to forced penetration (oral, anal, or vaginal). Fingers or objects (such as broomsticks, bottles, or knives) could be used instead of, or in addition to, a penis as a weapon of choice. Drugs such as gamma-hydroxybutyric acid (GHB), Rohypnol (flunitrazepam), ketamine, and alcohol are commonly used as "date rape" or "club drugs." These agents are used to disable the victim prior to a sexual assault.

Large studies have shown that 13% to 39% of women and 3% of men have experienced an attempted or completed sexual assault in their lifetime.[1,2] FBI and crime statistics grossly underestimate the incidence since only 16% of sexual assaults are reported to police.[1,2] In addition, the vulnerable populations such as homeless, sheltered, or institutionalized persons are not included in most large studies.[3] Approximately 300,000 to 700,000 adult women are victims of sexual assault annually in the United States, with 40,000 victims treated in Emergency Departments.[1,4]

Sexual assault is not generally a crime committed by strangers. Most women (78% to 82%) are sexually assaulted by someone known to them.[1,4–6] The assailant may include a spouse, boyfriend, family member, coworker, or neighbor. More than 50% of rape victims over the age of 30 are sexually assaulted by an intimate partner.[7] An acquaintance such as a contractor or package delivery person may be the perpetrator.

There is not a typical profile of a victim. Adolescent girls and young women face particularly high rates of sexual assault.[8] However, victims have been reported in all age groups. Sexual assault occurs across all socioeconomic groups, all racial backgrounds, and all ethnic backgrounds. Up to 39% of women will be sexually assaulted more than once during their lifetime.[1]

Some victims will not identify themselves as victims of sexual assault. They may be ashamed or fearful to disclose what happened. They also may be experiencing the rape trauma syndrome, a special category of posttraumatic stress disorder. The use of screening questions, as used for domestic violence, and a high index of suspicion are necessary to identify these patients. There is a significant increase in the utilization of medical resources after a sexual assault.[9]

The Emergency Department visit of a sexual assault victim is vital in assuring proper medical care, evidence collection, and treatment. Proper follow-up plans, medical appointments, and referrals to local rape crisis centers and/or hotlines are crucial for the mental and physical recovery of victims. The likelihood that the patient will seek follow-up care and pursue the case through legal avenues is strongly influenced by his or her initial experience in the Emergency Department. It is critical to not re-victimize the patient or make them feel responsible for the sexual assault.

INDICATIONS

Perform a sexual assault examination, including evidence collection, on all patients who present within 1 week of a sexual assault. Evidence collection has the highest yield if collected within 72 hours after the sexual assault. Proceed with the examination if the victim is unsure of when the assault occurred or when the patient is unsure if a sexual assault occurred. A thorough history and physical examination with extra attention to the areas violated should be performed to evaluate for injuries, even when the patient presents more than 1 week after the sexual assault. Evidence collection requirements vary from state to state. In some states, samples collected prior to assignment of a case number cannot be admitted as evidence. The Emergency Physician should become familiar with local laws. **Perform a complete history, as outlined in the technique sections, regardless of when the assault took place. Patients must consent to evidence collections (Figure 139-1).** Evidence collection should proceed if a patient is unable to consent due to a medical condition, with local statutes and hospital policy determining the release of evidence. Minors do not require parental consent for the initial evaluation of any potential life-threatening injuries. Many states require parental permission for the release of evidence.

CONTRAINDICATIONS

Life-threatening injuries and unstable vital signs must be managed per usual recommendations prior to evidence collection. Five percent of sexual assault victims have major nongenital physical injuries.[10] Victims must be able to consent to the examination and evidence collection unless prohibited by a medical condition.

EQUIPMENT

- Separate **paper bags** for clothing and undergarments
- Clean white sheet and large paper sheet to place on floor when patient disrobes
- Four sterile cotton-tipped swabs for oropharynx evidence collection
- Pharyngeal culturettes for gonorrhea and chlamydia
- Four sterile cotton-tipped swabs for vaginal/cervical/penile evidence collection
- Culturettes for gonorrhea and chlamydia of the vagina/penis
- Slides for vaginal wet mount for trichomonas
- Four sterile cotton-tipped swabs for rectal evidence collection
- Culturettes for gonorrhea and chlamydia of the rectum
- Extra sterile cotton-tipped applicator swabs for miscellaneous stains and bite marks
- Comb and a piece of clean white paper for loose pubic hairs
- Comb and a piece of clean white paper for loose head hairs
- Two sticks for fingernail scrapings
- Filter paper for blood collection
- Urine or blood collection equipment to test for pregnancy
- Equipment for serum collection to test for hepatitis, syphilis, and HIV
- Instant camera or forensic photographer
- Colposcope, as applicable
- Sterile water to moisten speculum and cotton-tipped swabs
- Change of clothing for the patient
- Separate envelopes to place evidence within for each body site
- Tape to seal all evidence

Most states have prepackaged evidence collection kits with most of the necessary equipment included. These kits usually do not contain paper bags for the clothes, culturettes, blood drawing equipment (i.e., needles, Vacutainers), and blood collection tubes; all of which are readily available in any Emergency Department.

PATIENT PREPARATION

Address any life-threatening injuries and unstable vital signs before proceeding to the formal sexual assault examination. Up to 5% of rape victims have major nongenital physical injuries.[10] **To best preserve evidence, do not to rip or cut any clothes. Life-threatening interventions always supersede evidence collection, but note on the patient's medical record if any clothing is cut or torn by medical personnel.**

Conduct the examination in a quiet, private room. It should ideally have the facilities to perform a pelvic examination so that the patient does not have to be moved multiple times. Assign a designated nurse and physician who are trained in the sexual assault protocol and aware of the multiple emotional manifestations that the patient may experience. **Safety and privacy must be ensured.** Notify a community- or hospital-based advocate upon the patient's arrival to the Emergency Department. Advocates can best define their own role. Allow the patient to decide if the advocate should stay for the examination and evidence collection. The number of providers should be kept to a minimum. All providers can be subpoenaed to testify in the event of legal action. Contact police per local laws and patient request. Alert hospital security to the possibility that the assailant may come to the hospital.

The patient must give written consent prior to the examination (**Figure 139-1**). **It is important to let the victim guide the process as much as possible to help them restore control of their life.** Let the victim know that you are their advocate. Obtaining consent has important legal and psychological implications for the patient. **The sexual assault victim has the right to refuse the sexual assault examination, any medical treatment, and any interviews by advocates or social workers.** Note in the medical record any and all portions of the sexual assault examination and treatment that the patient refuses. **Encourage the patient to at least have the examination, without the use of the sexual assault kit, so that you can provide proper medical treatment. Encourage the patient to allow the collection of evidence with the sexual assault kit in the event that they later change their mind and decide to prosecute the assailant.**

Discourage the patient from eating, drinking, changing clothes, urinating, or defecating prior to the examination. This is to best preserve evidence, especially if the patient is seen in close time proximity to the sexual assault. Perform examinations specific to the affected area earlier to accommodate the patient if they need to drink or void.

EXAMINATION OF FEMALE PATIENTS

Exact details of the examination will vary depending upon state and local evidence collection requirements. Some states have provisions for special Sexual Assault Nurse Examiners (SANEs) who are specially trained to perform the complete sexual assault examination and testify if the case is prosecuted. Other regions have a sexual assault team (SART) with representatives from healthcare, forensics, rape crisis centers, law enforcement, and the prosecutor's office. SANE and SART programs increase compliance with recommended medical care, quality of evidence collection, and the likelihood that charges will be filed and successfully prosecuted.[3]

The order of the examination may vary depending upon the patient's needs. The Emergency Department is often the first official system to which the victim reports an assault. **Patients may be reluctant to share their story with personnel in the criminal justice system if they are met with judgmental attitudes or insensitive treatment by emergency medical staff.**[12]

Collect a urine sample early if there is any possibility of the use of a "date rape" or "club drug." The decision to process the urine can be determined later. The window to detect drugs such as gamma-hydroxybutyric acid (GHB) or Rohypnol (flunitrazepam) can be as little as 8 hours after ingestion. Most toxicology screens will detect prescription drugs and recreational drugs that the patient may have taken. For this reason, some patients may decide not to have their urine tested.

HISTORY

Proceed with the history and physical examination once the patient is in a private room, has consented to the examination, and an advocate is made available. Obtain a complete history to guide the medical examination and help with possible legal matters (**Figure 139-2**). **Avoid judgmental questions that may feed into the victim's feeling of self-blame.** Aspects of the history should include the time and place of the assault, the race, gender, and number of assailants. Obtain and document a brief description of the assault including whether there was oral penetration, vaginal penetration, rectal penetration, and/or ejaculation. Elicit any use of force, restraints, foreign bodies, or lubricants. Ask the patient what they have done since the assault. Simple things such as changing clothes, douching, bathing, urinating, defecating, or using a tampon may change the ability to collect forensic evidence.

The past medical history should emphasize the gynecological history and include last menstrual period, type of birth control used if any, last consensual intercourse, previous sexually transmitted diseases, previous pregnancies, and previous gynecological surgeries. The time of the last voluntary intercourse is important, as mobile sperm may be found up to 72 hours in the cervix. Determine the tetanus immune status and provide immunoglobulin and boosters if needed. Determine if date rape drugs might have been given, especially if there seems to be a lapse of time between the assault and presentation to the ED.

PHYSICAL EXAMINATION

The physical examination serves to detect injuries and document them for future legal prosecution. A complete physical examination must be performed, even if the patient does not want to pursue legal matters. Although up to 70% of rape victims reported no physical injuries, 4% to 5% sustained serious physical injury, and 24% sustained minor physical injuries.[1,13] **It is important to help patients guide the examination and allow them to stop at points if they are not ready to proceed. Many patients will need encouragement through the examination.**

Note the patient's general appearance, affect, and emotional status. Instruct the patient to disrobe over a clean paper sheet if they are wearing the same clothes they wore prior to the assault. Place all clothes in paper bags, with the underwear in a separate paper bag. Fold the paper sheet, containing any debris, and place it in a collection envelope. Examine the entire body for abrasions, lacerations, bites, scratches, foreign bodies, and areas of ecchymoses. **Closely examine every laceration to ensure it is not a stab wound.** It is helpful to use a body diagram to document injuries (**Figure 139-3**).

Genital trauma after consensual sex is uncommon. However, genital injuries commonly occur after sexual assault at the posterior fourchette, labia minora, fossa navicularis (anterior to the fourchette), and hymen.[11] Commonly injured nongenital areas include the mouth, throat, wrist, breasts, and thighs.[12] Oral cavity injuries are common and include a torn frenulum and broken teeth. Bite marks on the genitalia and breast are common.[14] Use a Wood's lamp to examine the skin for fluorescent stains that may represent semen. Use an instant camera or a hospital photographer to document any bites, lacerations, scratches, abrasions, or any other injuries. **Photographs are much more informative than body diagrams.**

Collection of forensic evidence usually precedes the gynecological examination unless the patient is bleeding, has severe lower abdominal pain, or has pelvic pain. Most states have set evidence collection kits and the elements required will vary. Evidence is usually helpful up to 5 days after an assault. It is recommended to collect evidence up to a week after an assault as patients may not recall the dates exactly. Most sexual assault kits require fingernail scraping, head hair combing, saliva specimens, and blood type screening. Swab any stain on the patient's body that fluoresces under the Wood's light. Swab all orifices (oral, vaginal, and anal), even if not penetrated, as recollection of events may change and a negative examination in a nonpenetrated area helps to validate the patient's story. **Use only sterile water or sterile normal saline to moisten a swab.** Obtain samples of the patient's saliva by having them bite on a piece of filter paper in the kit. Obtain a sample of the patient's blood. Place five or six drops of blood on a piece of filter paper. Use a wooden stick to scrape under all the patient's fingernails over a piece of white paper to collect the scrapings. **Allow all specimens to air-dry before placing them in envelopes.**

Collect hair samples from the victim. Pluck two or three hairs from the scalp hair and place it in a labeled envelope. Comb the patient's pubic hair over a white piece of paper. Place the comb, paper, and any hair or debris in a labeled envelope. Pluck two or three hairs from the pubic region and place them in a labeled envelope. The process of plucking hairs is painful and somewhat insensitive to the patient. Consider asking the patient to pluck the hairs for the evidence collection. This allows them to actively participate in the process. These hair samples can also be obtained later if the case is prosecuted, as the patient's hair samples will not change. **Cutting off pieces of hair is of no value as the roots of the hairs are required for the forensic evidence process.**

Inspect the mouth and perioral structures for any signs of trauma. Carefully inspect the frenulum of the lower lip and tongue for bruising or tears. Examine the tonsils, the tonsillar pillars, and the oropharynx for bruising or lacerations. Swab the oral cavity thoroughly and allow the swabs to air-dry. These will later be tested for sperm

acid phosphate and the victim's blood group antigens. Obtain additional swabs for gonorrhea and chlamydia testing in the hospital laboratory. Prepare a wet mount to look for motile spermatozoa.

Thoroughly examine the anorectal area for signs of trauma. This includes abrasions, ecchymoses, and lacerations. Swab the rectum and anal canal. Send one swab to the hospital laboratory for gonorrhea and chlamydia testing. Place the remainder of the air-dried slides in envelopes for later sperm and acid phosphatase testing.

The gynecological examination is usually the most traumatic aspect of the examination for the patient. It may remind them of the assault. **Explain all procedures in simple terms prior to beginning. Allow the patient to help guide the examination.** Do all forensic evidence collection, including combing for pubic hairs and vaginal swabs, at the same time as the gynecological examination. Close attention to the external genitalia is important, as many patients are asymptomatic (**Figure 139-4**). Eight percent of patients have vulvar trauma.[15] **Only use sterile water to lubricate the speculum. Lubricants interfere with forensic evidence collection.** Examination of the hymen is important, as it is one of the most common areas of injury. A person's previous sexual history helps predict the location of lacerations of the vaginal wall. Lacerations are seen near the introitus in less sexually experienced patients and higher in more sexually experienced patients.

Collect baseline gonorrhea and chlamydia swabs at the time of the pelvic examination from pooled vaginal secretions and the endocervical canal. Obtain additional swabs to test for sperm acid phosphatase and blood group antigens. Colposcopy is used to detect and document more subtle injuries of the cervix and vagina. One study showed that colposcopy increased detection of genital trauma from 6% to 53% of victims.[16]

Toluidine blue can be used to identify small lacerations and abrasions that result from traumatic intercourse. It can increase the chances for detection of lacerations in sexual assault victims. Apply the dye with a cotton-tipped applicator to the external genitalia and wipe off the excess. Document and photograph any areas of uptake to toluidine blue. Toluidine blue should be used prior to the speculum examination, as the speculum can result in small lacerations that uptake the dye. Unfortunately, the dye is spermicidal and can interfere with wet mount examinations.

EXAMINATION OF MALE PATIENTS

Males should have a complete urogenital examination looking for abrasions, lesions, and bites (**Figure 139-4**). The same disrobing, specimens, and precautions should be observed in male sexual assault victims. Obtain oral, rectal, and urethral swabs for gonorrhea and chlamydia testing as well as for sperm acid phosphatase.

EXAMINATION OF CHILDREN

The procedure for a child is similar to that of an adult. Children are often referred to pediatric hospitals or specially trained physicians to perform the sexual assault examination. **Defer the sexual assault examination of a child to a specialist if you do not have experience in this area. The anatomy and examination of a child is different from that of an adult.** Restraining an uncooperative or combative child can result in significant psychological trauma. These children may require an examination under procedural sedation or general anesthesia.

LABORATORY INVESTIGATIONS

Decisions regarding STD testing should be individualized given the potential for STD diagnoses to be accessed later despite limitations in all 50 states on the evidentiary use of prior sexual history. Serum testing should be performed for HIV, hepatitis B, and syphilis.[17] These are baseline tests and will be repeated in later follow-up testing. Process the gonorrhea and chlamydia probes at the hospital laboratory. Nucleic acid amplification tests are the preferred tests for *C. trachomatis* and *N. gonorrhoeae* regardless of the site. A wet mount or other point of care testing should be performed for *T. vaginalis*. Toxicology screens should only be performed at the hospital laboratory if there is a medically necessary reason for the test, such as altered mental status. Individual states have protocols for urine testing, which is done at a crime lab to detect date rape drugs.

CHAIN OF EVIDENCE

The work does not stop after the evidence is collected. As each state has different rules for evidence collection, please verify the proper procedure in your current setting. No one should leave or enter the examination room until all evidence is properly tagged and secured. Seal all paper bags and envelopes with evidence tape. Place your signature across the sealed ends of each bag or envelope and the evidence tape. This will make it easier to determine if they have been opened and tampered with. Clearly label each bag or envelope with the patient's name and hospital identification number, the date of collection, the time of collection, the source of the sample, and the printed and signed name of the nurse or assistant. Secure all the evidence in a locked room or cabinet until it can be turned over to a law enforcement officer. Have the officer sign a form stating the officer's name and badge number, the date and time the evidence was transferred, and the name of the physician or nurse releasing the evidence to the officer (Figure 139-1). Both individuals must sign this form.

AFTERCARE

Referral to a Social Worker or Psychiatrist may be necessary, especially if a patient advocate is not available. Treat any injuries in the standard manner. Update the tetanus immune status as necessary. Make a written summary of the physical examination findings for the medical record (**Figure 139-5**). Place any photographs taken in the medical record.

Provide all follow-up instructions in writing (**Figure 139-6**). Arrange medical follow-up with a primary care physician in 1 to 2 weeks and again in 2 to 4 months. The follow-up appointment should include an examination for sexually transmitted diseases, HIV testing, and hepatitis immunizations.

Give all patients a 24 hour crisis phone number as well as a follow-up in 1 to 2 days with the local rape crisis center, if the community has one. The Rape, Abuse, and Incest National Network (RAINN) offers a 24-hour hotline (1-800-656-HOPE) as well as a website (www.rainn.org) with helpful information for the patient.

Arrange, with the help of the advocate or Social Worker, a safe place for the patient to stay. This is especially important if the offender is not in custody. Encourage the patient not to stay by themselves. A patient may need to be hospitalized in rare instances for psychiatric issues from the assault or for the patient's safety.

PREGNANCY PROPHYLAXIS

The risk of pregnancy after a sexual assault is estimated to be approximately 5% if the patient is of reproductive age.[4] Both the American College of Emergency Physicians (ACEP) and the American Congress of Obstetricians and Gynecologists (ACOG) support the provision of emergency contraception to victims of sexual assault.[18,19] There are two categories of emergency contraceptives: emergency contraceptive pills and the Copper-T380A intrauterine device (IUD). The only contraindication to emergency

PATIENT CONSENT/AUTHORIZATION TO RELEASE EVIDENCE TO LAW ENFORCEMENT AGENCY

Patient _____

DOB_____ Hospital Patient No. _____

CONSENT

I understand that in addition to consent for medical evaluation and treatment given to the hospital and physician, I also give consent to a medical examination for evidence of sexual assault. I understand that the evidence collected in the State Police Evidence Collection Kit will be sent to the Illinois State Police Forensic Sciences Command for the sole purpose of analysis to determine sexual activity relating to the investigation of sexual assault. I understand that this exam may include reference samples. I also understand that I may withdraw consent at any time for any portion of the exam.

_____
Patient, Parent, Guardian (please circle)

I understand that collection of evidence may include photographing injuries and that these photographs may include the genital area. Knowing this I consent to having photographs taken.

_____
Patient, Parent, Guardian (please circle)

RELEASE

I hereby authorize _____ to release to _____
(Name of hospital) (City) (Law enforcement agency name)

the following information covering treatment given to me on _____.
(Month) (Day) (Year)

	AUTHORIZED FOR RELEASE (check those which apply)	NOT AUTHORIZED FOR RELEASE
1. Copies of Forensic Laboratory Report Form	☐	☐
2. State Police Evidence Collection Kit	☐	☐
3. Photographs	☐	☐
4. X-rays or copies of x-rays taken in connection with exam	☐	☐
5. Clothing	☐	☐

Authorized for release (list clothing or miscellaneous items)

Article	Description

STEP 2

FORENSIC LABORATORY REPORT
(4 PAGES)

Illinois State Police
Division of Forensic Services

Please print, type or use a patient information stamp.

(patient stamp)

Patient Name	DOB	Age	
Race	Sex	Arrival Date	Arrival Time
Address		City	
County	State	Zip	Phone
Hospital			ER#
For Children: Name of Guardian			Relationship
Person providing history		Relationship to patient	

For children: Avoid multiple interviews. Take time to establish rapport. Avoid leading or yes/no questions. Use direct quotes. Avoid surprise or negative emotions, while still showing concern and support.

1. Chief complaint of person providing history to include physical injuries and methods employed by perpetrator, i.e., weapons, restraint, biting, threats.

2. Chief complaint in child's words to include physical injuries and methods employed by perpetrator, i.e., weapons, restraint, biting, threats.

3. Date of Assault	Time of Assault	4. Location & geographical surroundings of assault

5. Name(s), number, & race of assailant(s) if known.

6. Sexual acts described by patient/historian

Acts Described	Yes	No	Attempted	Unsure
Penetration of vagina by:				
penis				
finger				
foreign object				
describe object				
Penetration of rectum by:				
penis				
finger				
foreign object				
describe object				
Oral copulation of genitals:				
of victim by assailant				
of assailant by victim				

Acts Described	Yes	No	Attempted	Unsure
Masturbation:				
of victim by assailant				
of assailant by victim				
Did ejaculation occur?				
inside body orifice				
outside body orifice				
If outside body orifice, describe location				
Other sexual acts?				
If yes, describe				
Did assailant use condom?				
Did you bite your assailant?				
Were you bitten by your assailant?				
Victim was licked/sucked?				
If yes, where_____				
Victim licked/sucked assailant?				
If yes, where_____				

7. Post-assault hygiene/activity	Yes	No
urinated	☐	☐
defecated	☐	☐
genital wipe/wash	☐	☐
bath/shower	☐	☐
douche	☐	☐
tampon, sponge, diaphragm removed/inserted (circle)	☐	☐
oral hygiene/intake/vomit	☐	☐
changed clothes	☐	☐

8. Pertinent medical history
   a. Date of LMP
   b. Sexual activity within 72 hrs. of assault?
      Yes No
   c. Contraceptive used at time of assault?
   d. Communicable diseases of risk to lab personnel
      (e.g., hepatitis, TB, HIV, lice, etc.)

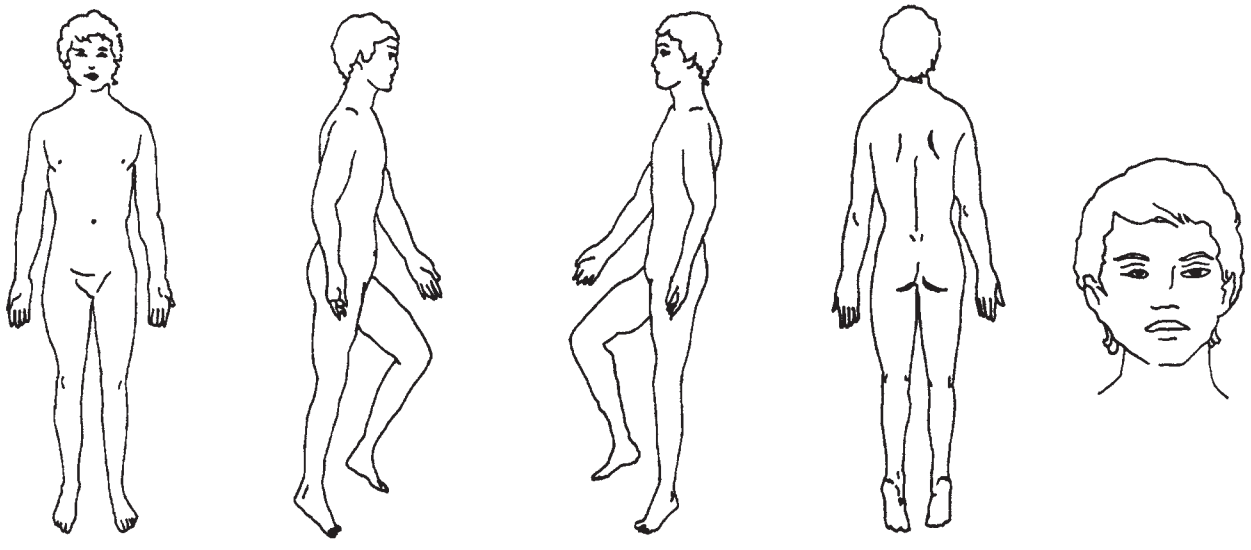
Please print, type or use a patient information stamp.

(patient stamp)



COMPLETE EVIDENCE COLLECTION STEPS 3, 4, AND 5

After STEP 5, obtain appropriate medical specimens from the mouth for clinical lab testing. Patient may rinse out his/her mouth after specimens are obtained. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

GENERAL EXAM

Trauma should be recorded on the diagrams below which may be used in a criminal proceeding. These include: lacerations, scratches, bruises (detail size, shape, color), erythema, bites, patterned injury, burns, fractures and stains/foreign materials on body, swelling, tenderness. Be sure to note even the most minor signs of trauma. In children: include anogenital or behavioral symptoms. Note general appearance.

Note abnormalities in diagram and/or text.

TEXT

GENITAL EXAM

- For children: Take time to establish rapport and proceed slowly. Extent of examination, including physical as well as specimens, must be decided on a case-by-case basis by the attending physician. If the examination would be too physically or emotionally traumatic for the child, then specimens may need to be obtained by gently using a moist swab on the external vaginal and rectal areas, especially with small hymenal openings.
- Note all discharge, stains, and foreign materials. Note any bleeding.
- Draw shape of hymen and anus in diagrams.
- Use sterile, non-bacteriostatic water or saline for lubrication of speculum.
- Record all acute trauma (lacerations, scratches, bruises [detail size, shape and color], erythema, bites, patterned injury, burns, swelling, tenderness) and chronic trauma (scarring, notching, pigmentary changes) on below diagrams.

ILSP502B

(White copy to hospital; yellow copy in kit)

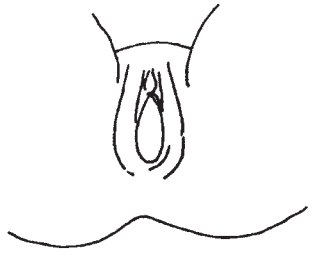
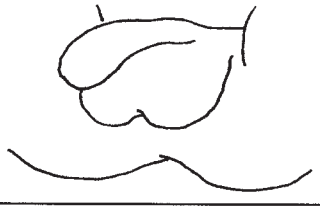
FORENSIC LABORATORY REPORT — PAGE 3



Please print, type or use a patient information stamp.

(patient stamp)

EXTERNAL GENITALIA

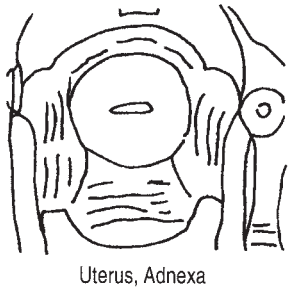


• Note abnormalities in diagrams and/or text.

Vulva/Hymen

• position during exam	lithotomy	knee chest	supine
• labia majora maneuver?	If yes, outward traction		lateral-down separation
• horizontal hymenal opening (with above position and maneuver)			mm
• description of hymen			
• draw picture of hymen on diagram			

Penis/Scrotum



• circumcised? Yes ☐ No ☐

INTERNAL EXAM

• As noted above, most children require only vaginal introital specimens without speculum or bimanual exams. Please individualize.

Vagina and Cervix

Uterus, Adnexa

• Note abnormalities in diagram and/or text.

• Note abnormalities on bimanual exam, if indicated.

COMPLETE EVIDENCE COLLECTION STEP 6

After Step 6, obtain appropriate medical specimens from the vagina/cervix or male urethra for clinical lab testing. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

RECTAL EXAM

• Digital or anoscopic exam at discretion of physician.

• Note abnormalities on above diagrams and/or text.

COMPLETE EVIDENCE COLLECTION STEPS 7 - 12

After Step 7, obtain appropriate medical specimens from the rectum for clinical lab testing. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.) After Step 11, obtain appropriate blood specimens for clinical lab testing. (DO NOT INCLUDE MEDICAL SPECIMENS IN KIT.)

ILSP502C

(Please print)

COMPLETE EVIDENCE COLLECTION STEP 13

FINAL INSTRUCTIONS

1. Make sure all information requested on all sample envelopes and bag labels have been filled out completely.
2. Separate all forms (Steps 1, 2, and 14) and follow distribution requirements on the bottom of each form.
3. With the exception of the large sealed and labeled clothing bags, return all other evidence envelopes/bags to the kit box.
4. Initial and affix red evidence tape on box top.
5. Fill out information required on kit box top.
6. Hand the sealed kit and sealed bags to investigating officer.

NOTE: If officer is not present at this time, place sealed kit and sealed bags in secure area, and hold for pickup by investigating officer.

COMPLETE EVIDENCE COLLECTION STEP 14

PATIENT DISCHARGE MATERIALS

Patient name	DOB/Age
Hospital name/phone	
Date of examination	ER#
Examining physician	

With your consent, a number of specimens were collected from you to provide evidence in court should your attacker be caught and you decide to prosecute.

Additional tests were conducted as follows: ☐ A blood test for syphilis, ☐ A culture for gonorrhea, ☐ Tests for chlamydia, ☐ Other tests_____

_____, and ☐ A pregnancy test to determine pre-existing pregnancy only, not to determine a possible pregnancy as a result of the assault.

VENEREAL DISEASE TREATMENT

☐ You were given an antibiotic to prevent gonorrhea. However, you must return in six weeks following this treatment for another test to be sure you do not have syphilis. Return for this test and possible treatment the week of _____ name of drug _____ dosage _____

☐ You were *not* given treatment to prevent gonorrhea or any other venereal disease because _____

☐ If you wish to obtain follow-up testing or treatment for venereal disease, please visit your local health clinic or contact _____

_____ (name, address, and telephone)

☐ Patient declines

PREGNANCY PREVENTION

☐ You were given medication to prevent pregnancy as a result of the sexual assault. If you should become pregnant despite having been given treatment, you should return immediately to the hospital emergency room or go to your private physician because the drug you were given may cause damage to the fetus. Name of drug _____ Dosage_____

☐ You were *not* given medication to prevent pregnancy because _____

If you want counseling, referrals and/or follow-up pregnancy testing information, consult the social service department of this hospital or call one of the agencies listed below for assistance.

Agency _____ Agency _____

Address _____ Address _____

Telephone _____ Telephone _____

☐ Patient declines

FOLLOW-UP

☐ An appointment was made for you at this hospital for follow-up *medical* treatment on (date) _____

☐ No appointment was made for follow-up medical treatment because _____

☐ An appointment was made for you at this hospital for follow-up *counseling* on (date) _____

☐ No appointment was made for follow-up counseling because _____

PSYCHOLOGICAL SUPPORT referral to

Was written and verbal information given to patient? ☐ Yes ☐ No

DOCUMENTATION

If the patient is less than 18 years of age, was DCFS notified, if appropriate? ☐ Yes ☐ No

Were police notified? ☐ Yes ☐ No Was Patient Consent and Authorization Form completed? ☐ Yes ☐ No

INFORMATION

I have received the following written information:

☐ Illinois Department of Public Health brochure, "After Sexual Assault" ☐ Attorney General's Office flyer "Illinois Crime Victims Compensation Act"

☐ Patient Medication information sheets listing anticipated effects and side effects of medicines given to me.

☐ This patient information sheet _____

Patient Signature Date

☐ I do not wish to receive this sheet _____

Patient Signature Date

FIGURE 139-6. Sample patient discharge instruction form. Courtesy of Illinois State Police.

contraception is pregnancy. Emergency contraceptive pills will not harm an existing pregnancy. IUD placement may disrupt a pregnancy or increase the risk of a serious infection and septic abortion. Early emergency contraceptive pills consisted of high doses of common oral contraceptive pills (Yuzpe method).[20] Emergency contraceptives which contain only the progestin component (levonorgestrel) are both better tolerated and more effective than the Yuzpe method.[21] Recent data have shown that a single, 1.5 mg dose of levonorgestrel to be equally effective up to 5 days after unprotected intercourse.[22]

In August 2010, the FDA approved ulipristal acetate (Ella®) for emergency contraception. Studies have shown pregnancy rates 42% lower than levonorgestrel when used up to 72 hours after unprotected intercourse, and 65% lower when used between 72 and 120 hours after.[23,24]

The Copper-T380A IUD (ParaGard®) is the most effective form of emergency contraception and can be inserted up to 8 days after unprotected intercourse.[25] There is no evidence to support the routine use of prophylactic antibiotics prior to placement of an IUD.[26] However, antimicrobial prophylaxis is recommended after sexual assault as described in the next section.

While ACOG believes that "emergency contraception should be available in hospitals and facilities where victims of sexual assault at risk of pregnancy are treated,"[19] there are hospitals that prohibit contraception and practitioners who morally object to it. In such cases, patients should be promptly referred to a center where they can receive the appropriate treatment.

ANTIMICROBIAL PROPHYLAXIS

Postexposure prophylaxis for sexually transmitted diseases is recommended since compliance with follow-up visits is poor. The risk of acquiring a sexually transmitted disease is relatively high and the side effects from the medications is relatively low. The most common infections diagnosed during sexual assault exams are trichomonas (12%), bacterial vaginosis (12%), gonorrhea (4% to 12%), and chlamydia (2% to 14%).[27,28] The current recommendation is to provide prophylaxis for gonorrhea and chlamydia. The current CDC guidelines recommend an empiric antibiotic regimen for chlamydia, gonorrhea, and trichomonas. The current CDC recommendation is intramuscular ceftriaxone (250 mg) or oral cefixime (400 mg) plus oral metronidazole (2 g) plus oral azithromycin (1000 mg) or doxycycline (100 mg) twice a day for 7 days.[17] The current guidelines do not recommend prophylaxis for syphilis. The treatment for bacterial vaginosis and trichomonas is a single 2000 mg dose of oral metronidazole. Trichomonas prophylaxis is controversial as ascending infections are rare. The side effects include significant nausea that may interfere or complicate pregnancy prophylaxis. As resistance emerges to various treatments, a yearly check of the current CDC guidelines is advisable.

Hepatitis B vaccination, without HBIG, is recommended if the patient has not been previously vaccinated.[17] This is especially important in high-risk exposures such as unprotected penetration, contact with the assailant's blood, or contact with the assailant's body fluid. Provide the first dose of the hepatitis B vaccine in the Emergency Department. Boosters are recommended at 1 to 2 months and 4 to 6 months.

There are no clear guidelines for postexposure prophylaxis for HIV. Clinical factors increasing the risk of HIV infection include the site of penetration (oral is lowest vs. vaginal vs. rectal being highest), trauma, and the presence of lesions from other STDs in the assailant or the victim. Possible benefits of postexposure prophylaxis should be discussed with the patient with case-specific risks and benefits of HIV prophylaxis. Have a specific discussion regarding the importance of adherence, close follow-up, and early initiation.[17] Consult the CDC website (www.cdc.gov) for the most current medication regimens for prophylaxis.

Treatment for the male sexual assault victim is the same except for trichomonas treatment and pregnancy prophylaxis. These are not necessary in the male patient.

If there are any questions, contact the National Clinician's Postexposure Prophylaxis Hotline (PEP Line) at 1-888-448-4911.

COMPLICATIONS

There are no physical complications to performing the sexual assault examination. **Be aware of potential psychological complications. Treat the patient with the utmost privacy and dignity to help them through this stressful situation and not victimize them. Do not add to the abuse that they have already suffered. Allow the patient to make decisions during the history and physical examination so that they have a voice in the process.**

SUMMARY

The Emergency Department plays a key role in providing quality treatment to the sexual assault victim. Providing compassionate care strongly influences the healing process from being a victim to becoming a survivor. It is important to perform a complete examination for trauma and not just focus on evidence collection. Careful collection and documentation of the elements of the evidence collection kit will impact successful prosecution. Proper follow-up care and a strong link to a local rape crisis center are important.

140 Culdocentesis

David L. Levine

INTRODUCTION

Culdocentesis is a procedure used to sample peritoneal fluid to help confirm a diagnosis or to obtain a culture. It has mainly been used for diagnosing a ruptured ectopic pregnancy or ruptured ovarian cyst.[1–9] Culdocentesis involves introducing a hollow needle through the posterior vaginal cuff and into the peritoneal space. This is a relatively simple and fast procedure. Ultrasound, with its improved resolution and availability, has virtually replaced culdocentesis as the test of choice.

ANATOMY AND PATHOPHYSIOLOGY

The key anatomy to be familiar with is the vagina and the pouch of Douglas, also known as the rectouterine pouch or the cul-de-sac. The rectouterine pouch is formed by reflections of the peritoneum between the posterior surface of the uterus and the anterior surface of the rectum. It is the most dependent intraperitoneal space in both the upright and supine positions. This allows blood, pus, and other free fluids to pool in this space. The rectouterine pouch separates the upper portion of the rectum from the uterus and the upper portion of the vagina. The small intestine and a small amount of peritoneal fluid often lie within the rectouterine pouch. The sensory innervation of the vagina is greatest near the introitus. There is minimal sensory innervation in the posterior vaginal fornix adjacent to the rectouterine pouch.

INDICATIONS

Culdocentesis has been used in the Emergency Department in the past to diagnose a ruptured viscus, particularly an ectopic pregnancy. The use of culdocentesis has decreased significantly with the emergence of improved serum and urine tests for pregnancy, increased accessibility to ultrasonography, and the increased resolution of ultrasound. Recent studies have clearly shown ultrasonography to be more sensitive and noninvasive in detecting a hemoperitoneum.[1] Despite this, there still remains three main indications to perform a culdocentesis.

The first indication is a hemodynamically unstable female patient of reproductive age with evidence of peritoneal irritation in the pelvic region. This patient most likely has a ruptured ectopic pregnancy and needs emergent surgery. A diagnostic test is usually not necessary to take the patient directly to the Operating Room if a rapid pregnancy test is positive. An unstable patient cannot be sent to the Radiology Department for an ultrasound. A culdocentesis may be performed if bedside ultrasonography is not available. Many Emergency Departments now have the availability of bedside ultrasound or have Radiology Technician available to perform bedside ultrasounds. Approximately 85% to 90% of patients with ruptured ectopic pregnancies have a positive culdocentesis.[2]

The second indication for a culdocentesis is a stable pregnant patient with ultrasonographic evidence of free fluid in the pelvis or pouch of Douglas. A culdocentesis can confirm if the fluid is blood. Approximately 65% to 70% of patients who have a stable presentation and unruptured ectopic pregnancy have a positive culdocentesis.

A culdocentesis is indicated if ultrasonography or laparoscopy is not readily available. A negative culdocentesis may be used to reassure the Emergency Physician that following serial quantitative beta-HCG levels can be performed before committing a stable patient to an operative procedure. A positive culdocentesis would indicate intraabdominal bleeding that requires immediate operative intervention.[3]

Other indications for a culdocentesis include the evaluation of ascites, blunt abdominal trauma, or in cases of pelvic inflammatory disease. It can be performed to obtain ascitic fluid to evaluate for infection, malignancy, or the type of fluid (i.e., exudate or transudate). Culdocentesis has been used in place of a diagnostic peritoneal lavage to detect a hemoperitoneum in blunt abdominal trauma since small amounts of blood tend to collect in the rectouterine pouch. Aspiration of clear peritoneal fluid excludes a hemoperitoneum. Ultrasonography and CT scanning have significantly reduced the usefulness of culdocentesis for this indication. Intraperitoneal fluid from patients with pelvic inflammatory disease can be cultured to guide treatment, especially in treatment-resistant cases.

CONTRAINDICATIONS

There are a few contraindications to performing a culdocentesis. Ultrasonography is the preferred diagnostic method to confirm intraperitoneal bleeding if it is available in a timely manner. A pelvic mass detected on bimanual pelvic examination is a contraindication. A pelvic mass may be a tubo-ovarian abscess, an appendiceal abscess, an ovarian mass, or a pelvic kidney. There is a concern of rupturing an abscess, if present, into the peritoneal cavity with the culdocentesis needle. Other contraindications include a nonmobile uterus and patients with a coagulopathy. The procedure is limited to patients beyond puberty on the basis of anatomy. It is difficult to perform the procedure through a small prepubertal vagina. **A patient with unstable vital signs and a positive bedside pregnancy test should be immediately taken to the Operating Room and does not require a culdocentesis; although they will require fluid and blood resuscitation until the Operating Room and Surgeon are available.**

Culdocentesis may be unsatisfactory in women with previous salpingitis and pelvic peritonitis because the rectouterine pouch may have been obliterated. **The failure to obtain blood does not exclude the diagnosis of a hemoperitoneum and, therefore, cannot exclude an ectopic pregnancy.**[4]

EQUIPMENT

- Exam table with stirrups
- Water-soluble lubricant
- Vaginal speculum
- Cervical tenaculum
- 19 gauge butterfly needle or 18 gauge spinal needle
- 25 and 27 gauge needles
- Ring forceps
- 20 mL aspirating syringe
- Povidone iodine or chlorhexidine solution
- Sterile water
- Cotton balls
- 4 × 4 gauze squares
- Local anesthetic solution with epinephrine
- 4% cocaine
- 20% benzocaine
- Red top test tube for laboratory analysis
- Purple top test tube for laboratory analysis
- Culture tubes
- Light source

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and alternatives (such as ultrasound or immediate laparoscopy) to culdocentesis to the patient and/or their representative. Obtain a signed consent for the procedure. If verbal consent is obtained, a statement in the chart should state the following: "The risks, benefits, alternatives, and complications were described and discussed in detail. The patient has a clear understanding of these and any questions were answered." A witness should be noted in the record.

Perform a bimanual pelvic examination to rule out a fixed pelvic mass and to assess the position of the uterus prior to the culdocentesis. Place the patient in the lithotomy position with the head of the table slightly elevated (i.e., reverse Trendelenburg) so that the intraperitoneal fluid gravitates into the rectouterine pouch. Place the patient's feet in stirrups. Procedural sedation or premedication with intravenous narcotics or sedatives is recommended and may make the procedure more tolerable for the patient. Premedication is not required in an unstable patient.

Some Emergency Physicians obtain stat upright plain radiographs in stable patients prior to the procedure. These are performed to assess for a pneumoperitoneum. This will also help in determining if a pneumoperitoneum was secondary to the procedure upon obtaining postprocedural radiographs.

TECHNIQUES

Insert a lubricated speculum as deep into the vagina as possible without causing the patient discomfort. Open the speculum widely so the blades are above and below the cervix (**Figure 140-1C**). Grasp

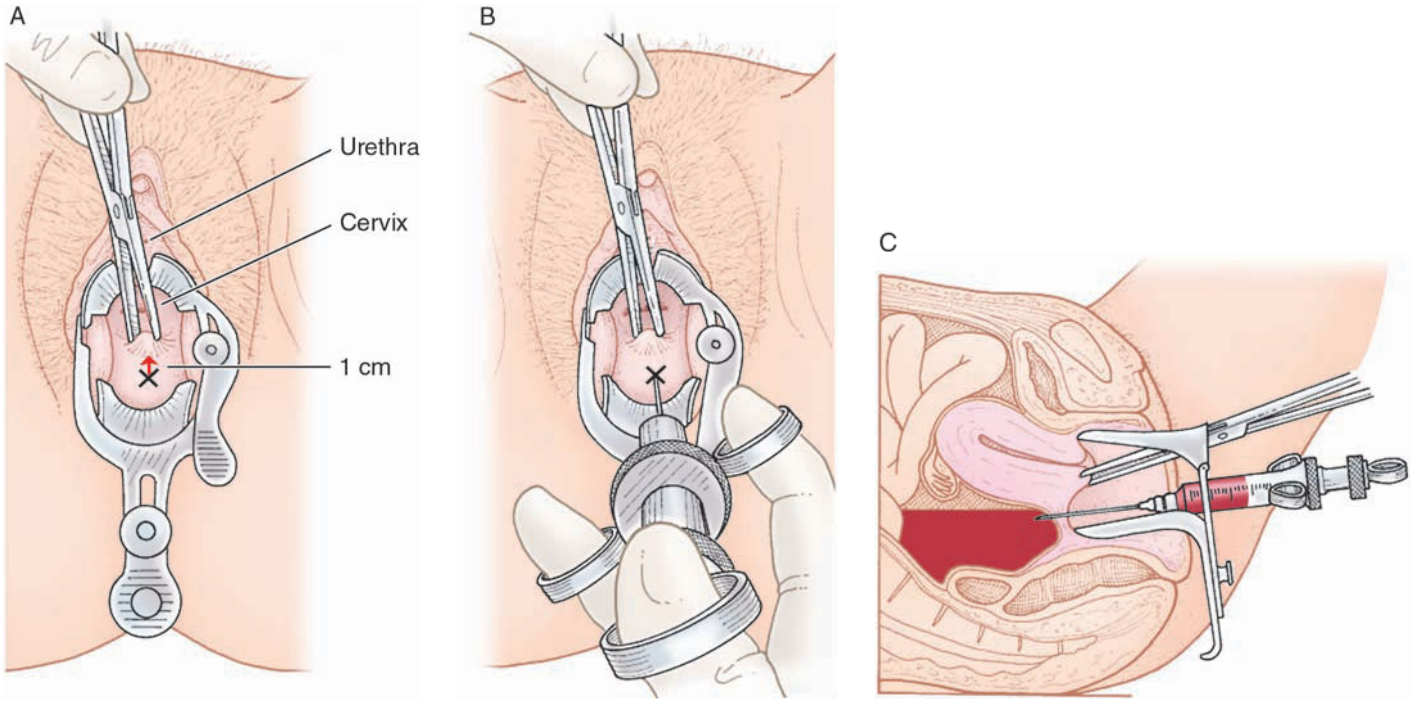

FIGURE 140-1. Culdocentesis. A speculum has been inserted in the vagina and opened. **A.** Grasp the posterior lip of the cervix with a toothed tenaculum and elevate it. The "X" marks a spot 1 cm from the junction of the cervix and posterior vaginal wall where the needle will be inserted. **B.** The needle used for anesthesia and culdocentesis are inserted 1 cm from the junction of the cervix and posterior vaginal wall. **C.** Midsagittal section of the female pelvis during a culdocentesis. The needle is inserted and aimed slightly posterior to access the fluid.

the posterior lip of the cervix with the toothed tenaculum or a ring forceps (**Figure 140-1A**). **Forewarn the patient that grasping of the cervix with a tenaculum may be painful.** Elevate the cervix to elevate a retroverted uterus from the pouch and to stabilize the posterior wall of the uterus during the needle puncture. This also results in a tightening of the vaginal wall adjacent to the rectouterine pouch to expose the puncture site and keep it from moving away from the needle as the vaginal wall is punctured.

Prepare the area. Swab any secretions out of the vagina. Swab the vaginal wall in the area of the rectouterine pouch with povidone iodine or chlorhexidine followed by sterile water. Some Emergency Physicians may optionally choose to topically anesthetize the area with a cotton ball soaked in 4% cocaine or 20% benzocaine prior to infiltrating with local anesthetic solution. Insert the cocaine or benzocaine soaked cotton ball into the posterior vaginal fornix area and allow it to remain for 3 minutes. The maximum dose of cocaine to apply to the cotton ball is 3 mg/kg. Arm a 5 mL syringe containing local anesthetic solution with epinephrine with a 25 gauge needle. Insert the needle in the midline and 1.0 cm posterior (inferior) to the point at which the posterior vaginal wall joins the cervix (**Figure 140-1B**). Inject 2 mL of local anesthetic solution containing epinephrine into the tissues of the vaginal wall.

Fill a 20 mL aspirating syringe with 2 to 3 mL of sterile saline. Local anesthetic solution can be used instead of saline, but note that it is bacteriostatic and any aspirated fluid cannot be cultured. Attach an 18 gauge spinal needle to the 20 mL syringe. Insert the spinal needle parallel to the lower blade of the speculum. Penetrate the vaginal wall in the midline and 1.0 cm posterior (inferior) to the point at which the vaginal wall joins the cervix (**Figure 140-1C**). Advance the needle 2.0 to 2.5 cm.[4,5] Slowly inject 0.5 to 1.0 mL of saline. It should flow freely and without resistance if the needle is within the rectouterine pouch (**Figure 140-1C**). It may otherwise be within the wall of the uterus or intestines. Withdraw and redirect the tip of the needle until the saline flows freely upon injection. Apply negative pressure to the syringe while slowly withdrawing the needle. **It is important to avoid aspirating any blood that has accumulated in the vagina from previous needle punctures or cervical bleeding.**

Fluid may not be aspirated. Withdraw the needle and reintroduce it slightly to the left or right of the midline. Avoid directing the needle too far laterally. This can result in the puncture of a mesenteric or pelvic vessel. Always repeat the procedure once if no fluid is obtained on the first attempt.

Place some of the peritoneal fluid into a red top and purple top test tube. Place some of the fluid into aerobic and anaerobic culture tubes. Observe the fluid for clotting. Transport the samples to the laboratory for Gram's stain, culture, cell count, and hematocrit.

ALTERNATE TECHNIQUES

Slight alterations in the described technique have been used successfully. Longitudinal traction on the cervix instead of grasping and elevating the posterior lip of the cervix is sometimes used to elevate the uterus. A 19 gauge butterfly needle held with ring forceps can be used instead of the spinal needle (**Figure 140-2**). This allows for good control of the needle during the puncture and also offers a built-in guide for needle depth. An assistant is required for this alternative to aspirate the tubing while the Emergency Physician positions and withdraws the butterfly needle.

ASSESSMENT

A normal culdocentesis when there is no pathology should yield 2 to 4 mL of clear-to-yellowish peritoneal fluid. There is no diagnostic value when there is no return of fluid of any type, also known

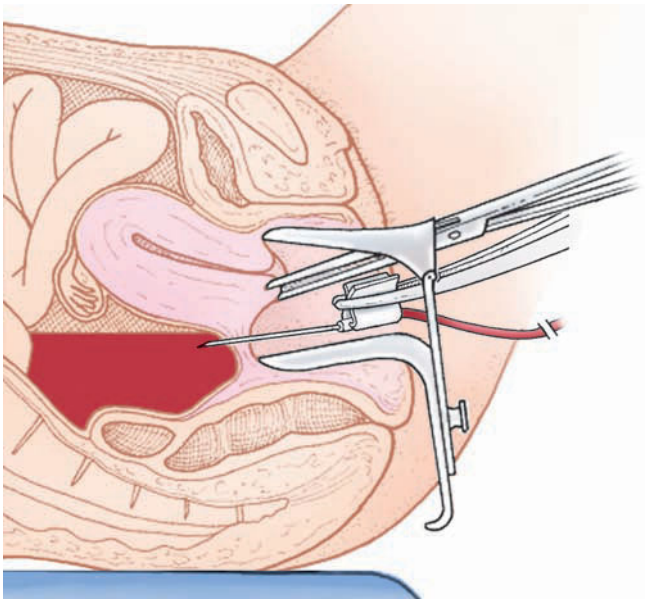

FIGURE 140-2. The alternate technique of using a butterfly needle and ring forceps to perform a culdocentesis.

as a dry tap. It is considered nondiagnostic if less than 2 mL of clotting blood is obtained. This may have come from a puncture site on the vaginal wall.

A hemoperitoneum is signified by the aspiration of more than 2 mL of nonclotting blood. It has been suggested that as little as 0.3 mL of nonclotting blood equates with a positive tap.[6] The finding of nonclotting blood with a hematocrit greater than 15% has been 70% to 97% predictive of a significant bleeding source, such as ectopic pregnancy.[3] Approximately 70% to 83% of ectopic pregnancies will have nonclotting blood on culdocentesis. In addition, 10% to 20% of ectopic pregnancies will have a negative or nondiagnostic culdocentesis. False positives will occur in 2% of cases.[7]

Culdocentesis is less sensitive with unruptured ectopic pregnancies, 70% versus 85% to 90% positive rate.[8] The quantity of blood greater than 2 mL has no further significance as it may be related to needle position or rate of bleeding. Blood remains nonclotted for days in the syringe due to defibrination activity of the peritoneum. A ruptured ectopic pregnancy, a hemorrhagic ovarian cyst, or a ruptured spleen can all result in a hemoperitoneum. Peritoneal bleeding usually has a hematocrit of greater than 10%. One study showed that 97% of cases with an ectopic pregnancy had a hematocrit of at least 15%.[9]

A positive culdocentesis with a positive pregnancy test is not always an ectopic pregnancy. A ruptured corpus luteum cyst is the most common cause of a false-positive result. The false-positive rate is estimated at 9%.

A culdocentesis is considered negative when the aspirated fluid is pus, cystic, or straw-colored if performed for the purpose of diagnosing an ectopic pregnancy. Greater than 10 mL of clear fluid most likely indicates a ruptured ovarian cyst, aspiration of an intact corpus luteal cyst, ascites, or possibly carcinoma. **Obtaining greater than 10 mL of clear fluid does not automatically rule out an ectopic pregnancy since it may coexist with other pathology.**[2]

Ultrasound was far superior in recent studies comparing ultrasound versus culdocentesis. The sensitivity and specificity of echogenic fluid for establishing a hemoperitoneum were 100% and 100%, respectively, compared with 66% and 80%, respectively, for culdocentesis.[1] The negative predictive value of a nondiagnostic culdocentesis was 25% compared to 100% for echogenic fluid in the ectopic pregnancy subgroup of patients.[1]

AFTERCARE

Aftercare is limited to local wound care of the puncture site. Proper postsedation monitoring and precautions are necessary. Bleeding from the tenaculum puncture sites on the cervix or the vaginal wall puncture site is usually self-limited. Apply manual pressure with a gauze square to provide hemostasis. Obtain upright plain radiographs to rule out an iatrogenic pneumoperitoneum from the procedure.

COMPLICATIONS

Complications associated with performing a culdocentesis are rare. The most common and serious complication reported includes the rupture of an unsuspected tubo-ovarian abscess.[4] Other complications include puncture of the gravid uterus, bowel perforation, perforation of a pelvic kidney, and bleeding from the puncture site in patients with bleeding disorders. Bowel and uterine wall punctures usually do not result in serious morbidity. Most complications are eliminated by a careful bimanual examination to detect a pelvic mass prior to the procedure.

SUMMARY

Culdocentesis can be very useful in evaluating for an ectopic pregnancy. It is easy to perform, rapid, and relatively safe. Its utility has decreased as the test of choice with the improved capability and availability of ultrasonography. It is indicated when ultrasound is not available or a patient is unstable and bedside ultrasonography is unavailable.

141 Prolapsed Uterus Reduction

Eric R. Snoey

INTRODUCTION

There is a progressive relaxation of pelvic support for the uterus and vagina with advancing age. This relaxation may in turn lead to symptomatically important uterine prolapse in susceptible women. The quality of life issues associated with uterine prolapse have become increasingly more relevant with women living a third of their lives in the susceptible period after menopause. Population-based studies note that up to 10% of women report symptoms of pelvic organ prolapse. The Women's Health Initiative study found evidence of uterine prolapse on physical examination in 14% of study participants. Manual reduction of the prolapsed uterus and placement of a pessary represents a safe and temporizing measure that may be performed in the Emergency Department. Surgical correction may ultimately be necessary. It is estimated that pelvic organ prolapse is responsible for more than 200,000 surgical repair procedures each year (22.7 per 10,000 women). This chapter will address the nonsurgical management of a prolapsed uterus.[1–4]

The structural support of the female pelvis is subject to a number of identifiable stresses that may predispose certain women

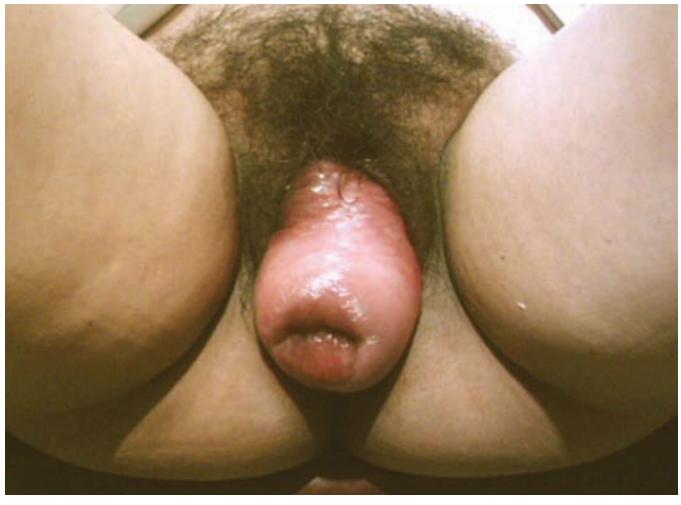

FIGURE 141-1. Uterine procidentia (Used with permission from: Cunningham GF, et al: *Williams Obstetrics*, 23rd ed, 2010).

to uterine prolapse later in life. Multiparity seems to be the most commonly shared trait, suggesting that birth trauma has a primary role to play. Alternative mechanisms include anything that may increase intraabdominal pressure, such as heavy lifting, ascites, obesity, large intraabdominal tumors, or pelvic tumors. Similarly, chronic respiratory disorders (e.g., asthma, bronchitis, or emphysema) may put undue tension on the pelvic floor musculature.[5] Two cases of acute uterine prolapse after restrained motor vehicle collisions were recently described.[6] It was hypothesized that the sudden increase in intraabdominal pressure from the lap belt was the cause of the prolapse. A congenital form of uterine prolapse may be seen in newborns due to vigorous crying.[7] The integrity of the pelvic connective tissues may have a role to play as suggested by the increased incidence of uterine prolapse in women with Marfan syndrome and other connective tissue disorders.[8]

Uterine prolapse is defined as the descent of the uterus and cervix down the vaginal canal toward the vaginal introitus. All forms of genital prolapse are described in reference to the hymen. The uterine displacement is typically graded on a scale of 0 to 4, with 0 referring to no prolapse, 1 halfway to the hymen, 2 at the hymen, 3 halfway out of the hymen, and 4 referring to total proplapse.[3] A first-degree or mild prolapse is defined with the cervix palpable as a firm mass in the lower third of the vagina. Patients with grades 0 or 1 prolapse are usually asymptomatic. Grade 3, or moderate prolapse, is characterized by the cervix being visible and projecting into or through the vaginal introitus. The patient may experience a falling-out sensation or may report the feeling of sitting on a ball. Additional symptoms include heaviness in the pelvis, low backache, lower abdominal discomfort, and inguinal discomfort. Grade 4, also known as severe prolapse or procidentia, involves the cervix and entire uterus projecting through the introitus, completely inverting the vaginal vault (**Figure 141-1**).[9] The uterine mass frequently has one or more areas of easily bleeding atrophic lesions secondary to exposure and local pressure effects. It may result in leukorrhea, abnormal uterine bleeding, or spontaneous abortions.[5]

ANATOMY AND PATHOPHYSIOLOGY

The pelvic diaphragm, the endopelvic fascia, and the vagina provide the primary support for the pelvic organs. The superficial muscles of the perineum lie below the pelvic diaphragm and indirectly support the pelvic organs by inserting centrally into the perineal body. The perineal body serves to fix the distal vagina and anus. The bony pelvis is the ultimate support for all the soft tissues of the pelvis.[8]

The pelvic diaphragm is made up of a bilaterally paired group of three striated muscles: the pubococcygeus (including the puborectalis), the iliococcygeus, and the coccygeus. The pelvic diaphragm is innervated by fibers originating from sacral segments four and five. The pelvic diaphragm is normally in a state of tonic contraction. It increases its tone reflexively in response to increases in intraabdominal pressure.[8]

The endopelvic fascia is the layer of fibrous connective tissue that envelops all pelvic organs. The endopelvic fascia develops supportive thickenings along lines of tension that are referred to as ligaments (e.g., uterosacral and cardinal ligament complex). These ligaments provide further support for the pelvic structures. The uterosacral and cardinal ligaments suspend the uterus and are in fact simple extensions of the endopelvic fascia.[8]

The vagina has supportive functions as well. The uterosacral and cardinal ligaments shift the upper one-third of the vagina posteriorly and laterally. This provides support for the cervix. The middle third of the vagina is attached bilaterally to the fascia overlying the pelvic sidewall musculature and supports the bladder. The lower third of the vagina is fused to the tissues about the vaginal outlet.

There are numerous causes that lead to the development of a prolapsed uterus. Prolonged labor can lead to significant pelvic floor damage, suggesting that women who delivered vaginally or who later required cesarean section because of failure to progress are more at risk.[8] As yet, no factor has been identified that allows the identification of apparently normal individuals in which pelvic floor dysfunction is destined to develop after vaginal delivery.[8] The quantity and quality of collagen appears to deteriorate in women after menopause, likely attributable to the resultant estrogen deficiency.[11,12] It is thought that defective connective tissue contributes significantly to uterine prolapse in the absence of other risk factors. One study of premenopausal women with uterine prolapse found a 25% reduction in the collagen content of tissues.[12] Conditions that affect spinal cord pathways and pelvic nerve roots (e.g., muscular dystrophy, trauma, myelodysplasia, meningomyelocele) can result in paralysis of the pelvic floor with the subsequent prolapse of pelvic structures. Spina bifida has been associated with the majority of cases of uterine prolapse in newborn girls and nulliparous women.[8]

Increased intraabdominal pressure is a major factor in the development of pelvic organ prolapse. Obesity contributes to pelvic prolapse by increasing intraabdominal pressure that is, in turn, transmitted to the pelvic organs. Chronic respiratory conditions that are associated with forceful coughing are also thought to predispose to uterine prolapse. Occupational and recreational activities, such as heavy lifting or repeated jumping, result in repeated and prolonged increases in intraabdominal pressure. A review of 1.6 million women found an increase risk of uterine prolapse in a group of nurses whose jobs required heavy lifting.[8] The deterioration in muscle function and connective tissue associated with aging together with gravity, childbirth, neurological deterioration, and hormonal status all combine to lead to a progressive decline in pelvic floor function in older women. This may be compounded by factors that increase intraabdominal pressure leading to the development of symptomatic pelvic floor prolapse.[11]

All aspects of the vaginal support should be carefully surveyed when examining a patient with a uterine prolapse. Look for the presence of a cystocele or rectocele. Examine the patient in the standing position, as well as in the standard dorsal lithotomy position, since the prolapse is almost invariably worse when the patient is upright.[11] It may be necessary to have the patient strain to assess

the full extent of the prolapse.[15] The examination may be facilitated by having the patient stand with one foot on a well-supported footstool. Some degree of a cystocele, urethrocele, enterocele, or rectocele may develop or may be associated with a uterine prolapse as the uterus progressively descends. Some authors recommend expanding the traditional speculum examination by using a single blade speculum (e.g., Sims speculum) to selectively visualize each portion of the vaginal vault for defects in pelvic support. Perform a rectovaginal examination with the patient in the standing position to detect an occult enterocele, suggested by the presence of small bowel easily palpable in the cul-de-sac using the thumb and forefinger.[13,14]

Asymptomatic uterine prolapse requires no treatment in the Emergency Department. The patient with only intermittent symptoms can prevent against prolapse by simply inserting a tampon or a diaphragm. This additional support may be used in anticipation of increased activity or prolonged periods of standing. The patient, however, should be informed that she is losing some aspects of pelvic support and should be referred to a Gynecologist for evaluation of future treatment options.[7] Lifestyle changes can prevent the progression or recurrence of prolapse, precluding the need for future surgical evaluation and complications. Most of these changes focus on decreasing unnecessary increases in intraabdominal pressure like losing weight, removing girdles, avoiding heavy lifting, stopping smoking, and treating allergies or pulmonary disease accordingly.[1] Kegel proposed a series of pelvic muscle exercises for the treatment of urinary incontinence, which can accompany uterine prolapse. These exercises strengthen the pelvic muscles and may be helpful early. They are of limited value in patients with significant prolapse since fascial attachments have already been disrupted.[7,16]

Symptomatic women can be treated conservatively or surgically. Pelvic organ prolapse is frequently not recognized until advanced disease is present because prolapse does not become symptomatic until the descending segment is at or through the introitus.[10] Therapeutic options are variable and relate to the age and health of the patient, the severity of the symptoms, and the degree of prolapse. The options for uterine prolapse include observation, reduction with or without supportive pessary therapy, vaginal hysterectomy with corrective therapy for pelvic relaxation (hysteropexy), and some form of colpocleisis (surgical obliteration of the vagina).[17]

INDICATIONS

Conservative management of symptomatic uterine prolapse in the Emergency Department involves reduction and subsequent fitting of the patient with a pessary. The pessary is largely used as an alternative to surgery or as a temporizing measure in patients awaiting surgery.[18] Preoperative use of a pessary in advanced degrees of prolapse may aid in decongesting the mucosa, improving circulation, and reestablishing vaginal tonicity. Patients desiring surgical management may be treated conservatively in the Emergency Department and referred to a Gynecologist. Symptomatic women who wish to complete childbearing before having a surgical repair may also be candidates for a vaginal pessary.[1] The gynecologic and obstetric indications for pessary support after reduction of the prolapsed uterus are listed in **Table 141-1**.[5]

CONTRAINDICATIONS

There are no absolute contraindications to the manual reduction of a prolapsed uterus. Pessaries are contraindicated in patients with acute genital tract infections and in those with adherent retroposition of the uterus.[5] Any vaginal inflammation, ulceration, infection, or atrophy should be treated before pessary fitting to decrease the likelihood of vaginal erosions and granulation tissue formation. These latter conditions can be mitigated by oral or topical estrogen supplementation. The use of large amounts of lubricants, such as K-Y Jelly, should be encouraged with the pessary in the event that estrogen is contraindicated.[18] Other contraindications include patients with impaired mental capacity, lack of patient dexterity, a history of noncompliance, or severe atrophic mucosal changes.

TABLE 141-1 The Indications for the Placement of a Pessary[5]

Gynecologic indications
Nonsurgical management of uterine prolapse
Aid in the healing of cervical stasis ulceration associated with uterine prolapse
Reduction of a cystocele, enterocele, or rectocele
To alleviate the complications of free uterine retroposition and adnexal prolapse
To determine if future hysteropexy will relieve backache associated with uterine malposition
To facilitate hysteropexy by holding the uterus in position for operation
To control stress urinary incontinence
To reduce infertility due to cervical retroposition
Obstetric indications
To avoid threatened abortion due to uterine retroposition and chronic passive congestion
To relieve urinary retention and/or pain that can accompany uterine retroposition in pregnancy
To prevent postpartum subinvolution or retroversion of uterus
To prevent and protect against abortion in cervical incompetence

EQUIPMENT

- Pessaries
- Standard pelvic bed
- Vaginal speculum
- Water-soluble lubricant
- Culture swabs
- Biopsy and Pap smear brush, optional
- Uterine forceps
- Sterile gloves
- Sedation, as needed

The vaginal pessary is of ancient lineage. They are now made of plastic, rubber, or silicone that functions to support the uterus, cervical stump, or hernias of the pelvic floor.[5] They are available in numerous sizes and shapes (**Figure 141-2**). Silicone pessaries have the advantage of being flexible and pliable while causing less vaginal discharge and odor than the rubber pessaries.[17] Pessaries elevate the vagina and maintain normal anatomic relations by supporting prolapsing structures against the perineal body and pubic bone. They thereby reduce vaginal relaxation and increase the tautness of the pelvic floor structures. Usually all that is needed is adequate support anteriorly and a reasonably good perineal body. Otherwise, the pessary may slip from behind the pubic symphysis and extrude from the vagina.[5] Unfortunately, the education of Emergency Physicians is somewhat compromised in the use of pessaries. Placement of a pessary is often a trial and error experience. Review the accompanying brochures to obtain the most satisfactory results from the pessary.[17]

PATIENT PREPARATION

Explain the procedure, its risks, and complications to the patient and/or their representative. Obtain an informed consent prior to performing the procedure. Place the patient in the lithotomy

FIGURE 141-2. Examples of different types of pessaries (Photo courtesy of CooperSurgical, Inc., Trumbull, CT).

position with both feet comfortably resting in standard stirrups. An assistant should be available to assist with positioning.

TECHNIQUES

The management of complete uterine prolapse in the Emergency Department depends upon successful replacement of the uterine fundus into the pelvis and subsequent fitting of the appropriate pessary. Refer the patient for surgical management upon discharge from the Emergency Department. An incarcerated uterus in the pregnant patient is an obstetrical emergency requiring immediate surgical elevation. Other indications include any pregnant patient who develops acute urinary retention or is at risk of aborting.[5]

UTERINE REDUCTION

Insert one gloved and lubricated hand into the vagina with the fingers extended to identify the margins of the cervix. Allow the uterine corpus to rest in the palm of the hand. Apply firm and gentle pressure to elevate the uterine fundus with the gloved hand by pressing against the cervix. Use the fingers on the edges of the uterus closest to the cervix to gently manipulate the uterus in the direction of the umbilicus. Gradually replace the uterus into the pelvis.

If this maneuver is not successful, insert a pessary into the posterior vaginal fornix while the patient is in the lithotomy position. Instruct the patient to sit up and assume the knee-chest position after insertion of the pessary. Instruct the patient to slip slowly into the prone position and then into the lithotomy position. The pessary will maintain the uterus in anteposition. It may be necessary to pack the vagina following manual reduction of a procidentia to maintain the uterine position as a preoperative management decision of an ulcerated or infected prolapse.[5,19] This should be performed in consultation with a Gynecologist.

FITTING OF THE PESSARY

Measure the distance from the introitus to the posterior vaginal vault using uterine forceps after reduction of the uterus. This measurement minus 1 cm is the approximate length of the pessary. To find the width (assuming an ovoid rather than a round pessary is required), place the forceps into the introitus to about the level of the cervix. Separate the handles until the blades touch the walls of the vagina. This represents the greatest diameter of the pessary.[5]

Liberally lubricate the pessary. Insert it with its widest dimension in the oblique diameter of the vagina to avoid painful distension of the introitus. Use the fingers of the nondominant hand to support the perineum. Slip the posterior bar behind the cervix using a finger on the dominant hand. The forefinger should pass easily between the sides of the frame and the vaginal wall at any point to ensure adequate fitting. If this is not possible, the pessary is too large.[5]

ASSESSMENT

Ask the patient initially to walk around the examination room to confirm comfort and exclude partial or complete expulsion of the pessary or recurrence of the prolapse. Replace the pessary with one of a different size or style to prevent any further prolapse.

AFTERCARE

Instruct the patient to remove the pessary each night and clean it with warm soapy water during the first few weeks of use. The soap should not contain any deodorants, detergents, or perfumes. These agents can irritate the vaginal mucosa and result in a chemical vaginitis. Weekly cleanings and overnight removal are adequate after the patient has become comfortable with its use. Apply vaginal cream once a week if the patient is not receiving systemic supplemental estrogen replacement. Warm, low-pressure acetic acid douches or acidic vaginal creams (such as ACI-JEL) may relieve irritation and prevent any discharge caused by the vaginal pessary.[5]

Refer the patient to a Gynecologist. Routine follow-up at 6 to 12 month intervals is recommended after several weeks of a well-managed and appropriately sized pessary. Additional care of these devices includes biannual pelvic examinations and replacement of pessaries every 12 to 18 months.[2] Patients should be counseled on the hazards of leaving the pessary in for prolonged periods of time and the importance of complying with recommended follow-up. It is not uncommon to have to change the pessary size and/or type. Patients are sometimes unable to manage the responsibilities of a pessary. A family member or a nurse trained in the insertion, removal, and care of the pessary is an appropriate alternative.

Advise all patients to return to the Emergency Department for difficulty urinating, defecating, signs of infection, or any problems with insertion and removal of the pessary.

COMPLICATIONS

Attempts at reducing the symptomatic uterine prolapse may be unsuccessful. Review the surgical and medical options with the patient and arrange the appropriate follow-up. Consult a Gynecologist before the patient is discharged from the Emergency Department.

A loose pessary is ineffective and usually will be expelled. The patient may experience pelvic pain, vaginal bleeding, vaginal ulcers, urinary retention, urinary fistulas, bowel fistulas, vaginal discharge, and/or dyspareunia if the pessary is too large or not removed and

cleaned periodically. **Therefore, proper fitting is important initially with appropriate follow-up to address these issues.**[17]

Minor complications include ulceration and abrasions of the vaginal mucosa secondary to local pressure effects. Pessaries act as foreign bodies and can become colonized by bacteria and lead to a vaginitis. Many patients experience a physiologic watery discharge with pessary use. This should not be confused with an infectious process that usually is accompanied by itching, burning, or odor. Severe vaginitis is more common in the elderly and debilitated patients because of the inability to remove and cleanse the pessary.[20,21] These conditions should be treated accordingly with discontinuation of the pessary until the infection has cleared and local care with estrogen or antibiotic creams.[18]

Serious complications are a result of prolonged, often decades long, uninterrupted use caused by neglect rather than the pessary itself.[18] Case reports described in the literature include vesicovaginal fistulas, rectovaginal fistulas, urosepsis, and malignancy.[22] Cervical and vaginal cancer associated with pessary use is a rare complication and is perhaps related to prolonged irritation or the chemical constituents of some of the older models of pessaries.[22] Pessary-related infections can occasionally develop local complications (e.g., abscess, sinus tract, pelvic cellulitis) or spread to other systems to cause systemic manifestations (e.g., pyelonephritis, peritonitis). Patient counseling and adequate follow-up is important.[18] **All of the complications are preventable and point to the need for periodic gynecologic examinations in pessary users.**[20]

SUMMARY

Reduction of the prolapsed uterus with subsequent pessary placement is a safe and acceptable mechanism for management of women who present to the Emergency Department with symptomatic prolapse. It is important that Emergency Physicians be familiar with this technique and recognize those women most at risk in order to avoid related complications.

SECTION 11

Genitourinary Procedures

142 Urethral Catheterization

Richard Dean Robinson and Eric F. Reichman

INTRODUCTION

Urethral catheterization is the most frequent manipulation of the urinary tract. It is routinely performed for diagnostic and therapeutic reasons in both urologic and nonurologic diseases.[1–11] Catheters may be inserted as an in-and-out procedure for immediate drainage, left in with a self-retaining device for short-term drainage, or left indwelling for long-term drainage.[6,7] Although this is one of the more routinely performed procedures in the Emergency Department, great care must be taken to avoid lower urinary tract injury, reduce the introduction of infection, and minimize patient discomfort. The basic principles underlying urethral catheterization are gender-neutral.[6,7] It is important to respect the patient's need for modesty and privacy as much as possible.

ANATOMY AND PATHOPHYSIOLOGY

The genitourinary system is frequently divided into upper and lower urinary tracts. The former refers to the kidneys and ureters or those structures above the bony pelvis. The lower urinary tract includes the bladder and urethra or those structures contained within or below the bony pelvis. Although the entire urinary tract may be catheterized, it is the lower tract, namely the urethra, which will be the focus of this chapter.

Averaging 4 cm in length, the female urethra is rarely a focus of difficulty. Most of the confusion related to urethral catheterization in the female results from poor anatomic knowledge of the external genitalia (**Figure 142-1**). The clitoris is often mistaken for the urethral meatus. This can result in catheter-related trauma, bleeding, patient discomfort, and frustration. After lateral retraction of the labia minora and exposure of the vaginal vault, the cephalad-most structure is the clitoris. Traveling in a caudal direction, the orifices encountered are the urethra, followed by the vagina, and the anus.

The male urethra is most often the site of catheter-associated difficulty.[3] In contrast to the female, the male urethra may extend upward of 20 cm in length and follows a tortuous course. The urethra is named based on the anatomic structure it traverses or travels with. The distal-most portion of the male urethra is the meatus, followed by the penile, bulbar, membranous, and prostatic portions (**Figure 142-2**). Resistance to the advancement of a catheter may occur at any point along the course of the urethra as a result of meatal stenosis, urethral strictures, urethral valves, false urethral passages, enlarged prostates, inflammatory processes, malignant processes, bladder neck contractures, urethral disruptions, and bladder neck disruptions. A careful clinical history and thorough physical examination will, in most

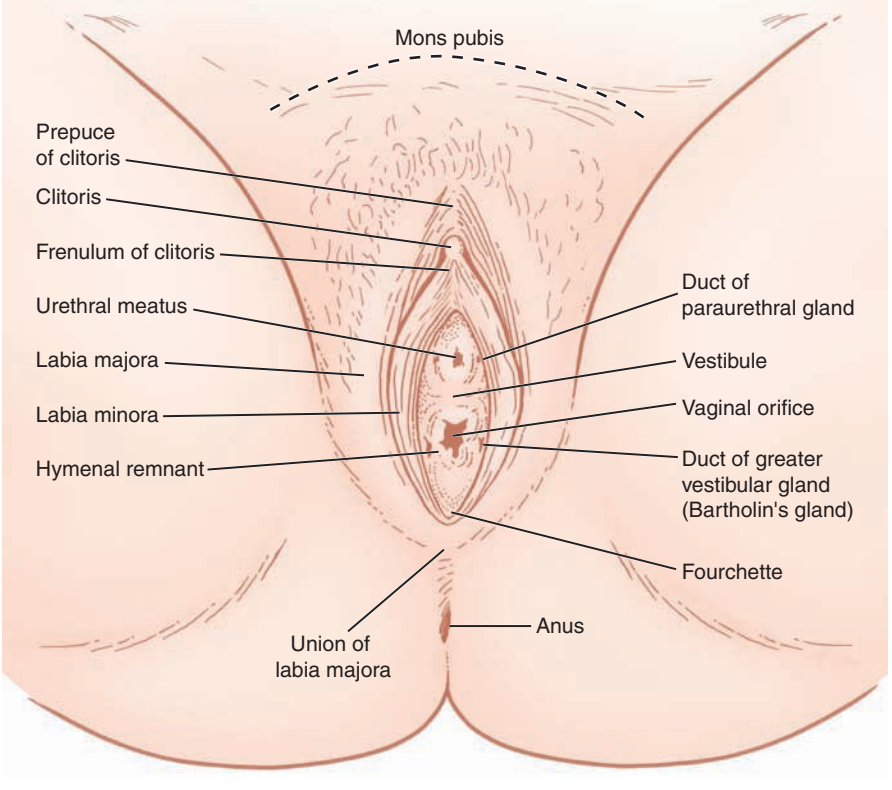

FIGURE 142-1. External anatomy of the female genitourinary tract.

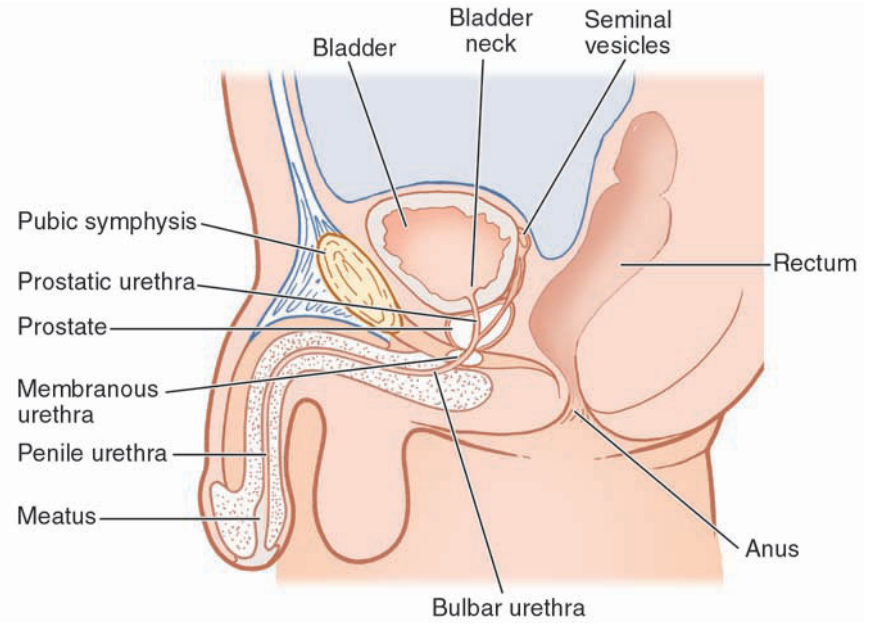

FIGURE 142-2. Anatomy of the male genitourinary tract.

cases, uncover these causes. The two most common sites that may be difficult for the catheter to pass are the junction between the bulbar and membranous urethra and the bladder neck.

INDICATIONS

Urinary catheterization can be performed for diagnostic and/or therapeutic reasons.[2,5] Urethral catheterization is often performed in females to collect urine for culture and avoid contamination from skin and vaginal flora. This is usually not necessary in males. Measurement of residual (i.e., postvoid) urine, urinary output monitoring, treatment of urinary incontinence, and to allow post-surgical healing are all indications for urethral catheterization. It can be performed to facilitate diagnostic studies, such as retrograde cystography and urodynamics. The main therapeutic indication for urethral catheterization is to relieve acute or chronic urinary retention. Patients with neurogenic bladders are often taught self-catheterization so they may perform this procedure at home. Other indications include bladder irrigation, instillation of medications into the bladder, surgery of the urinary tract or nearby structures, urodynamic testing, or in the intubated patient.

CONTRAINDICATIONS

The only absolute contraindication to urethral catheterization is in those patients with known or suspected traumatic injury to the lower urinary tract.[2,4,5] They should not undergo urethral catheterization until urethral continuity has been confirmed radiographically. Physical signs on examination that might suggest urethral trauma include blood at the urethral meatus, a perineal hematoma, or a high-riding prostate. Attempts at urethral catheterization may convert a partial urethral disruption into a complete disruption. Refer to Chapter 145 for the complete details regarding retrograde urethrography and cystography.

There are a few relative contraindications to urethral catheterization. Microscopic or gross hematuria in the absence of lower urinary tract trauma is not a contraindication to urethral catheterization. Patients with grossly bloody urine are at risk for urinary retention secondary to obstructing clots and require urethral catheterization for bladder irrigation. Although hypocoagulable states are not contraindications to urethral catheterization, great care must be exercised to avoid traumatic injuries and uncontrollable bleeding of the urethra. Prior placement of a penile prosthesis or an artificial urinary sphincter is not a contraindication to catheterization. However, vigorous attempts at inserting the catheter are discouraged. Urethral catheterization should not be performed in an uncooperative or combative patient unless they are sedated and/or restrained. A Urologist should be consulted prior to urethral catheterization in patients with known urethral strictures or recent surgery of the urethra or bladder neck.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Commercially available kit containing the components listed below
- Water-soluble lubrication gel
- Lidocaine jelly in penile applicator (e.g., Uro-jet, Int'l Medication Systems Ltd, South El Monte, CA)
- Sterile drapes
- Urethral catheters (Foley, coudé, filiform, and followers)
- Christmas tree adapter
- Pediatric feeding tubes, sizes 5 to 8 French
- Sterile saline
- 10 mL syringe
- Urine meter, if catheter is to be retained
- Urine collection system
- Urethral catheter leg strap, if catheter is to be retained
- 1 inch tape
- Benzoin solution
- Ultrasound (optional)

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. **Urethral catheterization must be performed using strict sterile technique.** All equipment needed to perform the

procedure should be assembled at the bedside prior to beginning the procedure. The preparation for a male patient will be described below. The preparation for a female patient will be described in the techniques section.

Place the male patient in a bed or gurney. In uncircumcised patients, the foreskin must be retracted to expose the glans penis and the urethra. If a phimosis is encountered, it should be approached accordingly. In the pediatric population, male infants and children often have a physiologic phimosis. Attempts at aggressive foreskin retraction should be avoided. Clean any dirt and debris from the penis. Apply povidone iodine or chlorhexidine solution, with cotton balls or swabs, and allow it to dry. Place sterile drapes around the penis to isolate a sterile field.

Generous lubrication and anesthesia of the male urethra is one of the most important aspects of urethral catheterization.[9–10,13–15] A water-soluble lubricant (e.g., K-Y Jelly) or local anesthetic lubricant (e.g., 2% lidocaine jelly) can be applied to the tip of the urethral catheter before it is inserted. Unfortunately, this provides little-to-no anesthesia. Ideally, commercially packaged sterile blunt-tip syringes of lidocaine jelly (e.g., Uro-jet) should be used. Insert the blunt tip of the syringe into the urethral meatus. Firmly squeeze the glans penis to form a seal around the syringe tip. Inject the anesthetic jelly into the urethra. Maintain the syringe tip in the urethral meatus and manual pressure on the glans penis for 10 seconds to prevent egress of the anesthetic jelly.

Prophylactic antibiotic coverage is generally not indicated for urethral catheter placement. Patients with penile prostheses, artificial urinary sphincters, prosthetic heart valves, vascular graphs, and other indwelling foreign bodies may benefit from prophylactic antibiotics. An intravenous dose of a cephalosporin, quinolone, or other antibiotic that covers skin and perineal flora may be administered just prior to inserting the urethral catheter.

MALE CATHETERIZATION TECHNIQUES

FOLEY CATHETER INSERTION

Foley catheters are the most commonly placed urethral catheters. A Foley catheter is a dual lumen tube that contains an inflatable cuff near the distal end (**Figure 142-3**). The distal end has two holes for urine to enter the catheter. Urine traverses the large inner lumen of the catheter to exit the proximal port. The second lumen is extremely small and allows air or fluid to flow into the inflatable cuff. The proximal end contains two ports. One port allows the egress of urine from the catheter. The second port is an inflation port. An air-filled or saline-filled syringe attaches to this port and is used to inflate the cuff. When inflated, the cuff prevents the distal end of the catheter from slipping out of the bladder.

Foley catheters come in a variety of sizes and styles. A 14 or 16 French catheter is the size most commonly used in adolescent or adult patients. The two-way catheter is most commonly used. It is designed for urinary drainage and described in the preceding paragraph. It is a dual lumen tube with a small lumen to inflate the cuff and a large lumen to drain urine from the bladder. Three-way catheters are employed when bladder irrigation, in addition to urinary drainage, is required. These catheters have a small lumen to inflate the cuff, an intermediate-sized lumen to instill irrigation solution, and a large lumen to drain urine from the bladder. In the Emergency Department, they are placed in patients with gross hematuria and the passage of blood clots that may or have caused an acute urinary retention.

Clean and prep the penis, anesthetize the urethra, and set up a sterile field as mentioned previously. Select an appropriately sized Foley catheter. Inflate the cuff to check its integrity. Deflate the cuff. Grasp the penis with the nondominant hand. Pull the penis taut and upright to straighten out the penile urethra (**Figure 142-4A**). Retract the foreskin if the patient is uncircumcised. **Do not forget to reduce the foreskin after inserting the catheter to prevent the formation if a paraphimosis.** Grasp the Foley catheter with the dominant hand. Dip the tip of the catheter in, or an assistant can apply, water-soluble lubricant or anesthetic jelly (**Figure 142-4A**). Insert the catheter into the penile urethra via the meatus. Continue to gently but firmly advance the Foley catheter into the urethra until the proximal ports are at the urethral meatus (**Figure 142-4B**). This ensures that the distal tip of the catheter and the cuff will reside within the bladder (**Figure 142-4C**). **If the distal end of the catheter is not completely within the bladder, inflation of the cuff inside the urethra will result in severe pain, hematuria, and possible urethral rupture.**

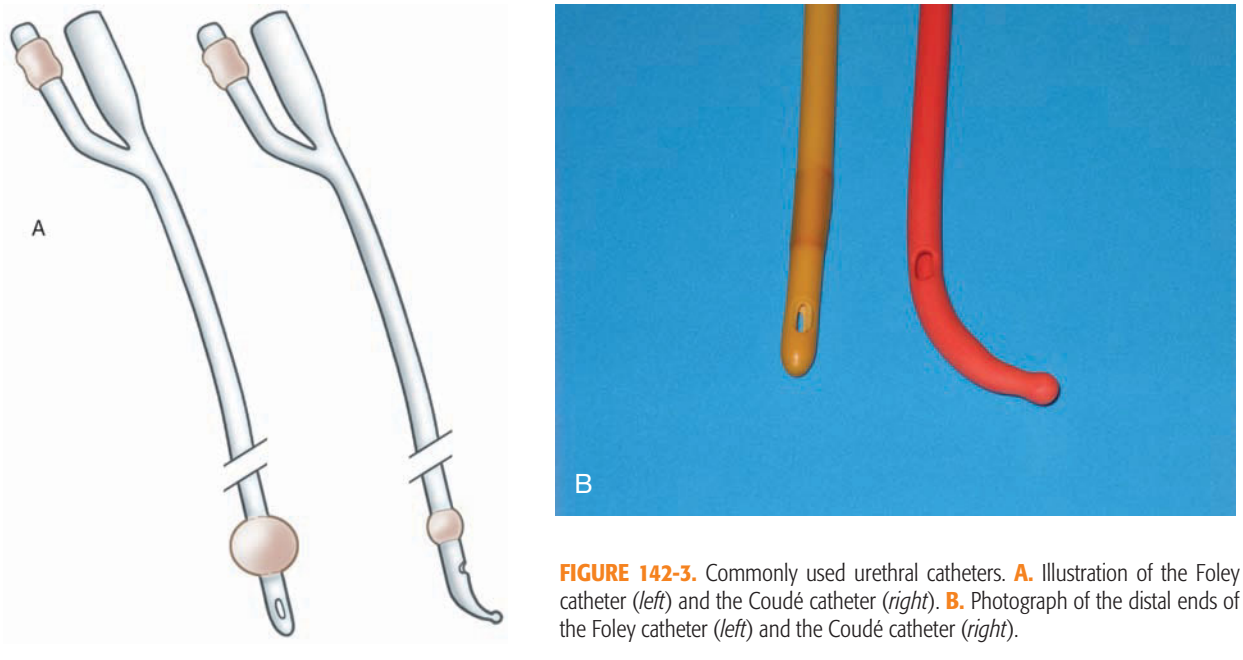

FIGURE 142-3. Commonly used urethral catheters. **A.** Illustration of the Foley catheter (*left*) and the Coudé catheter (*right*). **B.** Photograph of the distal ends of the Foley catheter (*left*) and the Coudé catheter (*right*).

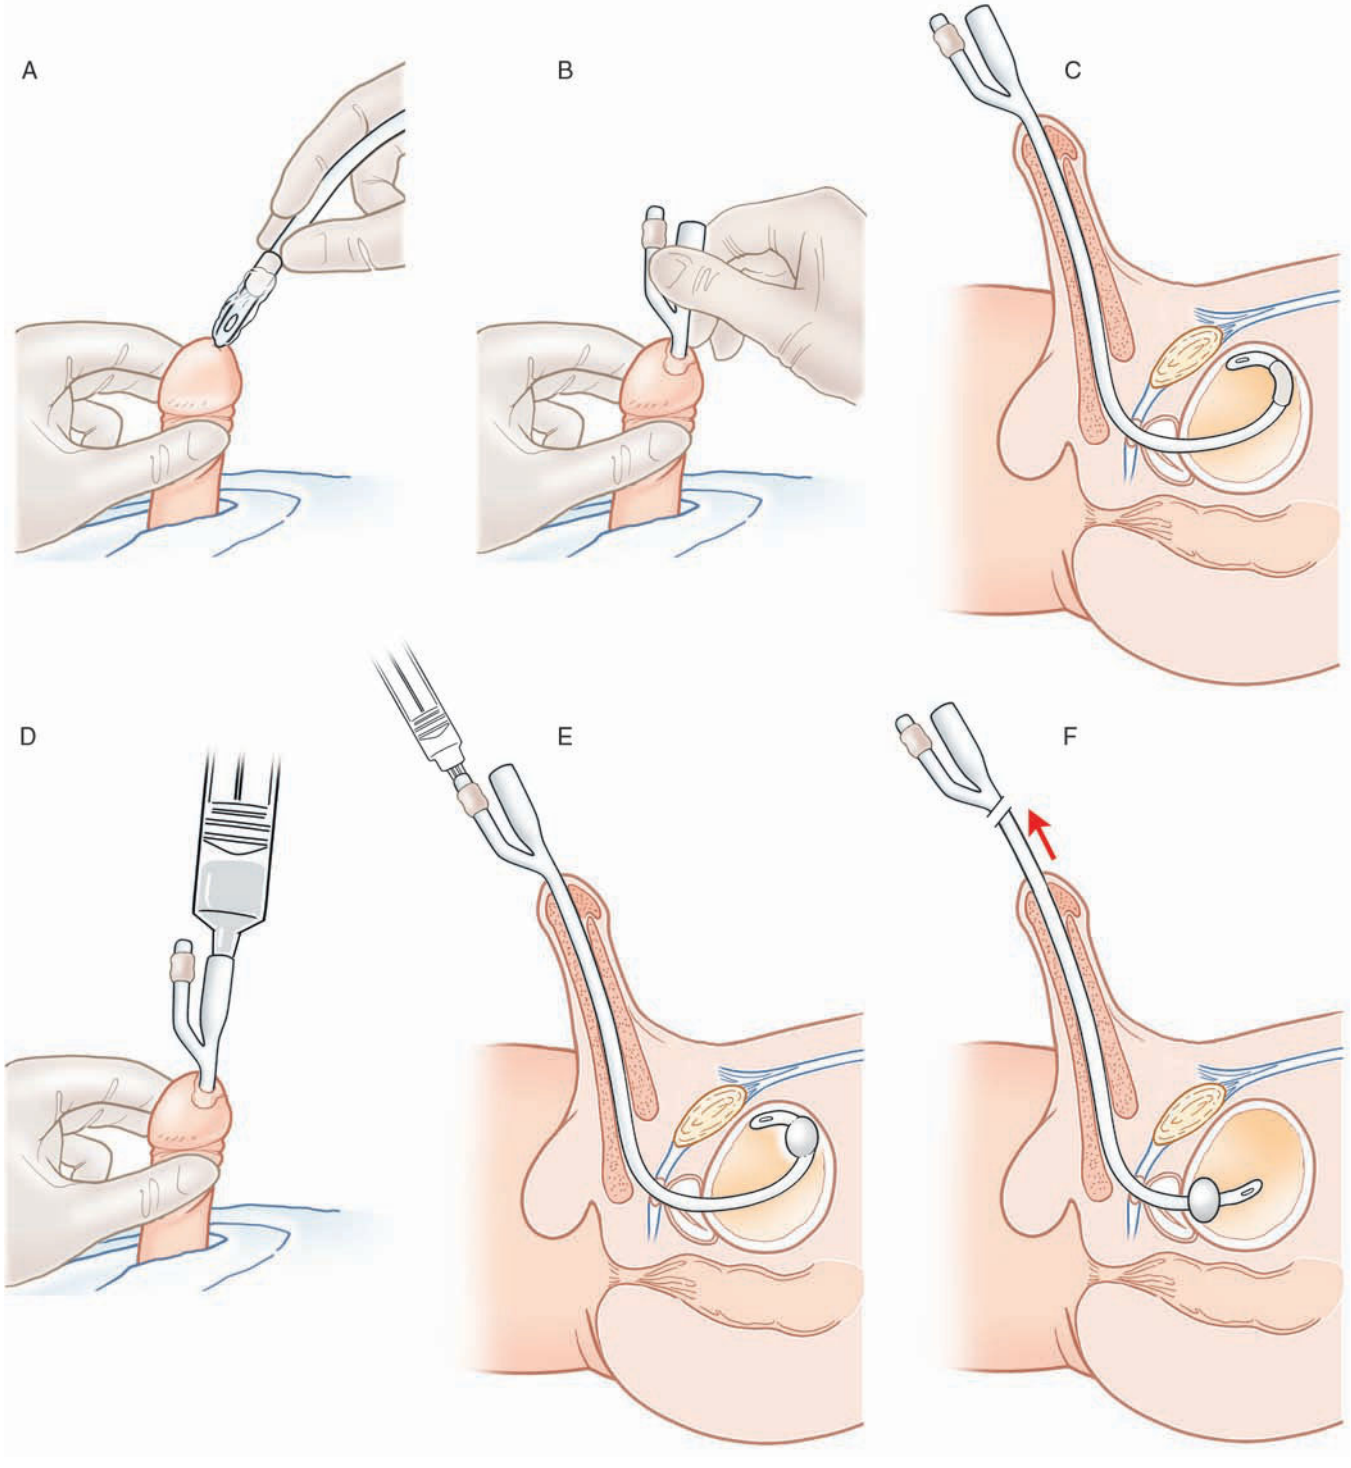

FIGURE 142-4. Foley catheter insertion. **A.** The lubricated catheter is inserted into the urethra. **B.** The catheter is advanced until the ports are at the meatus. **C.** Cross section of the male pelvis showing the distal catheter positioned within the bladder. **D.** Urine aspiration confirms proper placement of the catheter. **E.** The cuff at the tip of the catheter is inflated. **F.** The catheter is gently withdrawn to lodge the cuff against the bladder neck.

Urine should begin to spontaneously flow out of the large port. Insert the proximal end of the catheter into a sterile container to collect the urine. If urine does not spontaneously flow out of the large port, attach a 60 mL syringe to the port and aspirate urine to confirm proper placement of the catheter (**Figure 142-4D**). Consider using transabdominal ultrasonography to confirm proper catheter placement and the presence of urine within the bladder. If no urine is aspirated and/or ultrasound imaging does not confirm appropriate placement, remove the catheter from the urethra and reattempt the procedure.

Attach an air-filled or saline-filled syringe to the cuff inflation port (**Figure 142-4E**). Inject the air or saline to inflate the cuff (**Figure 142-4E**). Inject only the volume of air or sterile saline recommended by the catheter manufacturer. This can be found on the catheter package and is often printed on the cuff inflation port. Remove the syringe from the cuff inflation port. Gently withdraw

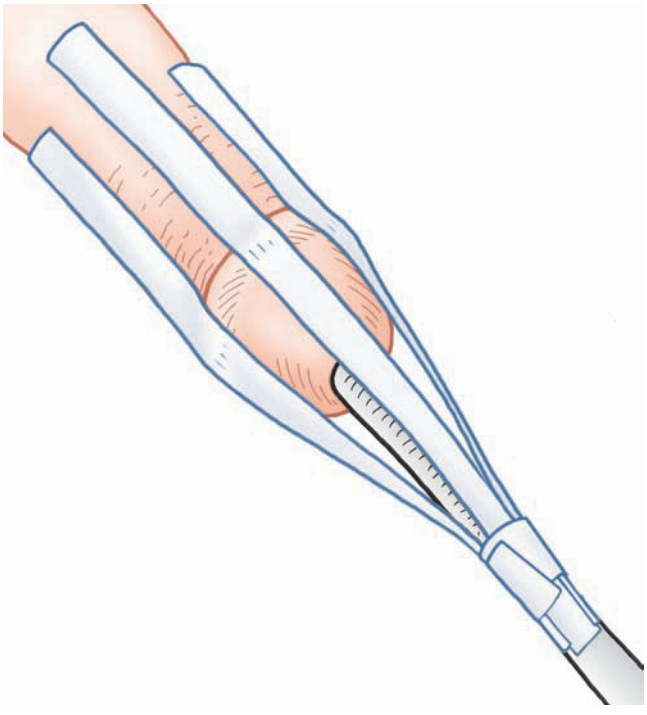

FIGURE 142-5. A method to secure the urethral catheter as it exits the penis.[5]

the Foley catheter until resistance is met. This signifies that the cuff is lodged against the bladder neck (**Figure 142-4F**). Attach an adapter and urine collection system to the urine port of the Foley catheter. Reduce the foreskin if present and it was retracted to insert the catheter.

Secure the catheter. Wrap tape around the urine port of the Foley catheter and continue it onto the adapter and first 3 to 5 cm of the collection tubing. This will prevent the system from disconnecting. Tape the collection tubing to the patient's thigh to prevent it from pulling out the adapter or the Foley catheter when the patient moves. Some authors also secure the Foley catheter as it exits the penile urethra (**Figure 142-5**).[5] This is especially important if a red rubber catheter or uncuffed coudé catheter is used as these cuffless catheters are not self-retaining. Place three thin strips of tape along the length of the penis and attached to the Foley catheter. Benzoin solution can be applied to the penis to aid in adhesion of the tape. Place a piece of tape circumferentially around the tape ends attached to the catheter. **Never apply tape circumferentially around the penis as it may cause ischemia.**

DIFFICULT URETHRAL CATHETERIZATION

Difficulty is commonly encountered when inserting a urethral catheter. Urethral pathology (e.g., valves, strictures, narrowing, or folds) or prostate enlargement can often be overcome by switching from a Foley to a coudé catheter and the application of digital assistance. If unsuccessful, the use of filiforms and followers can often be used to successfully insert the catheter. Foreskin edema from anasarca, pelvic lymphatic blockage, a paraphimosis, or penile trauma can often cover the glans penis and urethral meatus. Attempt to reduce the edema manually or with an elastic bandage (Chapter 148). Significant edema may require penile anesthesia and needle decompression (Chapter 148) or a dorsal slit of the foreskin (Chapter 150). A phimosis may be physiologic in children or acquired and the result of scarring in adults from repeated bouts of inflammation, infections, or sexually transmitted diseases. A phimosis may require a dorsal slit of the foreskin (Chapter 150) to allow for urethral catheterization or a dilation of the phimotic opening.

A relatively new device is the DirectVision™ microendoscope (PercuVision, Gahanna, OH). This consists of a rolling cart, fiberoptic endoscopic bundle, and tri-lumen silicone catheter. The cart houses a color monitor and the fiberoptic light source. A disposable fiberoptic bundle attaches to the light source and is inserted through the tri-lumen catheter. The fiberoptic bundle transmits light to the tip of the catheter and images back to the monitor. The system allows visually guided urethral catheterization in the male patient. It may decrease urinary tract trauma during catheterization, improve catheterization success rates, and simplify the catheterization process. At the time of this publication, this product cannot be recommended for routine urethral catheterization due to the initial expense of the system, the costs of the single-use disposable endoscopic bundles and catheters, and little clinical literature regarding its use in the Emergency Department. This device may be commonly used in the future as costs decrease and clinical information becomes more readily available.

COUDÉ CATHETER INSERTION

The coudé catheter is similar to a Foley catheter except that the distal end is curved and the tip has a small rounded ball (**Figure 142-3**). The catheter was designed to bypass the areas of the urethra that a straight catheter could not negotiate. A coudé catheter may be used if a Foley catheter cannot be passed into the bladder. It may also be used if the patient has a known urethral stricture, urethral valve, narrow urethra, or enlarged prostate.

The coudé catheter comes in various sizes and styles. Some models contain a cuff while others do not. The catheter is inserted into the urethra with the elbow on the tip of the catheter facing anteriorly. The procedure for placement of the catheter into the bladder is the same as that for a Foley catheter.

DIGITAL ASSISTANCE

Occasionally, the Foley or coudé catheter tip will become caught in a posterior fold of the urethra just distal to the urogenital diaphragm (**Figure 142-6A**). Place the fingers of the nondominant hand on the perineum between the scrotum and anus (**Figure 142-6B**). Apply upward pressure on the perineum to direct the catheter tip upward while simultaneously advancing the catheter with the dominant hand through the urogenital diaphragm and into the bladder. An assistant is often required to hold and stabilize the penis while the Emergency Physician uses their hands to manipulate the catheter and perineum.

If the patient has an enlarged prostate, the bladder neck is often elevated superiorly and anteriorly. Digital assistance on the skin of the perineum may be unsuccessful. A finger in the rectum may be used to move the catheter tip anteriorly so that it can be advanced into the bladder.

FILIFORM AND FOLLOWER CATHETERS

In patients with severe urethral strictures or urethral folds, it may be impossible to pass a Foley catheter or a coudé catheter. The next step in the progression to catheterize the bladder is to use filiform and follower catheters. Filiforms are very narrow, flexible, and solid catheters. Their sole function is to successfully negotiate a strictured urethral segment and enter the bladder. The distal end of the filiform catheter may be straight or pig-tailed and are available in a variety of sizes (**Figure 142-7A**). The proximal end of the filiform catheter is a standard size and contains a metal female connector (**Figure 142-7B**). The followers are flexible, hollow catheters that

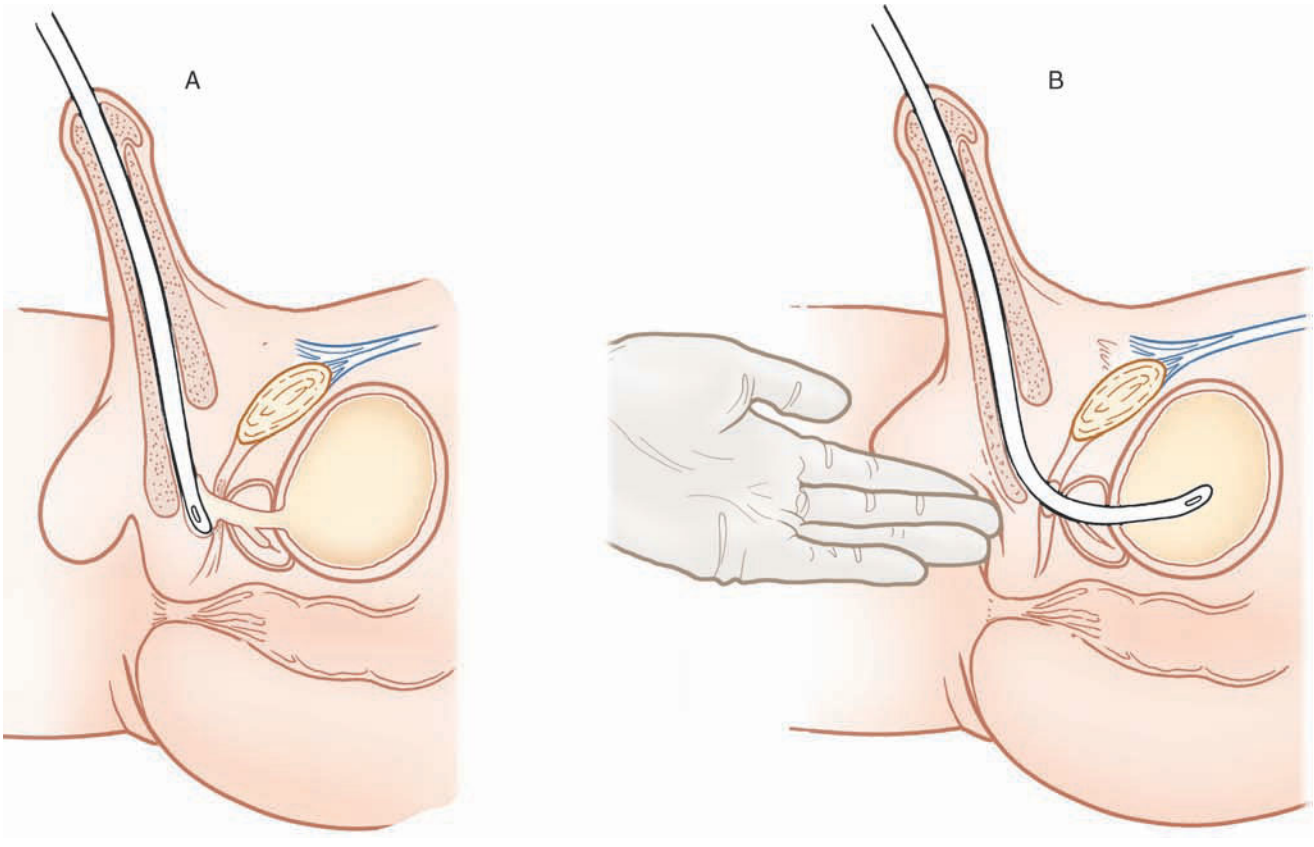

FIGURE 142-6. Digital assistance. **A.** The Foley catheter is caught in a posterior urethral fold. **B.** Digital upward pressure on the perineum will direct the catheter tip upward and through the urogenital diaphragm.

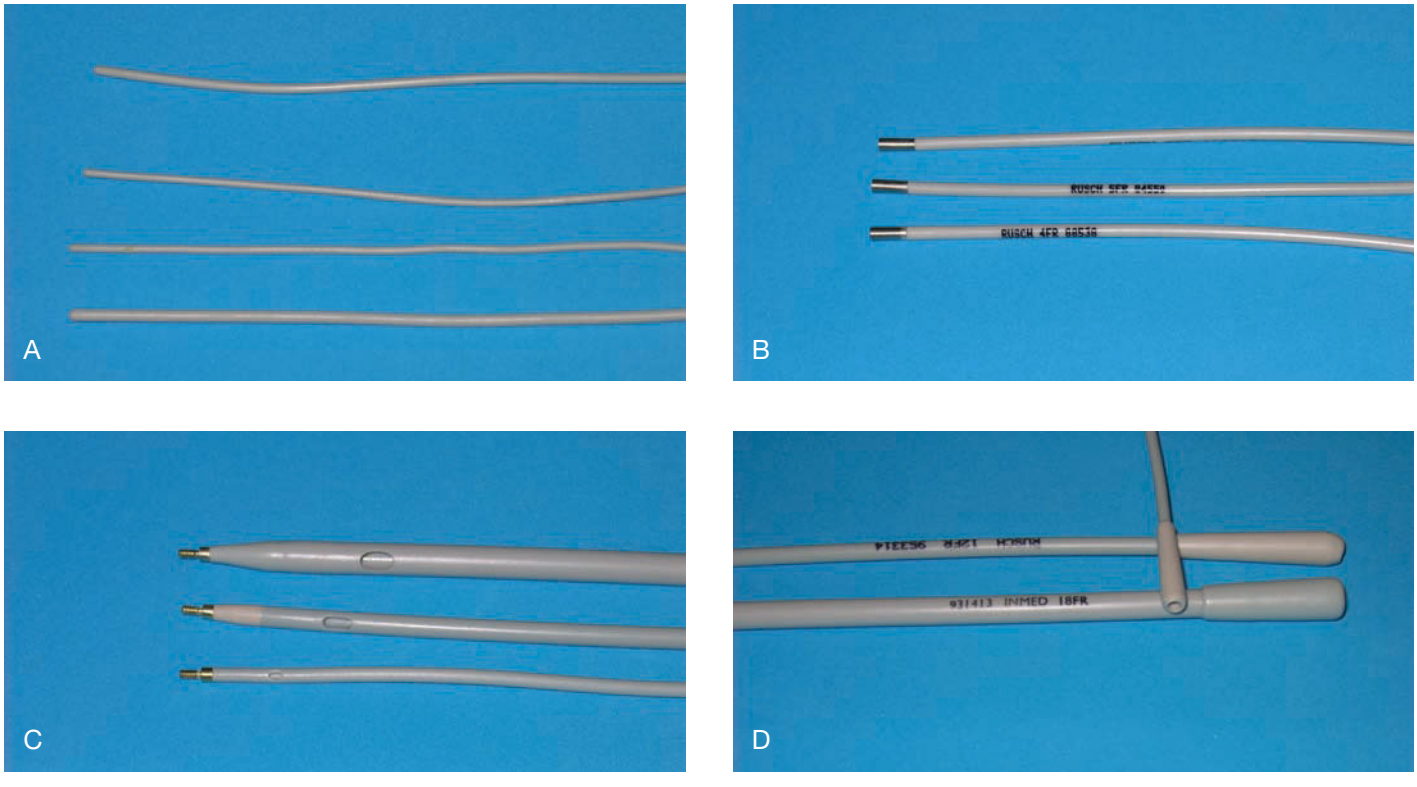

FIGURE 142-7. Photographs of the ends of the filiform and follower catheters. **A.** Distal ends of the filiform catheter. **B.** Proximal ends of the filiform catheter. **C.** Distal ends of the follower catheter. **D.** Proximal ends of the follower catheter.

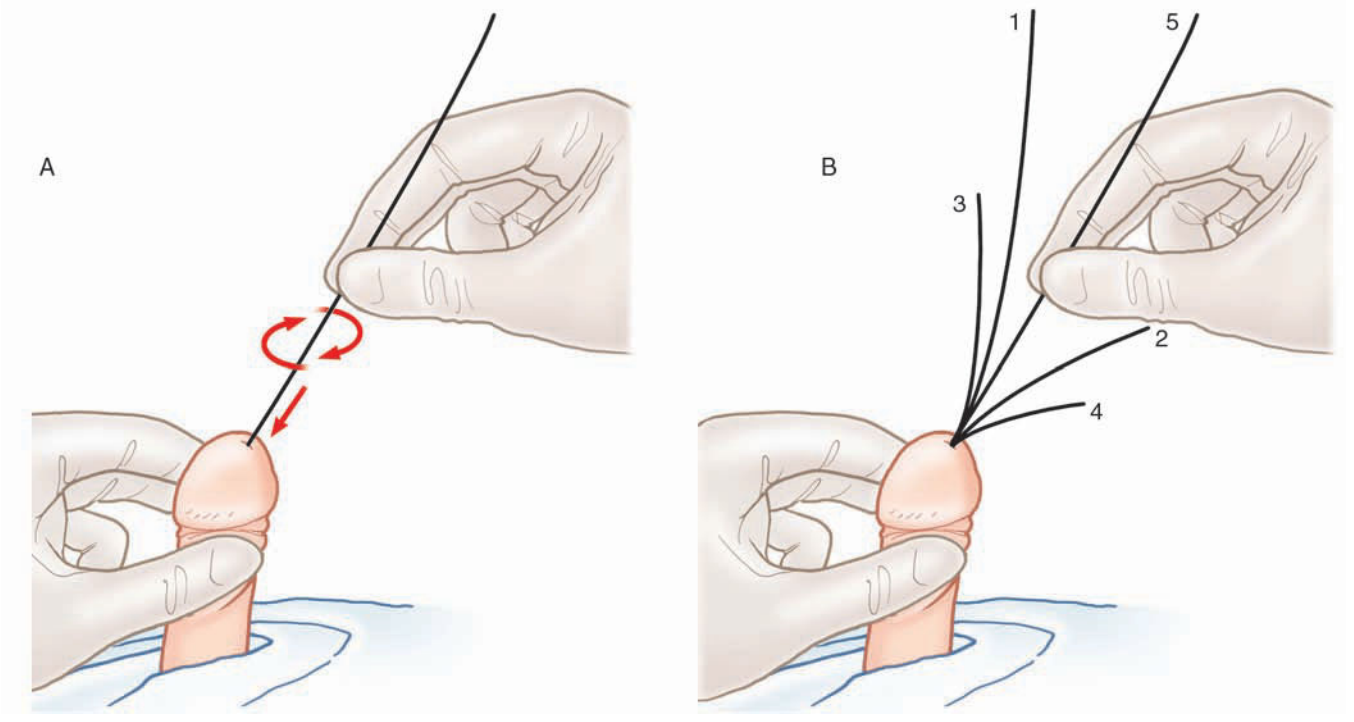

FIGURE 142-8. Insertion of the filiform catheters. **A.** The catheter is inserted and advanced into the urethra (*straight arrow*) with a twisting motion (*curved arrows*). **B.** Additional catheters are inserted until one advances into the bladder. The numbers represent the order of insertion of the filiform catheters.

attach to the filiform catheters. The distal end of the follower catheter contains a metal male connector, to attach to the proximal end of the filiform catheter, and a hole to allow urine to enter the catheter (**Figure 142-7C**). The follower catheters come in a variety of sizes and allow the physician to dilate the urethra and catheterize the bladder. The proximal end of the follower catheter is open and accepts a Christmas tree adaptor (**Figure 142-7D**).

A filiform and follower should be used only after unsuccessful catheterization attempts with a Foley catheter and a coudé catheter. The patient has already been prepped and draped for the prior catheterization attempts. Reinstill anesthetic jelly into the urethra to ensure adequate anesthesia. Numerous sizes and shapes of filiform and follower catheters should be available at the bedside. An assistant will be required to open each sterile packet and hand the filiforms and followers to the Emergency Physician as needed.

Grasp the cleaned, prepped, and anesthetized penis with the nondominant hand. Pull the penis taut and upright to straighten out the penile urethra (**Figure 142-8A**). Grasp a filiform catheter and dip the tip in water-soluble lubricant or anesthetic jelly. Gently insert and advance the filiform catheter into the urethra with a twisting motion (**Figure 142-8A**). Stop advancing the filiform catheter when resistance is met (**Figure 142-9A**). Insert a second well-lubricated filiform catheter into the urethra with a twisting motion until it meets resistance (**Figure 142-9B**). Gently attempt to advance the first filiform catheter. If it will not advance, insert

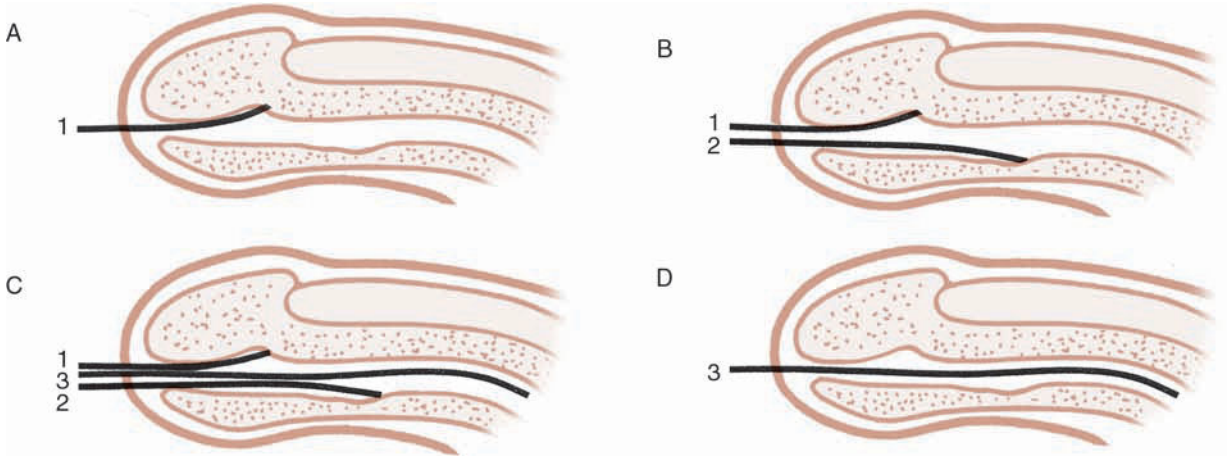

FIGURE 142-9. Midsagittal section of the penis demonstrating insertion of the filiform catheter. **A.** The filiform catheter is inserted until resistance is encountered. **B.** A second filiform catheter is inserted until it encounters resistance. **C.** A third filiform catheter is inserted and advances into the bladder. **D.** Filiform catheters #1 and #2 have been removed.

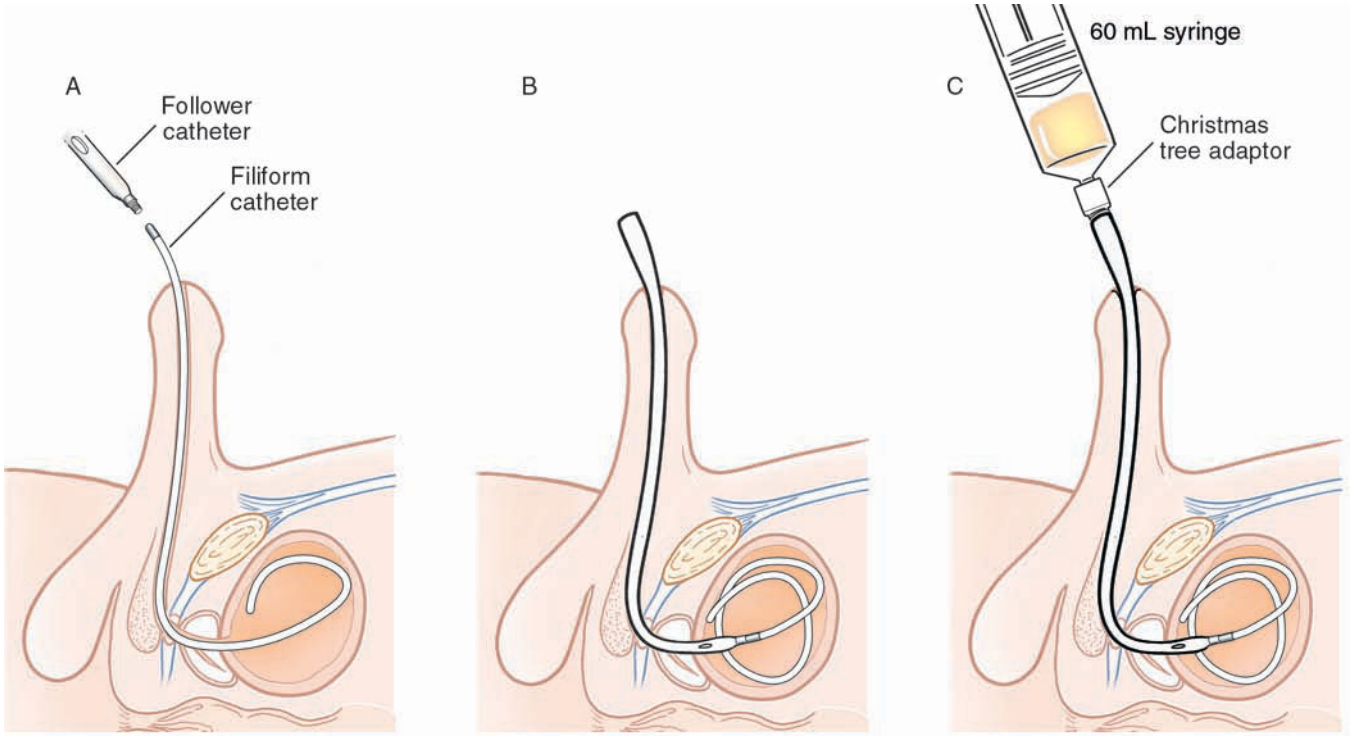

FIGURE 142-10. Insertion of the follower catheter. The filiform catheter has been previously inserted into the bladder. **A.** The follower catheter is screwed into the filiform catheter. **B.** The follower catheter is advanced into the bladder. **C.** Urine aspiration confirms proper placement.

a third filiform catheter (**Figure 142-9C**). Continue to insert filiform catheters and gently manipulate the previously inserted filiform catheters (**Figure 142-8B**). Continue this process until one filiform catheter advances into the bladder so that its proximal end is 2 cm from the tip of the penis (**Figure 142-9C**). Remove all the filiform catheters except the one that entered the bladder (**Figure 142-9D**).

Choose a follower catheter to insert into the bladder. Liberally lubricate the tip of the follower catheter and attach it to the filiform catheter (**Figure 142-10A**). Gently advance the follower catheter until its proximal end is 3 to 4 cm from the tip of the penis (**Figure 142-10B**). **If the follower catheter meets resistance during its advancement, do not force it into the urethra.** Instead, withdraw the follower catheter until the tip is 2 to 3 cm outside the penis. Remove the follower catheter from the filiform catheter. Attach a well-lubricated follower catheter onto the filiform catheter that is 1 or 2 French smaller and attempt to advance it into the bladder. Continue this process until a follower catheter can be completely advanced into the bladder. The filiform catheter will be completely curled up inside the bladder (**Figure 142-10B**).

Urine should spontaneously flow from the properly positioned follower catheter. If not, attach a 60 mL syringe and Christmas tree adaptor to the follower catheter (**Figure 142-10C**). Apply negative pressure to the syringe to aspirate urine and confirm the proper placement of the tip of the follower catheter. Attach a urinary collection system to the follower catheter and secure the catheter as described previously.

The patient with urinary obstruction cannot be discharged home with a filiform and follower inserted inside the bladder. If the follower catheter is a size 16 or 18 French, completely withdraw it and the filiform catheter and insert a 16 French Foley catheter. If the follower catheter is smaller than size 16 French, the urethra must be dilated. Withdraw the follower catheter until the distal tip is 2 to 3 cm outside the penis. Remove the follower catheter from the filiform catheter. Attach a well-lubricated follower catheter onto the filiform catheter that is 1 or 2 French larger than the previous one and gently advance it into the bladder. Continue this process until a follower catheter that is size 16 French easily passes into the bladder. Remove the filiform and follower catheters. Insert a size 16 French Foley catheter. Secure the catheter as described previously.

FEMALE CATHETERIZATION TECHNIQUES

Place the female patient supine in an examination bed. Place the patient in the frog-legged position. If an examination table equipped with stirrups is available, the patient can be placed in the lithotomy position. Separate the labia with the nondominant thumb and index finger to expose the vulva (**Figure 142-11A**). Identify the urethral meatus. Apply povidone iodine or chlorhexidine solution to the urethral meatus and surrounding vulva. Without moving the nondominant hand, apply sterile drapes to isolate the vulva. A lesser amount of anesthetic jelly is needed to lubricate the female urethra. Place anesthetic jelly on a sterile, cotton-tipped applicator. Insert the cotton-tipped applicator just into the tip of the urethral meatus for 8 to 10 seconds. Remove and discard the cotton-tipped applicator.

Grasp the Foley catheter with the dominant hand. Dip the tip of the catheter in, or an assistant can apply, water-soluble lubricant or anesthetic jelly. Insert the catheter into the urethral meatus (**Figures 142-11A & B**). Advance the catheter 6 to 8 cm to ensure the distal end and cuff are within the bladder. Urine should spontaneously begin to flow out of the large port. Insert the proximal end of the catheter into a sterile container to collect urine. If urine does not spontaneously flow out of the large port, attach a 60 mL syringe to the port and aspirate urine to confirm proper placement of the catheter. The remainder of the procedure is exactly the same as previously described for the male patient.

Some women may present with a cystocele, cystourethrocele, or urethrocele. These abnormalities result in the urethra running

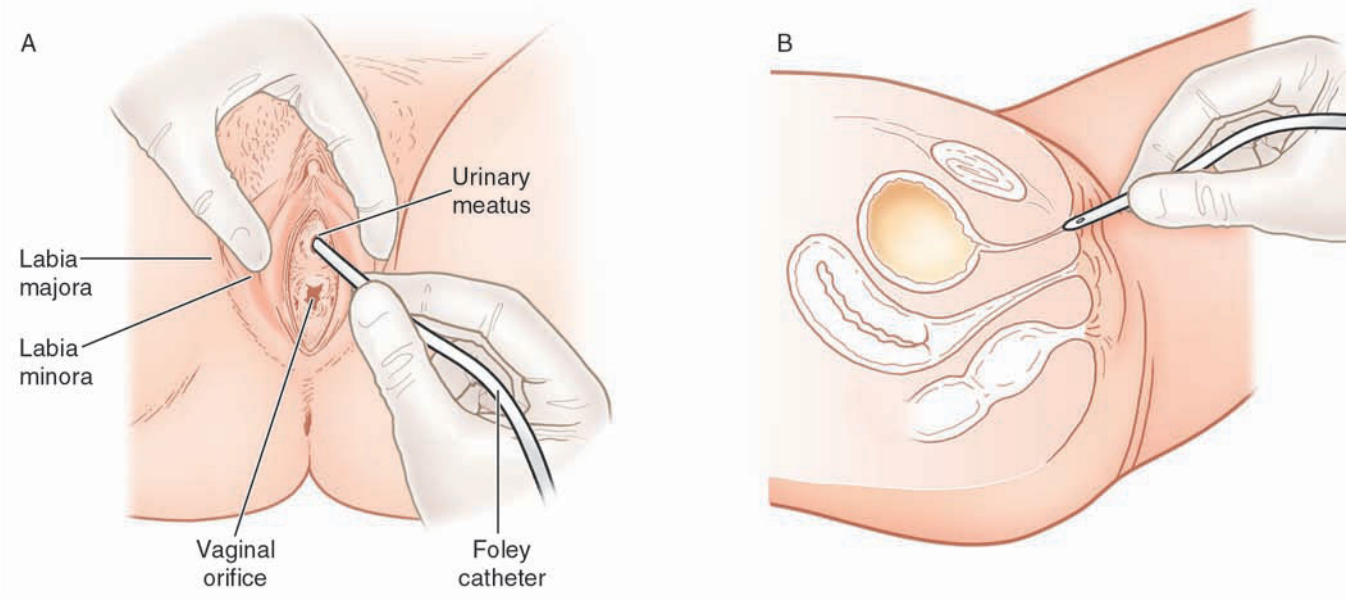

FIGURE 142-11. Female urethral catheterization. **A.** External view of the genitalia. The catheter is inserted into the urethral meatus and advanced. **B.** Midsagittal section of the female pelvis demonstrating catheter insertion.

posteriorly and downward, making urethral catheterization difficult. Insert your gloved and lubricated index and middle fingers into the vagina and gently push upward and anteriorly on the anterior vaginal wall. This maneuver will reposition the bladder and urethra to its normal position. While maintaining anteriorly directed pressure on the anterior vaginal wall, insert the urethral catheter in the usual manner.

INFANT AND CHILDREN CATHETERIZATION TECHNIQUES

The indications and contraindications for catheterization of infants and children are the same as for adults. The anatomy of the prepubertal child is similar to the adult, except for the difference in size and lack of secondary sexual characteristics. Identifying the urethral meatus can be difficult in uncircumcised boys. An assistant is often required to help position children during the procedure. Gently manipulate and retract the foreskin just enough to expose the meatus. It is worth noting that the urethral orifice may be difficult to identify in a young female due to abundant hymenal tissue covering the vaginal introitus. This can be circumvented by gentle lateral traction of the labia and downward pressure on the vaginal introital fold with a cotton-tipped applicator. The catheterization of newborns and infants is accomplished with an appropriately sized pediatric feeding tube, usually size 5 French in the neonate up to 8 French in newborns and infants. Small Foley catheters or feeding tubes (size 10 or 12 French) may be used in children aged 1 to 6 years. Children over 12 years of age can accommodate a 14 French catheter. The same techniques and cautions followed in the adult patient also apply to the pediatric patient.

ASSESSMENT

Urine drainage is the sign of appropriate catheter placement. Lubricating gel may plug the outflow port of the catheter. If no urine is seen, apply gentle pressure to the suprapubic area to force the flow of urine. Should this maneuver fail to initiate urine flow, irrigate the catheter with a small volume of sterile saline. The catheter will flush and withdraw fluid with ease if properly positioned in the urinary bladder. Use of an irrigation tray, which includes a 60 mL piston tipped syringe, is recommended. It may require greater than one fill (i.e., more than 60 mL of saline) to produce two-way flow. The inability to irrigate denotes obstruction or misplacement of catheter. Ensure that the catheter is inserted completely to the hub in males to prevent inadvertent inflation of the cuff in the membranous or prostatic urethra.

AFTERCARE

Always remember to reduce the foreskin after catheter placement to avoid the complication of a paraphimosis in uncircumcised males. Indwelling catheters should be secured to a closed gravity drainage system and attached to the anterior medial thigh. For long-term requirements in males, the catheter should be secured to the anterior abdominal wall to decrease the likelihood of stricture formation.

The patient may be discharged from the Emergency Department with a Foley catheter or coudé catheter. Instruct the patient on the proper care and emptying of the leg bag (**Table 142-1**). The patient

TABLE 142-1 Patient Instructions for the Proper Care of a Urinary Drainage Bag at Home

1. Always thoroughly wash your hands with soap and warm water before putting on gloves and emptying the drainage bag.
2. Never place the drainage bag on the floor to prevent contamination.
3. Always keep the drainage bag below the level of the genitals to prevent backflow of urine.
4. Clean the drainage port with an alcohol swab before emptying the bag.
5. Always empty the drainage bag into a clean container.
6. Do not touch the drainage port or allow it to touch the container.
7. Close the drainage port after emptying the bag and wipe it with an alcohol swab.
8. Discard the urine in the container and thoroughly wash the container with hot soapy water.
9. Discard the gloves and do not reuse them.
10. Always thoroughly wash your hands with soap and warm water after taking off your gloves.

should immediately return to the Emergency Department if they develop a fever, pain, hematuria, inability to void through the catheter, or abdominal pain. Consider prescribing a 3-day supply of broad spectrum antibiotics if the patient has valvular heart disease, mitral valve prolapse, cardiac valve replacements, a penile prosthesis, or an artificial joint.

COMPLICATIONS

GENERAL COMPLICATIONS

Creation of false passages, urethral perforations, bleeding, infection, and catheter misplacement are the complications associated with urethral catheterization. Urethritis is fairly common following catheterization, especially in patients with urethral strictures or prostatic enlargement. Epididymitis, cystitis, and pyelonephritis are uncommon complications and often seen with prolonged catheterization. Bacteremia can occur following the procedure. High-risk patients should receive antibiotic prophylaxis prior to catheterization. Iatrogenic trauma to the urethra can lead to strictures, hemorrhage, and hematuria. Creation of a false passage can occur by inserting the catheter alongside the urethra. Attempts at catheterization in a trauma patient with a urethral injury can convert a partial urethral tear to a complete tear. Failure to reduce the foreskin after catheter placement may result in a paraphimosis.

LEAKAGE AROUND THE CATHETER

Urine may occasionally leak out between the catheter and the walls of the urethra. Make sure that an appropriately size catheter has been inserted. Check the balloon to make sure it is properly inflated. Gently pull on the catheter to seat the balloon in the neck of the bladder. Too large of a catheter or balloon can irritate the urinary tract or bladder and result in bladder spasm and urine leakage. Check the catheter, tubing, and drainage bag for kinks. An occlusion distal to the catheter can result in retained urine, an overdistended bladder, and bladder spasm. Evaluate a urine sample for the presence of an infection. A urinary tract infection can result in bladder spasm.

DIFFICULTY REMOVING A CATHETER

A less common complication is difficulty removing an indwelling urethral catheter that has an inflated cuff. Ensure that the catheter is not clamped or kinked. This can compress the cuff inflation lumen. A vacuum may have formed in the inflation lumen causing it to collapse. Attach a syringe without the plunger to the inflation port and release the vacuum followed by aspiration to deflate the balloon. Gently turn the catheter clockwise and counterclockwise as the catheter may be compressed, kinked, or twisted. Gently advance the catheter further into the bladder and attempt to deflate the balloon. Gently inject 2 to 3 mL of sterile saline through the inflation port to open the inflation lumen or unclog it. Inspection of the valve sometimes reveals the problem. One may attempt to cut proximal to the valve in hopes of evacuating the cuff contents but this is not always successful.

In patients with a Foley catheter balloon that will not deflate, real-time ultrasound can facilitate percutaneous balloon puncture and removal of the catheter.[12] Prepare the skin, apply sterile single-use US gel to the patient's skin, and apply a sterile US probe cover. Stand to the side of the patient so that your dominant hand is cephalad (**Figure 143-7**). Position the US monitor on the opposite side of the patient so that it is easy to see (**Figure 143-7**). A longitudinal

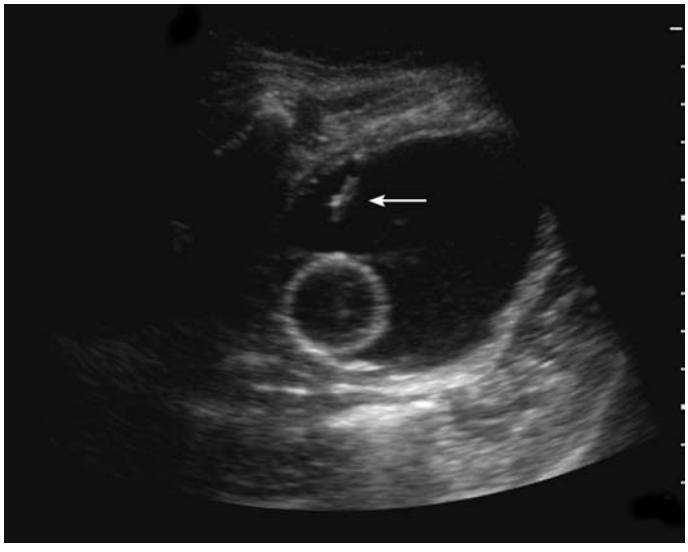

FIGURE 142-12. Longitudinal US view of the transabdominal spinal needle (*arrow*) approaching the Foley balloon.

US probe orientation is preferred for the dynamic approach since it allows visualization of the entire needle as it courses toward the bladder. Place the US probe marker to your left. This will ensure that the left–right orientation on the US screen matches the real-world orientation.

Place the longitudinally oriented US probe in the suprapubic area and move it from side to side to locate the largest bladder dimension. To deflate a Foley catheter balloon, make sure there is sufficient fluid in the bladder. If necessary, fill the bladder with enough sterile saline through the Foley catheter to make the bladder easily visible on ultrasound. Clamp the Foley catheter to retain the saline within the bladder. Instruct an assistant to apply gentle traction to the external portion of the Foley catheter to fix the balloon against the bladder neck.

Place a 5-inch, 22 or 24 gauge spinal needle on a 10 mL syringe. Position the spinal needle on the cephalad side of the US probe and angle it caudally (**Figure 143-8**). Insert and slowly advance the spinal needle. Look for the needle on the US screen as it is inserted and advanced. If the needle is a narrow gauge and the US probe is low frequency, the spinal needle will not necessarily be visible in the tissue. Rather, look for movements in the tissue as the spinal needle is advanced (**Figure 143-9**). Adjust the needle and the US probe side to side as needed to keep the needle in the same plane as the US beam. Continue to advance the spinal needle into the bladder (**Figure 142-12**). Continue to advance the spinal needle toward and into the inflated balloon. Puncture the balloon with the spinal needle. The balloon will deflate with a dramatic "pop." Remove the spinal needle. Remove the Foley catheter. Inspect the balloon to make sure there are no obvious missing fragments that are retained in the bladder.

Other options include transperineal cuff puncture, blind transabdominal cuff puncture, or injection of an organic agent (such as ether, acetone, mineral oil, or toluene) through the inflation port to dissolve the cuff. Occasionally, a narrow gauge guide wire may be placed through the cut balloon port to loosen any concretions that may have formed and allow the cuff to deflate. Obtain a plain radiograph of the pelvis to determine if the catheter is knotted within the bladder.[16] This will require cystoscopic manipulation to unknot the catheter. These techniques to reduce the cuff should be performed in consultation with a Urologist.

SUMMARY

Although urethral catheterization is one of the most routinely performed urologic procedures, it is not a benign process and should be attempted with mindfulness. A working knowledge of genital and perineal anatomy, along with a thorough clinical history and physical examination, is paramount to successful catheter placement and avoidance of complications. Liberal amounts of lubrication and topical local anesthetic should always be used when inserting the catheter. Those patients requiring chronic indwelling catheters should be versed in catheter care and have routine medical evaluations for catheter change and follow-up.

143 Suprapubic Bladder Aspiration

Richard Dean Robinson, Sam Hsu, and Eric F. Reichman

INTRODUCTION

Suprapubic bladder aspiration is the introduction of a needle through the anterior abdominal wall and into the bladder to obtain a urine specimen under strict sterile technique. It is performed primarily to diagnose urinary tract infections.[1–9] It is most commonly performed in children under the age of 2 years as part of the septic work-up.[7] The procedure is quick, simple to perform, safe, and has a low rate of complications. The main advantage of suprapubic bladder aspiration is that it bypasses the urethra and minimizes the risk of obtaining a contaminated urine specimen.

Urinary sampling remains the cornerstone for the diagnosis of many disease processes including metabolic derangements, infectious processes, catabolic states, and neoplastic conditions. In cases when the usual means of voided urine collection or bladder drainage is not possible or preferable, suprapubic bladder aspiration becomes a viable option both therapeutically and diagnostically. If properly performed, this technique can yield an uncontaminated urine sample without urethral or skin flora contamination.

ANATOMY AND PATHOPHYSIOLOGY

The urinary bladder of the neonate and infant begins as an abdominal organ (**Figure 143-1A**). As the child grows the pelvis enlarges and the bladder migrates down into the pelvis. The bladder eventually assumes its retropubic position that is maintained throughout life (**Figure 143-1B**).

The anatomic knowledge required to perform this procedure is minimal. The pubic symphysis is in the midline and forms the anterior border of the bony pelvis. The bladder resides posterior and superior to the pubic symphysis in the young child. The needle will pass through the skin and subcutaneous tissue of the lower abdominal wall, the rectus sheath, the peritoneum, and the bladder wall.

The adult urinary bladder resides behind the pubic symphysis and has both retroperitoneal and intraperitoneal attachments (**Figure 143-1B**). A working knowledge of this anatomy makes percutaneous bladder manipulation both safe and possible. The rectum lies just inferior and posterior to the urinary bladder. This relationship must be kept in mind when attempting percutaneous access. The bladder dome has peritoneal attachments and access in this area carries the potential for bowel injury and intraperitoneal bladder perforation.

Multiple major vascular structures, including the common iliac and hypogastric vessels, reside in the bony pelvis alongside the bladder. These structures are lateral to the bladder and eccentric percutaneous access may result in troublesome hemorrhage.

INDICATIONS

Suprapubic bladder aspiration is the preferred method of urinary sampling and drainage in instances where voided specimens are undesirable or unattainable, and when urethral catheterization is not technically possible or contraindicated.[1–10] It offers a means

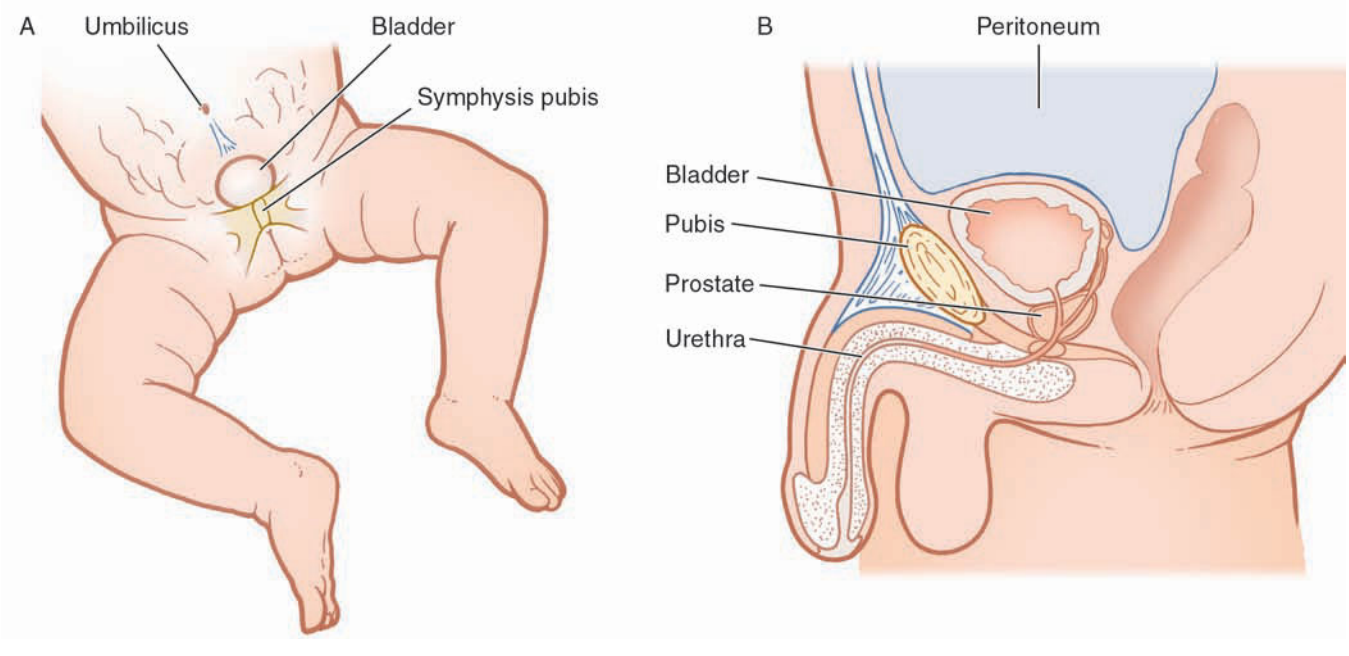

FIGURE 143-1. Position of the bladder. **A.** The bladder is an abdominal organ in the neonate and infant. **B.** The bladder is a pelvic organ in the older child, adolescent, and adult.

of obtaining an uncontaminated urine sample from the bladder. Obtaining a urine sample by urethral catheterization in the neonate or young child may be technically difficult, in which case suprapubic aspiration is a viable alternative. Although urethral catheterization may be an easier method of urine collection in the child or adult, suprapubic aspiration may be required to isolate infravesicular infections, to rule out contamination with asymptomatic bacteriuria, or in cases of urinary retention from a phimosis. The procedure may be performed to temporarily relieve acute urinary retention.

CONTRAINDICATIONS

The single most important aspect of suprapubic bladder manipulation is the presence of an identifiable (by palpation, percussion, transillumination, and/or ultrasonography) and distended urinary bladder. Under no circumstances should "blind" percutaneous access be attempted if the bladder is not palpable or visualized with the aid of ultrasonography.

Any physical alteration, spinal deformities, extremity contractures, truncal obesity, or other conditions that would preclude patients from lying supine and inhibiting bladder palpation are contraindications to this procedure. Skin infections overlying the puncture site are a contraindication to bladder aspiration. Abnormalities in genitourinary anatomy or enlargement of pelvic structures (e.g., ovarian cysts, uterine fibroids) increase the chance of complications with bladder aspiration. Known neoplastic processes of the lower genitourinary tract heighten the possibility of complications. Similarly, distention or enlargement of the abdominal viscera can increase complication rates. The return of ascitic fluid may lead to a false sense of security when the needle is actually intraperitoneal.

Patients with a coagulopathy are at an increased risk for troublesome hemorrhage from any percutaneous procedure, including suprapubic bladder access. Patients with a bleeding diathesis, anticoagulant therapy, or thrombocytopenia should be corrected prior to performing the procedure. In individuals with prior abdominal surgery, the peritoneal cavity has been violated and the bowel may be displaced more caudal and extend to the level of the urinary bladder. This heightens the risk of inadvertent bowel injury. The procedure should not be performed in patients with abdominal distention or the suspicion of an intestinal obstruction. An uncooperative patient should be sedated and/or restrained for the procedure.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- 22 to 24 gauge needle or spinal needle, 1½ to 3 inches long for neonates, infants, and young children
- 22 to 24 gauge needle or spinal needle, 3 inches long for older children, adolescents, and adults
- 10 mL syringe
- Injectable local anesthetic solution, most commonly 1% lidocaine
- 4 × 4 gauze squares
- 25 gauge needle and 3 mL syringe for anesthetic administration
- Sterile towels or drapes
- Specimen containers for urine analysis and culture
- Bandage
- Ultrasound (US) machine (recommended)
- Sterile US gel
- Sterile US probe covers
- 5 to 10 MHz linear US probe for neonates, infants, and children
- 2 to 5 MHz curvilinear abdominal US probe for adolescents and adults

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents.

It is important to identify the distended bladder by palpation, percussion, transillumination, or ultrasonography. Transillumination of the full bladder may be conducted in the neonate. Place the patient supine (**Figure 143-2**). Ultrasonography should be used, if available, even if the bladder is readily palpable. Ultrasound can be used to identify the bladder, confirm the bladder is distended with urine, guide the needle aspiration, and increase the success of the procedure.[10–13] If the bladder is readily distended, it appears on ultrasound as an anechoic (black) square-like structure just below the abdominal musculature.[6] Placement of a gel-filled sterile glove

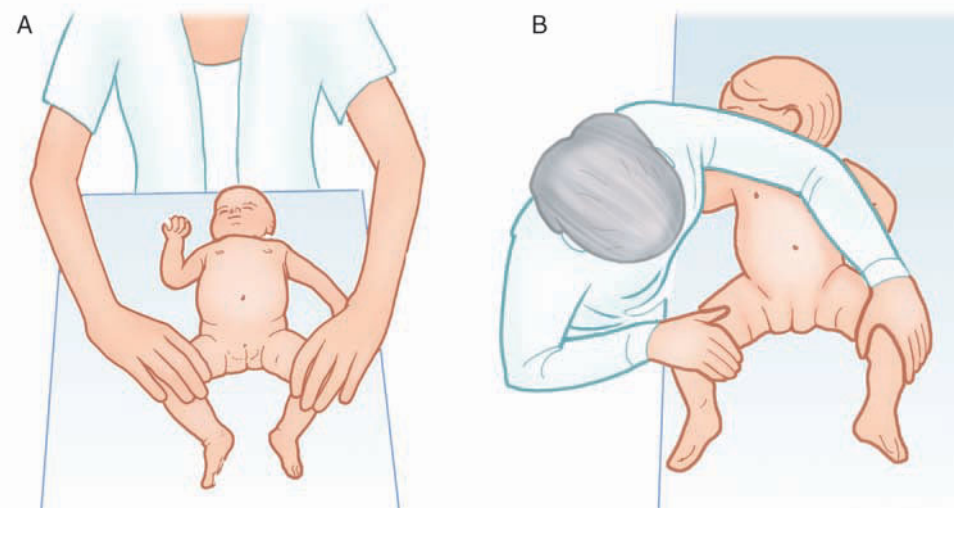

FIGURE 143-2. The frog-leg position. **A.** The infant. **B.** The older child.

over the probe maintains sterility during ultrasound-guided procedures. Identify and mark the skin location immediately above the bladder where it is closest to the skin.

Prepare and drape the abdomen in a sterile fashion from the umbilicus to the pubis. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes. Inject a local anesthetic agent, usually 1% lidocaine, to raise a subcutaneous wheal in the area of the intended skin puncture site. Many consider this step to be optional in the neonate as the amount of discomfort caused by placement of the anesthetic is similar to the actual puncture for bladder aspiration. Slight differences in technique are required for suprapubic bladder aspiration of the infant, child, and adult.

TECHNIQUES

NEONATES AND INFANTS

Have an assistant place and hold the infant supine in the frog-leg position (**Figure 143-2A**). Identify the needle insertion site in the midline and 2 cm cephalad to the pubic symphysis (**Figure 143-3**). The use of US is recommended to assist in determining the proper needle insertion site. Inject 1 mL of local anesthetic solution subcutaneously and into the abdominal wall musculature at the needle insertion site.

Place a 22 or 24 gauge spinal needle onto a 10 mL syringe. Occlude the urethra to prevent reflexive micturition. Apply manual pressure to the urethral meatus of the female (**Figure 143-4A**) or the glans penis in the male (**Figure 143-4B**). Insert the needle through the insertion site and at a 20° angle from the true perpendicular to the skin (**Figure 143-4**). Advance the needle cephalad while applying negative pressure to the syringe. Stop advancing

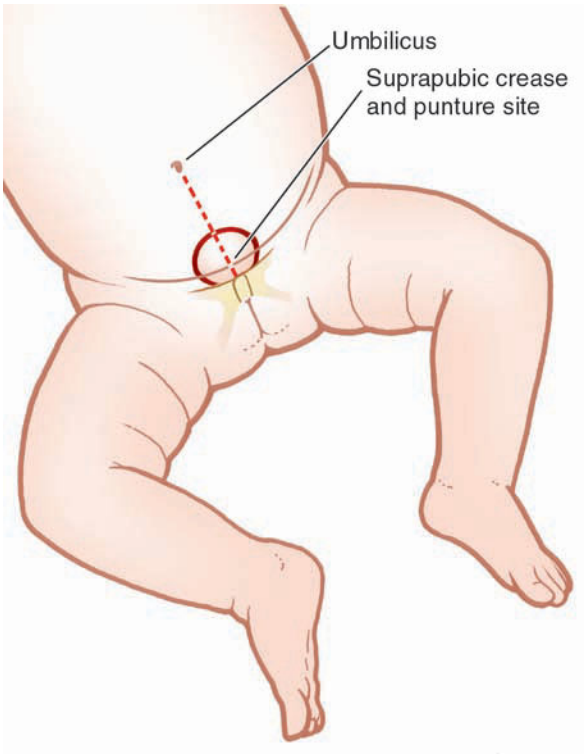

FIGURE 143-3. Anatomical landmarks for suprapubic bladder aspiration in the neonate and infant. A line is drawn from the umbilicus to the pubic symphysis (*dotted line*). The intersection of the line with the suprapubic crease is the landmark for insertion of the needle.

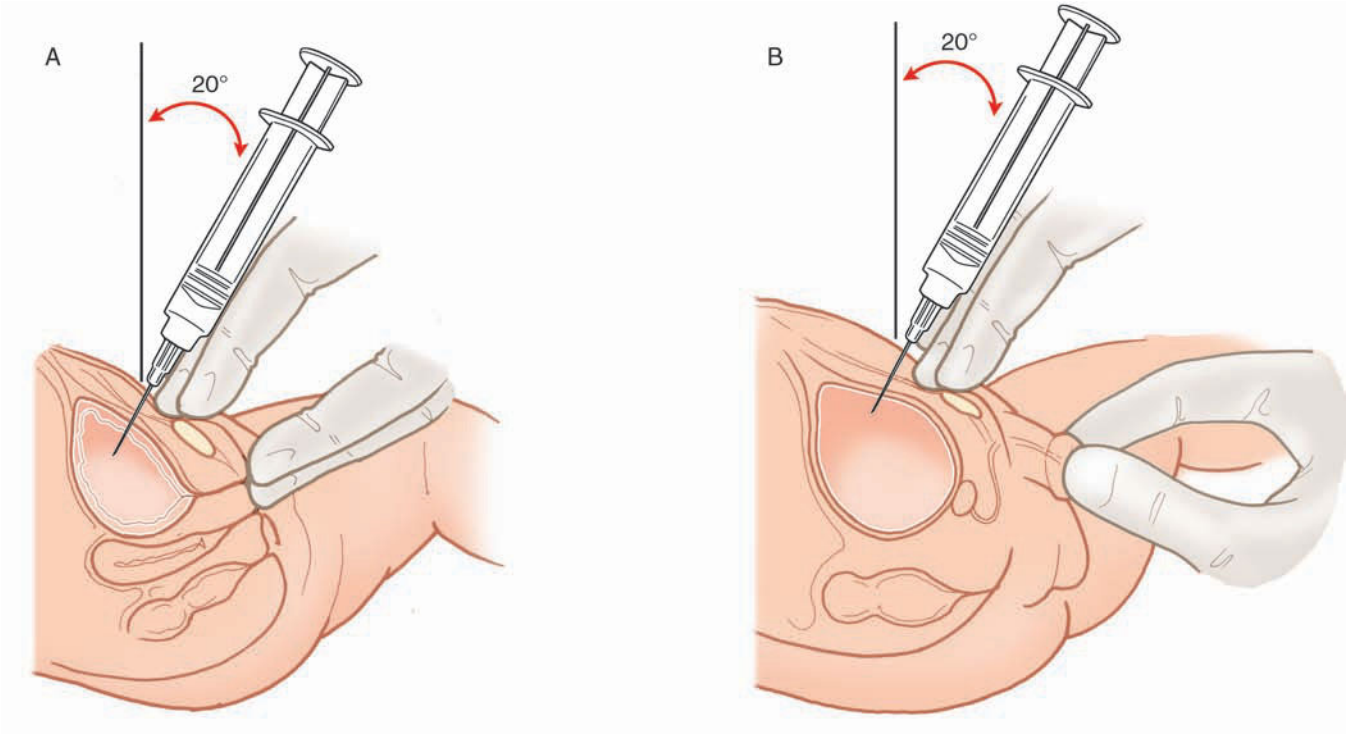

FIGURE 143-4. Suprapubic bladder aspiration in the infant. **A.** Digital pressure on the urethral meatus will prevent micturition in the female. **B.** Digital pressure on the glans penis will prevent micturition in the male.

the syringe when urine is aspirated. The bladder appears to tent as the needle pierces its anterior wall when ultrasonographic guidance is used.[6] If no urine is aspirated, withdraw the needle to the subcutaneous tissue and readvance it in a slightly different direction (e.g., 0° to 10° to the true perpendicular). If the procedure is unsuccessful on the second attempt, delay further attempts until the bladder is more distended, consult a Urologist, or obtain urine through urethral catheterization. After urine is obtained, remove the needle and apply a bandage to the skin puncture site.

OLDER CHILDREN

The positioning of the older child is similar to that of the neonate or infant (**Figure 143-2B**). The procedure is similar to that of the infant, although it is more important to identify the location of the distended bladder to assure a successful aspiration. The use of US is recommended to assist in determining the proper needle insertion site. The urinary bladder of the older child may be in the abdomen or may have migrated into the pelvis.

ADOLESCENTS AND ADULTS

Place the patient supine. Identify the bladder by palpation or ultrasonography. Identify the needle insertion site in the midline and 2 to 4 cm cephalad to the pubic symphysis. Inject 1 to 3 mL of local anesthetic solution subcutaneously and into the abdominal wall musculature at the needle insertion site.

Place a 3 inch, 22 to 24 gauge spinal needle onto a 10 mL syringe. Insert the needle through the insertion site and at a 60° angle to the skin of the abdominal wall (**Figure 143-5**). Advance the needle caudally while applying negative pressure to the syringe. Stop advancing the needle when urine is aspirated. If no urine is aspirated, withdraw the needle to the subcutaneous tissue and readvance it in a slightly different direction (e.g., 50° to the skin of the abdominal wall). After urine is obtained, remove the needle and apply a bandage to the skin puncture site.

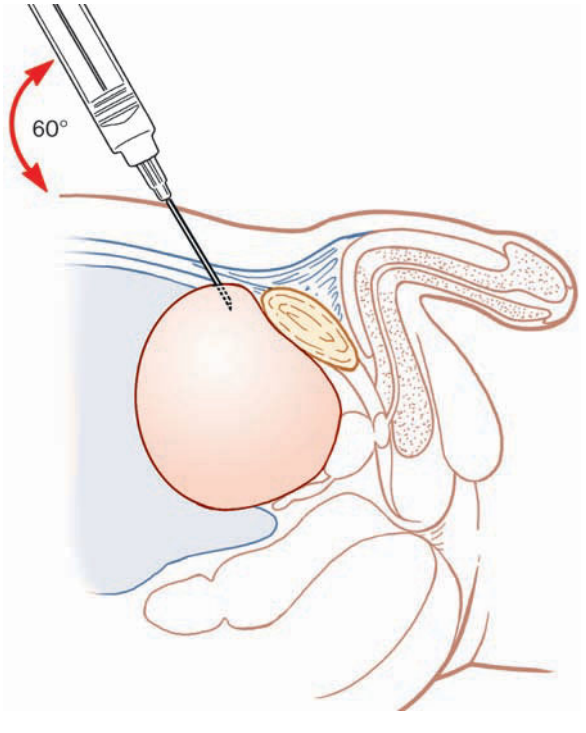

FIGURE 143-5. Suprapubic bladder aspiration in the adult.

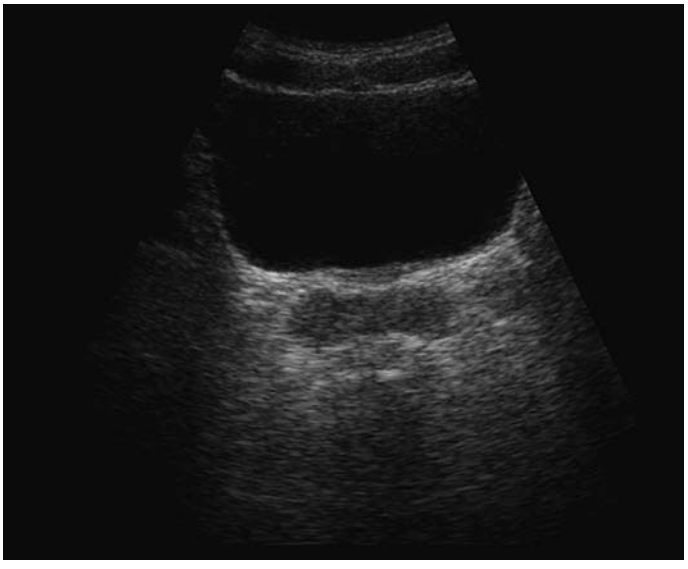

FIGURE 143-6. Transverse US view of the bladder.

ULTRASOUND TECHNIQUE

Ultrasound can ensure there is sufficient urine to aspirate and locate a bladder that is located off midline or deep in the pelvis. It is especially helpful in infants and toddlers, who have small bladders. There are no contraindications to using ultrasound other than those for the procedure itself. For adults, a general-purpose curvilinear abdominal or phased-array probe provides the best combination of penetration and field of view into the abdomen. A linear probe can be used for children. Either a static or dynamic (real-time) technique can be used. The static technique is preferred as it is the easier technique to learn and master. The dynamic technique will increase the success rate for small bladders with minimal urine.

Image the bladder to ensure there is sufficient urine to aspirate. Place the US probe transversely and just superior to the pubic symphysis. If the bladder is not immediately visible, slowly fan the probe cephalad and caudal until it appears. If the bladder is not visible, repeat the scan just off the midline. The bladder will appear anechoic (**Figure 143-6**). Moderate to large bladders are amenable to the static US technique. Bladders smaller than 2 cm in anteroposterior or transverse diameter have a lower success rates for aspiration and the dynamic US technique may be necessary to obtain urine.[11]

STATIC US TECHNIQUE

Identify the bladder using US and center the image on the US machine screen. Angle the US probe so that the largest dimensions of the bladder appear on the screen. **Note the angle of the US probe as this will correspond to the angle of entry for the needle.** Make sure that the bladder is centered on the screen. Move the probe off midline, if necessary, to minimize lateral angulation. This will prevent the need to angle the needle laterally to reach the bladder. Note the depth on the screen from the skin to the bladder in order to gauge the necessary needle length. Mark the entry point on the skin where the middle of the probe meets the skin. Prep the skin and proceed with procedure as described previously.

DYNAMIC US TECHNIQUE

Prepare the skin, apply sterile single-use US gel to the patient's skin, and apply a sterile US probe cover. Stand to the side of the

FIGURE 143-7. The US machine is positioned in the same sight-line as the procedure. The physician's dominant (*right*) hand is cephalad and controls the needle. Note, the US probe cover has been removed for clarity and should be used during the procedure.

FIGURE 143-8. The spinal needle is inserted under the cephalic side of the longitudinally oriented US probe and angled caudally. Note, the US probe cover has been removed for clarity and should be used during the procedure.

patient so that your dominant hand is cephalad (**Figure 143-7**). Position the US monitor on the opposite side of the patient so that it is easy to see (**Figure 143-7**). A longitudinal US probe orientation is preferred for the dynamic approach since it allows visualization of the entire needle as it courses toward the bladder. In infants and toddlers, there may not be enough space to place the US probe longitudinally and a transverse probe orientation may be necessary. In either case, place the US probe marker to your left. This will ensure that the left–right orientation on the US screen matches the real-world orientation.

Place the longitudinally oriented US probe in the suprapubic area and move it from side to side to locate the largest bladder dimension. Place the procedure needle on a 10 mL syringe. Position the procedure needle on the cephalad side of the US probe and angle it caudally (**Figure 143-8**). Insert and slowly advance the needle. Look for the needle on the US screen as it is inserted and advanced. If the needle is a narrow gauge and the US probe is low frequency, the needle will not necessarily be visible in the tissue. Rather, look for movements in the tissue as the needle is advanced (**Figure 143-9**). Adjust the needle and the US probe side to side as needed to keep the needle in the same plane as the US beam. Aspirate as the needle is advanced. When the needle appears to enter the bladder, aspiration should result in urine return. Remove the US probe once urine is aspirated. The remainder of the procedure can proceed as previously described.

For the transverse orientation, position the US probe so that the image of the bladder is centered on the screen. Position the procedure needle attached to a syringe just superior to the center of the US probe (**Figure 143-10**). Slowly advance the needle toward the bladder. Angle the needle slightly more caudal than the US probe since the entry point of the needle is superior to the US probe. The needle will be seen on screen in cross section and will appear as an echogenic point with a ring-down artifact or bright shadow (**Figure 143-11**). As the needle is advanced toward the bladder, the US probe may need to be fanned slightly cephalad or caudal to keep the needle tip in view. Aspirate as the needle is advanced. When the needle appears to enter the bladder, aspiration should result in urine return. Remove the US probe once urine is aspirated. The remainder of the procedure can proceed as previously described.

ASSESSMENT

If the first attempt at aspiration is unsuccessful, withdraw the needle to a subcutaneous position and redirect it at a different angle. This should be done only if the bladder is clearly identified. If the procedure is unsuccessful on the second attempt, the procedure should be delayed until the bladder is more distended. Consultation with a Urologist may be necessary.

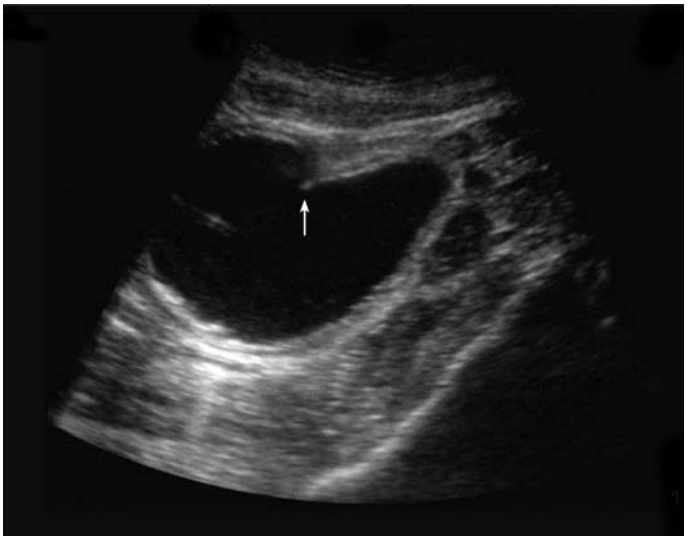

FIGURE 143-9. Longitudinal US appearance of the spinal needle. The anterior bladder wall is tenting as the needle is about to enter the bladder. The needle tip (*arrow*) is visible while the needle is not seen within the tissues.

FIGURE 143-10. The spinal needle is inserted under the cephalic side of the transversely oriented US probe and angled caudally. Note, the US probe cover has been removed for clarity and should be used during the procedure.

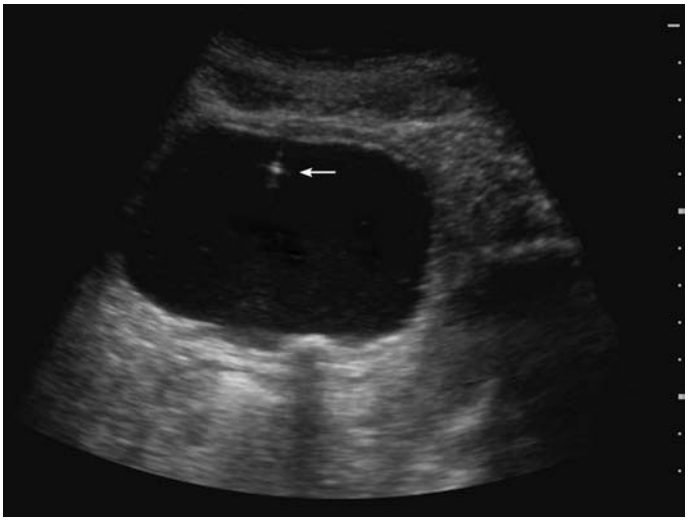

FIGURE 143-11. Transverse US appearance of the spinal needle. The hyperechoic needle tip (*arrow*) is visible with a small ring-down (*bright shadow*) artifact immediately below it.

AFTERCARE

No specific care is required after performing a suprapubic bladder aspiration. **Microscopic hematuria can occur following the procedure although gross hematuria is uncommon.** The patient may complain of mild pain or soreness in the suprapubic area. This can be relieved with acetaminophen or nonsteroidal anti-inflammatory drugs. The patient, if discharged, should be given specific instructions to return immediately if they develop gross hematuria, abdominal pain, fever, nausea, vomiting, or infection at the puncture site.

COMPLICATIONS

Numerous complications can be associated with suprapubic bladder aspiration.[1–16] Fortunately, these are rare occurrences. Bowel perforation, intraabdominal viscera injury, uncontrolled hemorrhage, and needle misplacement are the major complications of suprapubic bladder aspiration. Infectious complications include abdominal wall cellulitis, abdominal wall abscess, sepsis, and peritonitis. Hematomas of the abdominal wall, bladder wall, and pelvis are usually self-limited and require no treatment.

In the unfortunate situation when bowel contents or continuous blood is aspirated, the appropriate surgical consultant should be contacted. Generally, simple penetration of the bowel is considered harmless and requires no specific treatment. Observe the patient for the development of signs and symptoms of peritonitis.

To avoid complications, it is key that the bladder be clearly identified prior to inserting the spinal needle. The use of ultrasonography may aid in substantial reduction of complications arising from needle misadventure. The use of strict aseptic technique should avoid most infectious complications. Delaying the procedure for infants who have urinated within the last hour and the correction of any bleeding diathesis before performing the procedure can help avoid complications.

Do not mistake ascites as urine on ultrasonography. Ascites will outline the bowel and appears in many places around the abdomen. Fluid in the bladder has rounded borders and is localized. It is easy to lose sight of the needle tip and misdirect the needle as it advances through the tissue. Always fan the US probe to keep the tip of the needle in sight. In some cases, the needle may not be visible. Look instead for tissue movement.

SUMMARY

In those clinical situations when transurethral urine collection is not desired or possible, suprapubic bladder aspiration is an alternative. A thorough understanding of the pelvic and abdominal anatomy, along with a complete history and physical examination, is necessary to assure patient safety and avoid complications. This procedure is safe and effective to obtain urine as long as the bladder can be properly identified by palpation, percussion, or ultrasonography. Suprapubic bladder aspiration provides urine that is free from urethral contamination.

144 Suprapubic Bladder Catheterization (Percutaneous Cystostomy)

Richard Dean Robinson, Sam Hsu, and Eric F. Reichman

INTRODUCTION

Complaints involving the lower genitourinary system are among the most common urologic problems encountered by the Emergency Physician. The collection and evaluation of urine plays a critical role in the process of diagnosis and treatment. Volitional voiding and transurethral urinary catheterization are the preferred methods of bladder drainage and can be accomplished in most instances. There are situations when the transurethral route is contraindicated or technically not possible and alternate avenues must be explored. A percutaneous approach to urinary bladder drainage and decompression becomes the solution, offering both therapeutic and diagnostic results.[1–9] Suprapubic bladder catheterization has been used for decades as an effective means of accessing the bladder.

Suprapubic bladder catheterization, or percutaneous cystostomy, has become the treatment of choice for the patient with acute urinary retention regardless of the cause. It is commonly performed in the trauma patient with a known or suspected urethral injury. The catheters are well tolerated, easy to care for, and can easily be replaced and/or removed. The placement of a suprapubic catheter into the bladder is fast and may be performed under local anesthesia. It is a relatively safe procedure but does have potential complications that are significant.

ANATOMY AND PATHOPHYSIOLOGY

Residing in the retropubic space approximately 5 cm above the superior margin of the symphysis pubis, the adult urinary bladder has both retroperitoneal and intraperitoneal attachments. A working knowledge of this anatomy makes percutaneous bladder manipulation both safe and possible. The rectum lies just inferior and posterior to the urinary bladder and this relationship must be kept in mind when attempting percutaneous access. The bladder dome has peritoneal attachments and access in this area carries a risk of bowel injury and intraperitoneal bladder perforation.

Multiple vascular structures, including the common iliac and hypogastric vessels, reside in the bony pelvis alongside the bladder. These structures are lateral to the bladder and eccentric percutaneous access may result in troublesome hemorrhage.

INDICATIONS

Suprapubic bladder catheterization is indicated in cases when the transurethral route of bladder drainage or decompression is technically not possible or contraindicated. This includes patients with iatrogenic urethral injuries, obstructing urethral lesions, bladder neck lesions, enlarged prostates (e.g., benign hypertrophy or cancer), urethral strictures, urethral scarring, an obstructing phimosis, a urethral foreign body, and a suspected or known traumatic urethral or prostatic disruption. Continuous bladder irrigation can be accomplished via a combined suprapubic and transurethral route.

CONTRAINDICATIONS

Suprapubic catheterization is absolutely contraindicated in the absence of an easily palpable and distended or ultrasonographically localized and distended urinary bladder.[9] Under no circumstances should "blind" percutaneous access be attempted. The bladder must be distended to push the bowel away from the anterosuperior surface of the bladder.

Patients with a coagulopathy are at an increased risk for troublesome hemorrhage from any percutaneous procedure, including suprapubic bladder catheterization. Any coagulopathy, bleeding diathesis, platelet dysfunction, and/or thrombocytopenia should be corrected prior to performing this procedure.

In individuals with prior lower abdominal surgery or traumatic injury, the peritoneal cavity has been violated and the bowel may be displaced more caudal and to the level of the urinary bladder. The bowel may be adhesed to the anterior abdominal wall. This heightens the risk of inadvertent entry into the peritoneal cavity and injury to the bowel.

Relative contraindications to percutaneous bladder catheterization include patients who have a history of pelvic cancer or pelvic radiation therapy, ascites, urinary tract infections, or who are uncooperative. A history of pelvic cancer or irradiation will increase the risk of anatomical distortion, adhesions, and scarring. Attempts at suprapubic cystostomy increase the risk of peritoneal and/or bowel perforation. The return of ascitic fluid may lead the physician to a false sense of security when the catheter is actually intraperitoneal. Urine leakage in patients with a urinary tract infection may result in bacteremia, peritonitis, and/or sepsis. In these circumstances, consult a Urologist for an open suprapubic cystostomy or Interventional Radiology for a percutaneous cystostomy using fluoroscopic or ultrasonic guidance. An uncooperative patient will require parenteral sedation or procedural sedation prior to performing this procedure.

Any physical alteration, spinal deformities, extremity contractures, truncal obesity, or other conditions that would preclude patients from lying supine and inhibiting bladder palpation are also contraindications to performing a percutaneous cystostomy.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Percutaneous cystostomy catheter kit
- Foley catheter, 14 to 16 French
- 60 mL catheter-tipped syringe
- 10 mL syringes
- 24 to 25 gauge spinal needle, 3 inches long
- #11 Surgical scalpel blade on a handle
- 3-0 nylon suture
- Needle driver
- Local anesthetic solution, with or without epinephrine
- 4 × 4 gauze squares
- 25 gauge needle, 1 inch long
- 18 gauge needle
- Urine meter or urine leg bag
- Sterile towels
- Sterile drapes
- Tincture of benzoin
- 2 inch tape
- Ultrasound machine (recommended)

The percutaneous cystostomy catheter kit is commercially available and prepackaged by several manufacturers. One type contains a cystostomy tube, an obturator, and connector tubing (**Figures 144-1, 144-2, & 144-4**). Another type uses a Seldinger-type kit with a peel-away sheath (**Figure 144-3**).

A commonly used suprapubic catheter kit is the Rutner Percutaneous Suprapubic Balloon Catheter Set (Cook Urological Inc., Spencer, IN). It consists of a 10 French catheter that is 22 cm long, a needle obturator, a connecting tube, and a 3 mL syringe (**Figures 144-1 & 144-2A**). The proximal end of the catheter has two ports (**Figures 144-1 & 144-2B**). One port is for the insertion of the obturator through the catheter. The obturator screws and locks into this port. The other port is an inflation port for the cuff of the catheter. A 3 to 5 mL syringe attaches to this port. The obturator is a hollow tube that tapers to a sharp point distally. When properly inserted and locked into the port, the obturator will project 2.5 mm from the distal end of the catheter (**Figures 144-1C & 144-2C**). The cuff is donut-shaped and centered 1 cm from the tip of the catheter (**Figure 144-2D**). The connector tube has a stopcock at its distal end that attaches to the catheter (**Figure 144-2E**). The proximal end of the connector tube has a flared flange to attach to a urine drainage system.

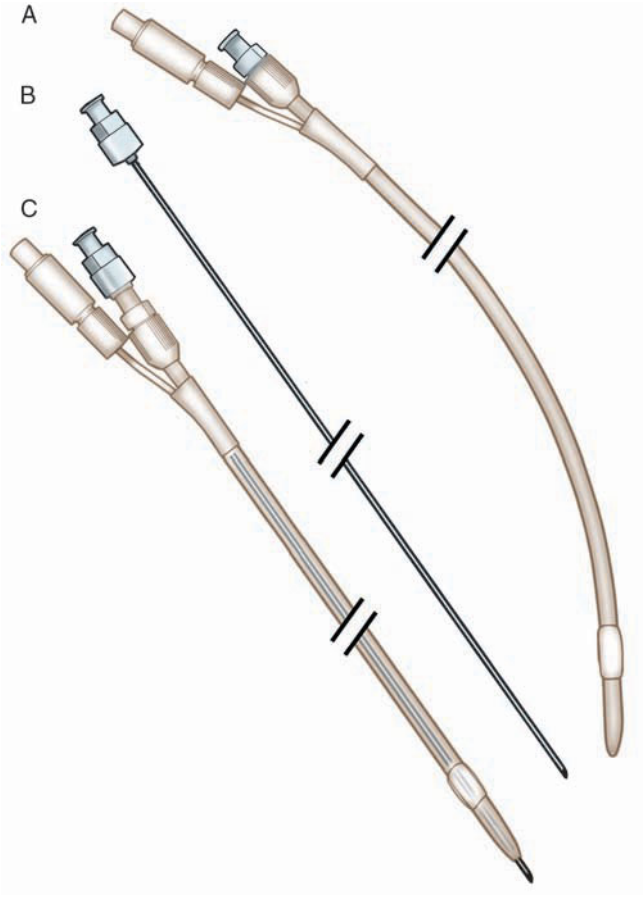

FIGURE 144-1. Schematic of a catheter and obturator system. **A.** The catheter. **B.** The obturator. **C.** The obturator within the catheter.

PATIENT PREPARATION

As with all procedures, the risks and benefits of suprapubic bladder catheterization should be discussed with the patient and/or their representative. Obtain an informed consent and place it in the medical record.

Place the patient supine. Clean any dirt and debris from the abdominal wall. Shave the lower abdomen if the patient is hirsute. Identify the bladder by palpation, percussion, and/or ultrasonography. Apply povidone iodine or chlorhexidine solution to the lower abdomen, from the umbilicus to the pubis, and allow it to dry. Consider the administration of parenteral analgesics, sedatives, or procedural sedation as this is a painful procedure.

Anesthetize the abdominal wall. Fill a 10 mL syringe with local anesthetic solution. Apply a 24 to 25 gauge spinal needle onto the syringe. Identify the insertion site in the midline and 4 to 5 cm above the pubic symphysis. The use of ultrasound to verify the bladder location and to ensure that no loops of bowel are present between the abdominal wall and bladder is recommended.[9] Make a skin wheal with the local anesthetic solution at the insertion site. Insert the spinal needle at a 20° to 30° angle from true vertical and aimed caudally (**Figure 144-3A**). Advance the needle through the subcutaneous tissue, rectus sheath, and retropubic space while simultaneously aspirating and injecting 5 to 10 mL of local anesthetic solution. A loss of resistance will be felt as the spinal needle traverses the rectus sheath and enters the retropubic space. Continue to aspirate while advancing the spinal needle until the bladder is entered and urine fills the syringe. The bladder appears to tent as the needle pierces its anterior wall when ultrasonographic guidance is used.[8] **Note the needle direction and depth of insertion required to enter the bladder.**

TECHNIQUES

SELDINGER TECHNIQUE WITH A PEEL-AWAY SHEATH

This method is similar to that of placing a central venous catheter. The needle is used to locate the bladder. Place the needle on a 10 mL syringe. Insert the needle through the skin wheal of local anesthetic solution located in the midline and 4 to 5 cm above the pubic symphysis. Direct the needle caudally and at a 20° to 30° angle from the true vertical (**Figure 144-3A**). **It is important to ensure that the needle enters, and is advanced, in the midline.** This area is avascular. If the needle is paramedian, it may traverse the rectus muscles and inferior epigastric vessels resulting in significant hemorrhage. Advance the needle caudally while applying negative pressure with the syringe. Stop advancing the needle when urine is aspirated into the syringe. Advance the needle an additional 2 to 3 cm into the bladder from the point at which urine is initially aspirated into the syringe. The aspiration of urine will confirm the proper position of the needle within the bladder.

Firmly hold the needle against the abdominal wall. Carefully remove the syringe from the needle. **Do not allow the needle to move as it may shear the bladder wall.** Advance the guidewire through the needle and into the bladder (**Figure 144-3B**). Withdraw the needle over the guidewire while leaving the guidewire in place. Make a superficial stab incision with the #11 scalpel blade adjacent to the guidewire. This will facilitate passage of the dilator and sheath. Insert the dilator through the peel-away sheath. Advance the dilator and peel-away sheath as a unit over the guidewire and into the bladder (**Figure 144-3C**). Remove the guidewire and dilator as a unit (**Figure 144-3D**), leaving only the peel-away sheath (**Figure 144-3E**).

Insert a Foley catheter through the peel-away sheath and completely into the bladder (**Figure 144-3F**). The Foley catheter should be two sizes (2 French) smaller than the size of the peel-away sheath. Urine should spontaneously flow from the Foley catheter. If not, insert a 60 mL catheter-tipped syringe into the Foley catheter and aspirate (**Figure 144-3G**). The flow of urine will confirm that the catheter is properly positioned within the bladder. Inflate the cuff of the Foley catheter. Attach a urine collection system to the proximal end of the Foley catheter (**Figure 144-3H**).

Remove the peel-away sheath. Grasp the free ends or arms of the peel-away sheath. Pull the free ends upward and opposite each other (**Figure 144-3H**). The peel-away sheath will split in half as it is withdrawn over the Foley catheter and out of the abdominal wall. Gently withdraw the Foley catheter to lodge the cuff against the bladder wall (**Figure 144-3I**).

OBTURATOR TECHNIQUE

Prepare the equipment. Insert the obturator through the catheter and lock it in position. Inflate the cuff with sterile saline and check its integrity. Deflate the cuff. Inflate and deflate the cuff two more times to soften the cuff. The spinal needle was previously used to infiltrate local anesthetic solution and locate the urinary bladder. This maneuver allows the operator to determine both the depth and angle needed for bladder entry.

Make a 3 to 4 mm stab incision in the midline and 4 to 5 cm above the pubic symphysis through the skin wheal of local anesthetic solution with a #11 scalpel blade. Place the tip of the obturator-catheter unit in the skin incision. **It is important to ensure that the unit enters, and is advanced, in the midline.** This area

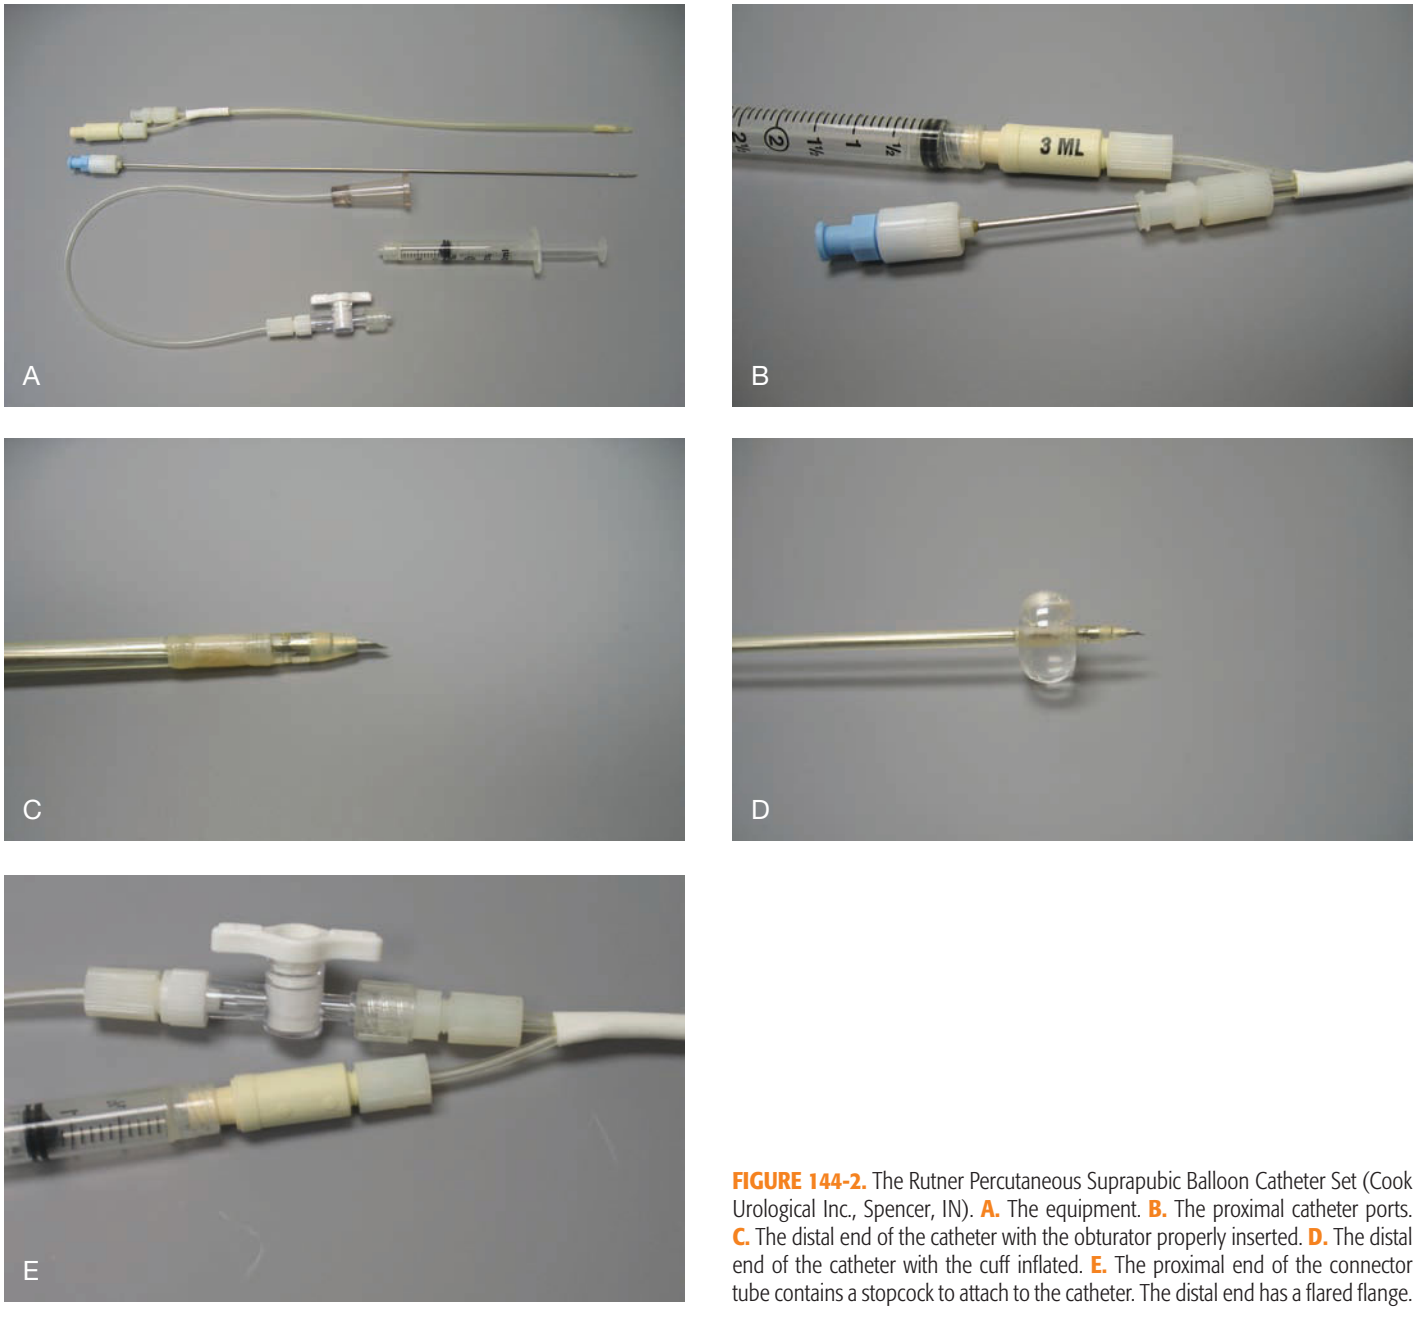

FIGURE 144-2. The Rutner Percutaneous Suprapubic Balloon Catheter Set (Cook Urological Inc., Spencer, IN). **A.** The equipment. **B.** The proximal catheter ports. **C.** The distal end of the catheter with the obturator properly inserted. **D.** The distal end of the catheter with the cuff inflated. **E.** The proximal end of the connector tube contains a stopcock to attach to the catheter. The distal end has a flared flange.

is avascular. If the unit is paramedian, it may traverse the rectus muscles and inferior epigastric vessels resulting in significant hemorrhage. Direct the unit caudally and at a 20° to 30° angle from true vertical (**Figure 144-4A**). Place the nondominant hand on the lower abdominal wall. Grasp the tip of the obturator-catheter unit with the thumb and index finger of the dominant hand. The hand and fingers will stabilize the unit and control the depth of insertion.

Advance the obturator-catheter unit with the dominant hand. Resistance may be felt as the trocar traverses the linea alba. Apply firm pressure to the unit to advance through the linea alba. **Do not plunge as the unit is advanced.** Continue to advance the unit through the retropubic space until resistance is felt. The tip of the trocar is now against the anterior bladder wall. Advance the unit with a short and rapid stabbing motion to enter the bladder (**Figure 144-4A**). Urine should spontaneously flow from the proximal end of the obturator. If not, attach a syringe to the obturator and aspirate. The flow of urine will confirm that the tip of the obturator-catheter unit is properly positioned within the bladder. Advance the unit an additional 2 to 3 cm into the bladder to ensure the cuff is completely within the bladder.

Inflate the cuff of the catheter (**Figure 144-4B**). Unscrew the obturator from the catheter. Securely hold the catheter, with the nondominant hand, as it exits the abdominal wall. Remove the obturator from the catheter (**Figure 144-4C**). Attach the stopcock at the distal end of the connector tube to the catheter (**Figure 144-4D**). Gently withdraw the catheter to lodge the cuff against the bladder wall. Attach a urine collection system to the proximal end of the connector tube.

ULTRASOUND TECHNIQUE

Ultrasound (US) can ensure there is sufficient urine to aspirate and locate a bladder that is located off midline or deep in the pelvis.[10] It is especially helpful in infants and toddlers, who

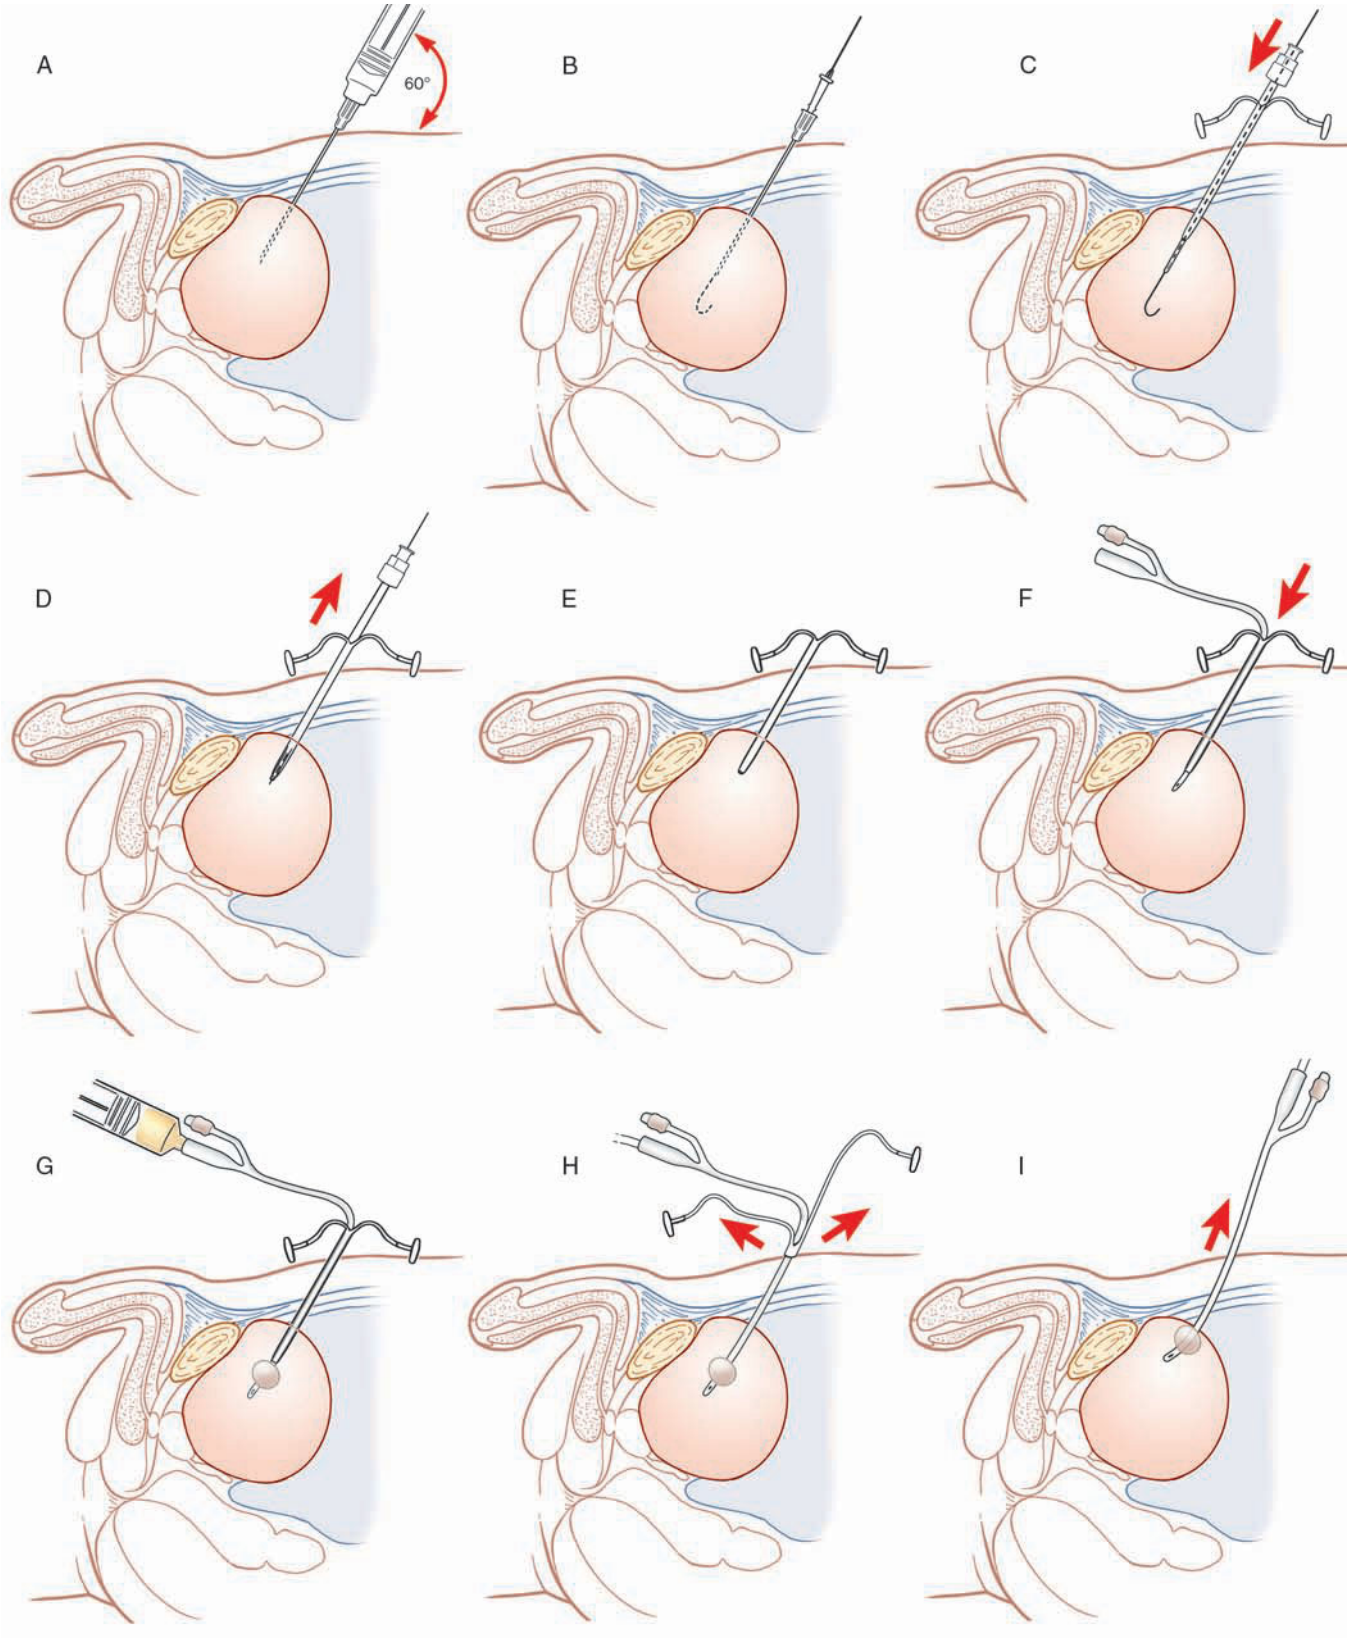

FIGURE 144-3. The Seldinger technique with a peel-away sheath. **A.** The finder needle is inserted 60° to 70° to the skin and advanced into the bladder. **B.** The syringe has been removed and the guidewire inserted through the needle. **C.** The needle has been removed. The dilator and peel-away sheath are inserted over the guidewire as a unit and into the bladder. **D.** The dilator and guidewire are removed. **E.** The peel-away sheath remains through the skin and into the bladder. **F.** A Foley catheter is inserted through the peel-away sheath and into the bladder. **G.** Urine is aspirated from the bladder. The system is inserted 60° to the skin and advanced into the bladder. **B.** The balloon is inflated. **C.** The obturator is removed while the catheter remains within the bladder. **D.** The collecting tube is attached to the catheter.

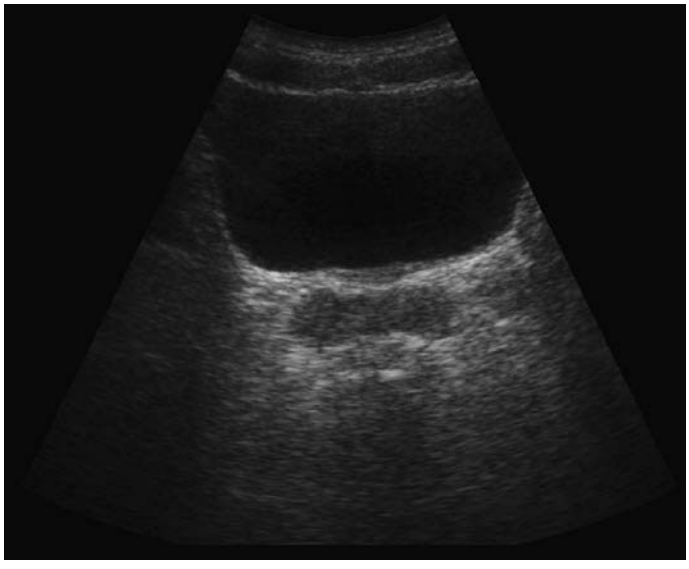

FIGURE 144-5. Transverse US view of the bladder.

FIGURE 144-6. The US machine is positioned in the same sight-line as the procedure. The physician's dominant (*right*) hand is cephalad and controls the needle. Note, the US probe cover has been removed for clarity and should be used during the procedure.

have small bladders. There are no contraindications to using ultrasound other than those for the procedure itself. For adults, a general-purpose curvilinear abdominal or phased-array probe provides the best combination of penetration and field of view into the abdomen. A linear probe can be used for children. Either a static or dynamic (real-time) technique can be used. The static technique is preferred as it is the easier technique to learn and master. The dynamic technique will increase the success rate for small bladders with minimal urine.

Image the bladder to ensure there is sufficient urine to aspirate. Place the US probe transversely and just superior to the pubic symphysis. If the bladder is not immediately visible, slowly fan the probe cephalad and caudal until it appears. If the bladder is not visible, repeat the scan just off the midline. The bladder will appear anechoic (**Figure 144-5**). Moderate to large bladders are amenable to the static US technique. Bladders smaller than 2 cm in anteroposterior or transverse diameter have lower success rates for aspiration and the dynamic US technique may be necessary to obtain urine.

STATIC US TECHNIQUE

Identify the bladder using US and center the image on the US machine screen. Angle the US probe so that the largest dimensions of the bladder appear on the screen. **Note the angle of the US probe as this will correspond to the angle of entry for the needle.** Make sure that the bladder is centered on the screen. Move the probe off midline, if necessary, to minimize lateral angulation. This will prevent the need to angle the needle laterally to reach the bladder. Note the depth on the screen from the skin to the bladder in order to gauge the necessary needle length. Mark the entry point on the skin where the middle of the probe meets the skin. Prep the skin and proceed with procedure as described previously for either the Seldinger or obturator technique.

DYNAMIC US TECHNIQUE

Prepare the skin, apply sterile single-use US gel to the patient's skin, and apply a sterile US probe cover. Stand to the side of the patient so that your dominant hand is cephalad (**Figure 144-6**). Position the US monitor on the opposite side of the patient so that it is easy to see (**Figure 144-6**). A longitudinal US probe orientation is preferred for the dynamic approach since it allows visualization of the entire needle as it courses toward the bladder. In infants and toddlers, there may not be enough space to place the US probe longitudinally and a transverse probe orientation may be necessary. In either case, place the US probe marker to your left. This will ensure that the left–right orientation on the US screen matches the real-world orientation.

Place the longitudinally oriented US probe in the suprapubic area and move it from side to side to locate the largest bladder dimension. Place the procedure needle on a 10 mL syringe. Position the procedure needle on the cephalad side of the US probe and angle it caudally (**Figure 144-7**). Insert and slowly advance the needle. Look for the needle on the US screen as it is inserted and advanced. If the needle is a narrow gauge and the US probe is low frequency, the needle will not necessarily be visible in the tissue. Rather, look for movements in the tissue as the needle is advanced (**Figure 144-8**). Adjust the needle and the US probe side to side as needed to keep the needle in the same plane as the US beam. Aspirate as the needle is advanced. When the needle appears to enter the bladder, aspiration should result in urine return. Remove the US probe once urine is aspirated. The remainder of the procedure for the Seldinger technique can proceed as previously described. The US procedure is the same if using the obturator technique; just substitute the catheter-obturator unit for the needle described above.

For the transverse orientation, position the US probe so that the image of the bladder is centered on the screen. Position the procedure needle attached to a syringe just superior to the center of the US probe (**Figure 144-9**). Slowly advance the needle toward the bladder. Angle the needle slightly more caudal than the US probe since the entry point of the needle is superior to the US probe. The needle will be seen on screen in cross section and will appear as an echogenic point with a ring-down artifact or bright shadow (**Figure 144-10**). As the needle is advanced toward the bladder, the US probe may need to be fanned slightly cephalad or caudal

FIGURE 144-7. The spinal needle is inserted under the cephalic side of the longitudinally oriented US probe and angled caudally. Note, the US probe cover has been removed for clarity and should be used during the procedure.

to keep the needle tip in view. Aspirate as the needle is advanced. When the needle appears to enter the bladder, aspiration should result in urine return. Remove the US probe once urine is aspirated. The remainder of the procedure for the Seldinger technique can proceed as previously described. The US procedure is the same if using the obturator technique; just substitute the catheter-obturator unit for the needle described above.

ASSESSMENT

The return of urine confirms the correct placement of the catheter into the bladder. If the catheter ceases to work after initially functioning properly, inspect it for kinks. Flush the catheter with sterile saline to remove any potential clots. A catheter that flushes easily but cannot be subsequently aspirated suggests that the tip has been withdrawn into the perivesical space of the pelvic cavity or that the catheter is kinked. The catheter is kinked if saline cannot be flushed through or aspirated. The catheter is properly positioned within the bladder if saline flushes and aspirates without difficulty. Consider the use of ultrasound to confirm catheter placement and presence of urine within the bladder.

FIGURE 144-9. The spinal needle is inserted under the cephalic side of the transversely oriented US probe and angled caudally. Note, the US probe cover has been removed for clarity and should be used during the procedure.

AFTERCARE

Secure the catheter to the abdominal wall (**Figure 144-11**). Place 4 × 4 gauze squares over the pubic symphysis to bolster the catheter as it exits the abdominal wall. Apply tincture of benzoin to the abdominal wall and allow it to dry. Tape over the catheter and gauze. The ends of the tape should be applied to the dried benzoin solution. Prophylactic antibiotics are not required unless a urinary tract infection is present.

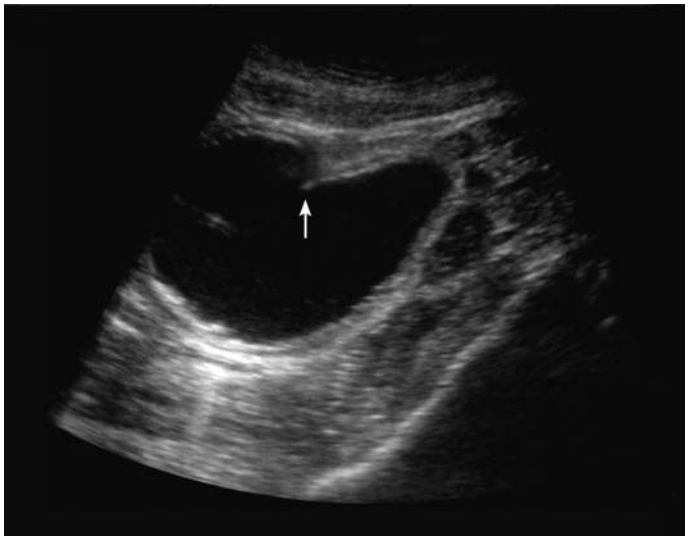

FIGURE 144-8. Longitudinal US appearance of the spinal needle. The anterior bladder wall is tenting as the needle is about to enter the bladder. The needle tip (*arrow*) is visible while the needle is not seen within the tissues.

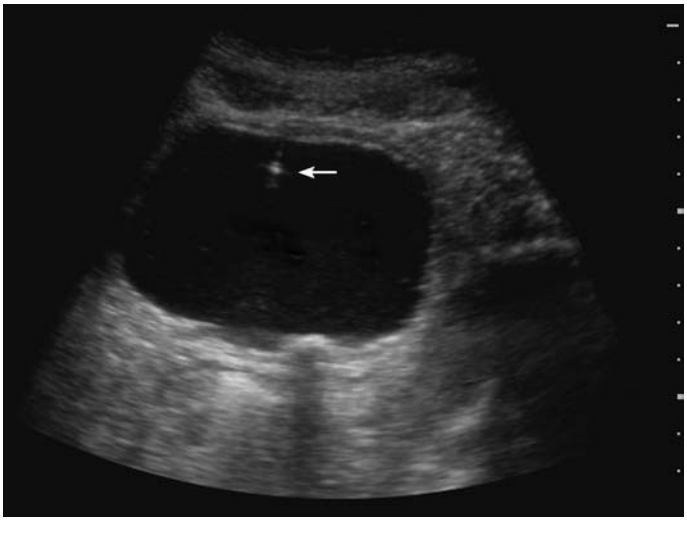

FIGURE 144-10. Transverse US appearance of the spinal needle. The hyperechoic needle tip (*arrow*) is visible with a small ring-down (*bright shadow*) artifact immediately below it.

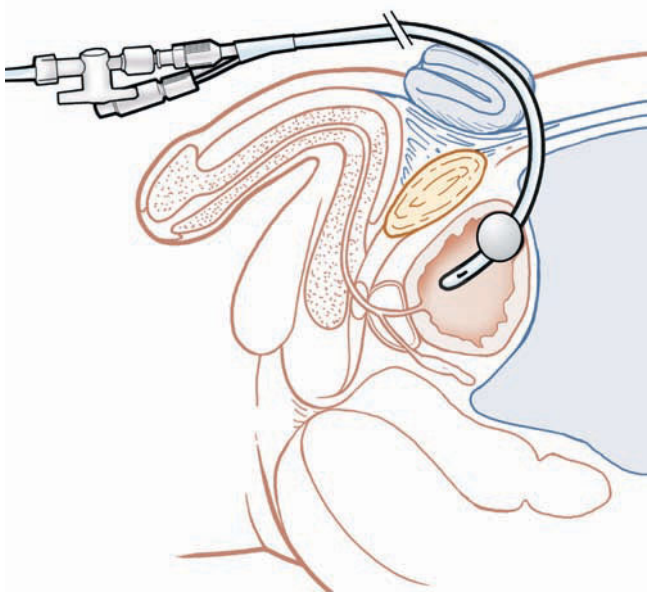

FIGURE 144-11. Secure the catheter. Place gauze squares on the skin to make a gentle curve in the catheter without kinks. Tape the catheter to the abdominal wall.

Examine the puncture site twice a day for any signs of infection. Routine wound care should be performed at the puncture site. If removed within 7 days, the bladder wall and abdominal wall will heal without complications. A transurethral catheter should be inserted to ensure urine egress through the urethra and not the bladder wall while the suprapubic catheter tract heals. After 10 to 14 days, the tract of the catheter is epithelialized and mature. The catheter may be exchanged through the mature tract if necessary. Suprapubic tubes should not be left in place for more than 4 weeks.[9]

COMPLICATIONS

Bowel perforation, intraabdominal visceral injury, uncontrolled hemorrhage, vascular injury, peritonitis, catheter misplacement, and catheter migration are the major complications of suprapubic cystostomy catheter placement.[1–11] Perforation of the bowel can be prevented by ensuring that the bladder is distended by palpation, percussion, or ultrasonography. Intraperitoneal perforation is more common in patients with ascites, a distended abdomen, or prior abdominal surgery. Gross hematuria is common and transient. Through-and-through perforation of the bladder can injure the rectum, vagina, and/or uterus. Other minor complications are associated with length of indwelling catheter time and include infections (e.g., cellulitis and abscesses), occasional bleeding, and stone formation.

When catheter placement is in doubt or when a previously draining tube no longer continues to drain, simple flushing and irrigation will usually suffice. Bedside ultrasound is a quick means to confirm catheter placement. However, if concern persists, a gravity cystogram under fluoroscopy is diagnostic. In the unfortunate situation when bowel contents or continuous blood is aspirated or flows from the catheter, the appropriate surgical consultations should be obtained.

SUMMARY

In those clinical situations when transurethral bladder decompression is no longer an option, percutaneous access is the preferred alternative. Years of experience have demonstrated suprapubic bladder catheterization to be an effective and relatively safe method of accessing the bladder. A prior understanding of the associated anatomy is paramount to avoid of adverse results.

145 Retrograde Urethrography and Cystography

Richard Dean Robinson and Eric F. Reichman

INTRODUCTION

Urinary tract injuries may result from blunt trauma, penetrating trauma, urologic procedures, or may arise spontaneously.[1–14] Bladder injuries occur in up to 15% of pelvic fractures.[1–3] Associated urethral injuries occur in up to 11% of males and up to 6% of females.[1–3] **The role of retrograde urethrography and cystography in the trauma patient is to rule out a partial urethral rupture, complete urethral rupture, or a bladder rupture.** On initial presentation to the Emergency Department there are clear indications for performing these procedures. The importance of proper training in these techniques must be stressed to avoid iatrogenic or secondary urologic injury.

The evaluation of a traumatically injured patient should include, if appropriate, an assessment of the bony pelvis and the genitourinary system. The identification of a pelvic fracture must be followed by an examination of the lower genitourinary tract to rule out associated injury. Patients with disruption of the pubic symphysis, pubic rami, or a vertically unstable pelvic fracture have a high incidence of concomitant bladder trauma. Those with an isolated acetabulum, femur, or iliac crest fracture have a low incidence of bladder injury or rupture.[13] Unfortunately, the lack of a pelvic fracture does not eliminate the possibility of a bladder or urethral injury.

The most common signs seen in patients with genitourinary tract injury are gross hematuria (82%) and abdominal tenderness (62%).[4] Other signs of genitourinary tract injury include blood at the urethral meatus, inability to void, swelling or ecchymosis of the perineum or penis, a boggy prostate, and a high riding prostate. In the presence of any of these signs, an evaluation of the genitourinary tract is indicated. These assessments should be made early and intervention instituted.

Traditional teaching suggests that urethral catheterization should be avoided if a potential injury to the bladder and/or urethra is suspected. This teaching requires a retrograde urethrogram and cystogram to be performed to rule out any injuries prior to urethral catheterization. A preliminary study suggests that blind urethral catheterization despite a potential injury may be safe.[15] Larger and additional studies are required before this change in practice can be safely recommended.

ANATOMY AND PATHOPHYSIOLOGY

The lower urinary tract in males consists of the urethra and bladder (**Figure 145-1**). The urethra is divided into the fossa navicularis, the penile urethra, the bulbar urethra, the membranous urethra, and the prostatic urethra based on its anatomic location. The bladder neck opens into the trigonal canal and funnels into the bladder. The male posterior urethra is 5.0 to 5.5 cm long, fixed to the urogenital diaphragm, and is the area most susceptible to injury.[2,5] The female urethra is short, not rigidly fixed to the pubis

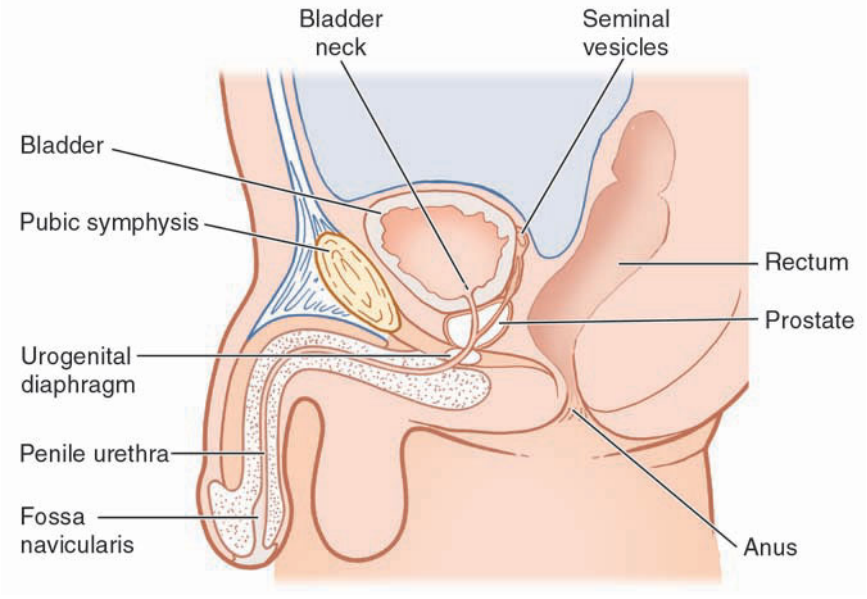

FIGURE 145-1. Anatomy of the male genitourinary tract.

or pelvic floor, mobile, and much less susceptible to injury.[3] The female urethra is equivalent to the membranous and prostatic (posterior) urethra in the male.[6]

The periurethral striated sphincter is composed of muscle from the urogenital diaphragm. This muscle layer unites with the distal smooth muscle at the intermuscular incisura. This is frequently seen on the voiding cystourethrogram and may be mistaken for a stricture or posterior urethral valves. The urogenital diaphragm surrounds the membranous urethra and may compress the urethra during voiding or on retrograde flow of contrast.[6]

The verumontanum and urethral crest protrude into the male prostatic urethral lumen and may extend into the membranous urethra. The prostatic gland ducts, prostatic utricle, ejaculatory ducts, and urethral gland ducts usually do not fill on voiding cystourethrogram; and when visible, filling usually denotes a distal obstruction. These structures, however, may fill during aggressive injection of contrast during the retrograde urethrogram.

On the lateral view of the bladder, the anterior and posterior baseplate (of which the trigone is part) is seen as a diagonal plane sloping downward from posterior to anterior. The bladder neck is visualized at the junction of the anterior one-third and the posterior two-thirds of the plane. Anteriorly, the pubis abuts the baseplate. The fundus of the bladder becomes more dome shaped as it fills with fluid. It may be compressed by the uterus or colon in the midline or on either side.[6]

INDICATIONS

The retrograde urethrogram is to be employed in blunt and penetrating traumatic presentations of males when there is any indication of a urethral injury. Indications include penetrating injury when involvement of the lower genitourinary tract is suspected, pelvic fractures, perineal or lower abdominal trauma with gross hematuria, blood at the urethral meatus, inability to void, swelling of the perineum or penis, ecchymosis of the perineum or penis, hematoma of the perineum or penis, a high riding prostate, or a boggy prostate.[7,8,13] Other indications include urethral strictures and obstructions, congenital abnormalities, periurethral or prostatic abscess, and fistulae or false passages. In females, it may be indicated if urethral diverticula are suspected.

Retrograde cystography should follow retrograde urethrography, especially in patients who recall having a full bladder at the time of trauma and are later unable to void or have small amounts of bloody urine.[9] Retrograde cystograms are nearly 100% sensitive for detecting rupture, provided that adequate distension is accomplished and that postvoid images are obtained.[13]

CONTRAINDICATIONS

There are few contraindications to retrograde urethrography and cystography. However, the patient's overall condition must be taken into consideration. The lifesaving procedures, such as securing an airway and stabilizing life- and limb-threatening injuries, must take precedence. Because septic shock and irreversible renal damage can occur, a relative contraindication in the setting of acute urethritis exists when the suspicion of genitourinary tract trauma is very low. **A urethral injury identified on the retrograde urethrogram is the only absolute contraindication to transurethral bladder catheterization and retrograde cystography**. Consult a Urologist if, in a patient with pelvic trauma, there is any difficulty in passing a urethral catheter into the bladder. **Do not try to advance a catheter against resistance as iatrogenic injury can result**. There is a small risk of allergic reactions to the contrast media. Patients with previous reactions should receive nonionic agents and be premedicated with corticosteroids and antihistamines.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- Sterile drapes
- Viscous lidocaine suspension
- Foley catheter, 5 to 18 French (**Table 145-1**)
- Brodney clamp
- Contrast material
- 60 mL catheter tip syringe
- Toomey syringe
- Christmas tree adaptor
- Surgical clamp
- Lead apron

TABLE 145-1 Estimated Foley Catheter Size Based on Patient Age

Patient age	Catheter size (French)
Premature or newborn	5
3–12 months	8
1–2 years	8–10
2–8 years	10
8–10 years	10–12
10–12 years	12
12–14 years	12–14
14+ years	16–18

A variety of contrast agents are available and may be used to perform retrograde urethrography and cystography. The agents used are specific to each institution. Most commonly used are full strength Hypaque (50% diatrizoate sodium), Renografin-60 (diatrizoate sodium), or Cystografin. Alternatively, the same agents can be diluted with sterile saline in a 1:10 dilution.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. While a formal consent is usually not obtained since this is an emergent procedure, document in the medical record that the "risks and benefits were explained to the patient." If not contraindicated, administer parenteral sedation. Place the patient in a 45° oblique position with their left side on the bed. Flex the left leg at the knee and abduct the hip. Place a radiolucent wedge or rolled towels under the patient to maintain the oblique position. Completely extend the right leg. This is the ideal patient position. The degree of patient mobility and the medical condition may dictate an alteration of this position. In patients with pelvic fractures, all radiographs should be taken with the patient in a supine position.

Prepare the penis and urethra. Clean any dirt and debris from around the penis. Retract the foreskin if the patient is uncircumcised. Apply povidone iodine or chlorhexidine solution to the penis and allow it to dry. Apply sterile drapes to delineate a sterile field. **The retrograde urethrogram must be performed under sterile conditions. Insert viscous lidocaine into the urethral meatus to anesthetize the urethra. Do not use lidocaine jelly as this may impede the flow of contrast material**. Allow the lidocaine to remain in the urethra for 2 to 4 minutes prior to performing the procedure to provide adequate analgesia.

Obtain a flat plate or KUB (kidney, ureters, and bladder) radiograph. This will be a baseline film for future reference. Carefully examine the radiograph for curvature of the spine, pelvic fractures, fractures of ribs 9 to 12, unilateral or bilateral loss of the normal psoas muscle shadow, or vertebral transverse process fractures. Any of these findings can signify a urinary tract injury. Observe and note any radiopaque material that may be present prior to the injection of contrast material.

The Emergency Physician should dress appropriately for the procedure. Since the Emergency Physician must be near the patient during the procedure and while radiographs are taken, put on a lead apron. Dress in a sterile gown and gloves. A cap and mask are not required.

RETROGRADE URETHROGRAPHY TECHNIQUES

FOLEY CATHETER TECHNIQUE

The Foley catheter technique is the preferred method. The Foley catheter causes little or no discomfort, is flexible, and the patient may be able to move if necessary. There is no leakage of contrast from the urethra and onto the patient, which can cause artifacts on the radiographs and make interpretation difficult. An advantage to using the Foley catheter is that it can subsequently be advanced into the bladder to perform the cystogram. The newer types of catheters have two cuffs; one at the tip and the other near the balloon inflation hub of the catheter. The proximal cuff will expand when the pressure in the distal cuff exceeds the maximum safe pressure during cuff inflation. This allows the excess pressure to be directed away from the distal cuff and not cause an iatrogenic urethral injury. There are some disadvantages to this method. The inflated cuff may conceal an injury of the distal urethra at the fossa navicularis. Air bubbles are difficult to eliminate from the catheter. This may impair the flow of the contrast material or produce artifacts due to air in the urethra. Air bubbles in the Foley catheter will alter the integrity of the study. Prime the tubing with contrast before inserting it into the urethra to eliminate any air. Place an X-ray plate under the patient's hips and pelvis.

Insert the catheter into the urethra. Advance it until the cuff is within the fossa navicularis (**Figure 145-2A**). Inflate the cuff with approximately 3 mL of sterile saline, or to the point that it is snug and does not cause pain to the patient.[10] Gently straighten the urethra by directing the tip of the penis toward the dependent shoulder or nipple and over the thigh. Avoid traction on the penis or the Foley catheter as it tends to narrow the urethra and/or dislodge the catheter. Attach a contrast-filled syringe to the proximal end of the Foley catheter (**Figure 145-2A**). Gently inject 50 to 60 mL of contrast material over 5 to 10 seconds.

Obtain a plain radiograph at or near the end of the injection. Have the film developed and review the image. The entire urethra should be visible in a lateral projection. Repeat the procedure if this is not achieved. Allow the contrast to drain from the urethra through the Foley catheter and into a container. Deflate the cuff and remove the catheter from the urethra. Obtain an additional plain radiograph of the pelvis as a washout image. Have the film developed and review the image for any abnormalities in the urethra. Although not necessary, fluoroscopy may aid in obtaining an adequate study.[10]

Great care should be taken so as not to allow any contrast to leak out of the catheter or urethra. Any spill of contrast material will cause distortions on the radiographs. The contrast may also cause skin irritation. It should be wiped and rinsed off the skin immediately if this occurs.

SYRINGE TECHNIQUE

If a proximal urethral injury is suspected, the alternative method is to use a 60 mL catheter-tipped Toomey syringe or a 60 mL syringe with a Christmas tree adaptor. Because it is not flexible and cannot be fixed inside the penis, the syringe must be held in place at all times during the procedure. The penile shaft must also be held to secure the tip of the syringe inside the urethra. There is a significant chance of contrast leakage from the urethra using this technique.

Clear, prep, and drape the penis as described previously. Place an X-ray plate under the patient's hips and pelvis. Grasp and cradle the patient's penis with the nondominant hand. Insert the tip of the contrast-filled syringe into the urethra. Firmly squeeze the glans penis between the thumb and the index and long fingers (**Figure 145-2B**). This will secure the catheter tip within the fossa navicularis. Do not squeeze the shaft of the penis with middle, ring, or little fingers as this can occlude the urethra. Gently straighten the urethra by directing the tip of the penis toward the dependent shoulder or nipple and over the left thigh. The

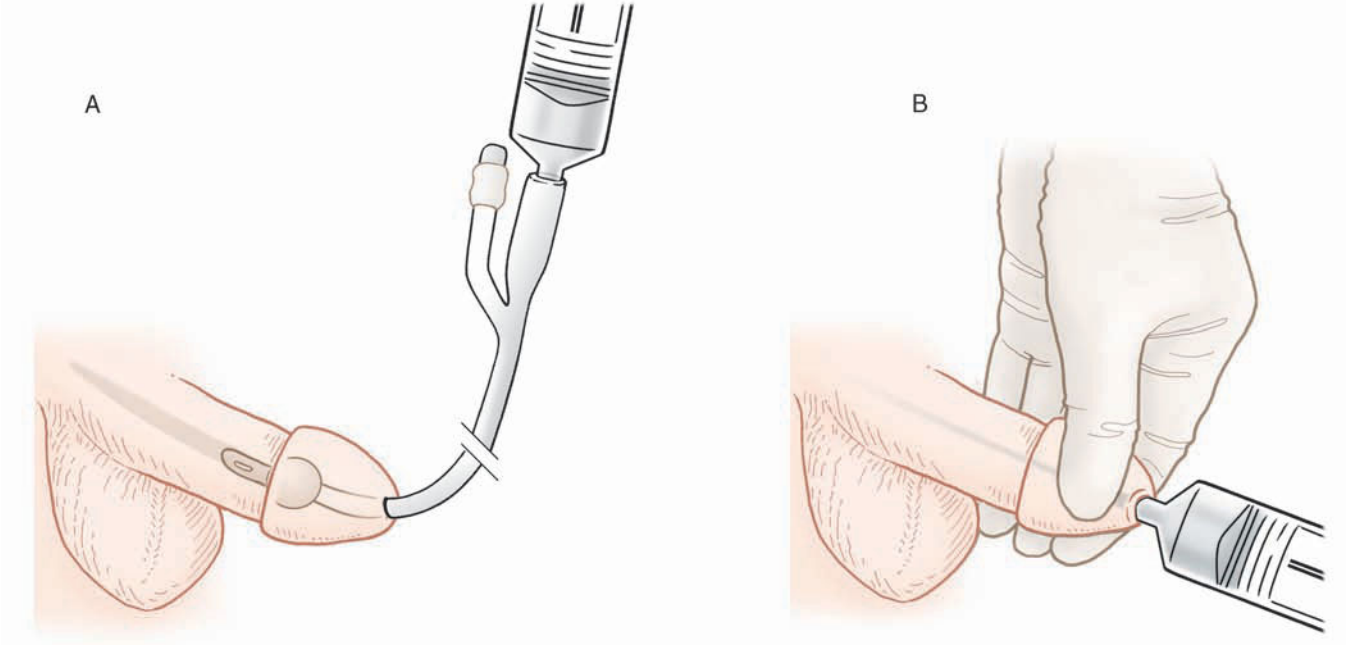

FIGURE 145-2. Retrograde urethrography. **A.** Foley catheter technique. **B.** Syringe technique.

remainder of the procedure is as described above in the Foley catheter section.

BRODNEY CLAMP TECHNIQUE

The Brodney clamp is a cage with rubber feet that clamp behind the corona of the glans.[10] In the center of the device there is a blunt-tipped obturator that inserts into and occludes the urethral meatus. It may be used instead of a Foley catheter or 60 mL syringe for the procedure. The advantage of this device is that both the fossa navicularis and the distal urethra are visible on the radiograph. Air bubbles are easily eliminated from the obturator. The disadvantages of the clamp are that it is not flexible and it is heavy. It must be held during the procedure and fluoroscopy is impossible. If the patient moves, the clamp tends to dislodge. The clamp is difficult to use in older children, adolescents, adults, and in the presence of a phimoses.[10] Brodney clamps are usually not stocked in the Emergency Department and may be difficult to obtain in a timely manner.

Clean, prep, and drape the penis as mentioned previously. Insert the blunt-tipped obturator of the clamp into the urethra. Rotate the feet of the clamp so that they are grasping the coronal sulcus of the penis. These should not be so tight as to occlude the urethra ventrally. The remainder of the technique is as described in the Foley catheter section.

RETROGRADE CYSTOGRAPHY TECHNIQUE

Any abnormalities in the retrograde urethrogram, such as extravasation of the contrast from the urethra or evidence of strictures, should prompt an urgent consult by a Urologist. If the study is normal, the retrograde cystogram should be performed. Gently advance and fully insert a Foley catheter into the bladder (**Figures 145-3A & B**). Inflate the cuff at the tip of the Foley catheter (**Figure 145-3B**). Gently pull on the Foley catheter to lodge the cuff at the bladder neck (**Figure 145-3C**). Attach a 60 mL catheter-tipped syringe, without the plunger, to the Foley catheter. Pour contrast material into the syringe and let it drain by gravity into the bladder to overdistend the bladder. Continue to allow contrast to fill the bladder until 300 to 400 mL of contrast material is in the bladder of an adult or any child older than 11. In younger children, the instilled volume (in mL) is estimated by the formula weight (kg) × 10 in children <1 year of age, (age in years + 2) × 30 in children >1 year of age, or to the point of initiating a bladder contraction.[11] If a bladder contraction occurs, refill the bladder to the volume that initiated the contraction and clamp the Foley catheter. Volumes less than these can result in a false-negative study. After the contrast is instilled, clamp the Foley catheter with a hemostat.

Obtain two plain radiographs. These are the anteroposterior (AP) and the oblique, or the lateral, views of the pelvis. Evaluate the radiographs for proper bladder filling with contrast and for extravasation of contrast. Release the hemostat and allow the contrast to drain out of the bladder through the Foley catheter and into the container. Obtain another AP radiograph of the pelvis (washout film). This film is often helpful in picking up obscured areas of extravasation not visible on the initial film. Review the radiographs for intraperitoneal and extraperitoneal bladder rupture.

ALTERNATIVE TECHNIQUE

A novel approach to the use of plain radiography may be the use of computed tomography (CT) retrograde urethrography.[16] Although this case report will not change current clinical practice, it may be an alternative in the trauma patient requiring a CT scan of the pelvis and may reduce the time for patient evaluation.

The technique is similar to the Foley catheter technique described previously. Place the Foley catheter into the distal urethra, inflate the balloon, and inject 10 mL of contrast material. Clamp the Foley catheter. Obtain a thin-cut CT scan through the pelvis, perineum, and penis. Instruct the CT technician to run a computerized three-dimensional reconstruction of the CT scan. Evaluate the CT reconstruction for contrast extravasation, urethral occlusion, and/or urethral narrowing.

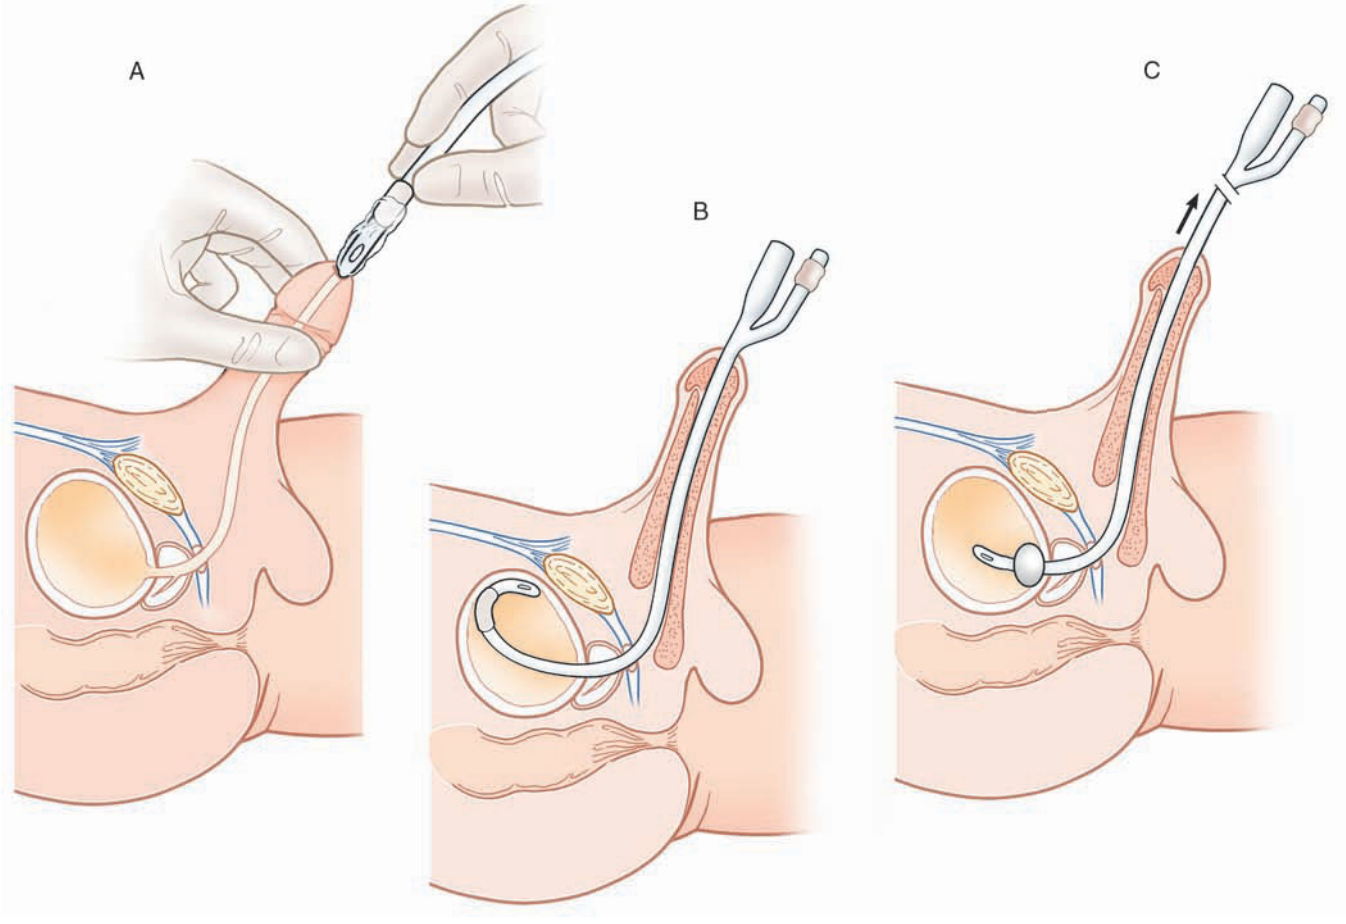

FIGURE 145-3. Retrograde cystography. **A.** The Foley catheter is inserted into the penis. **B.** The Foley catheter is advanced until it is inside the urinary bladder. **C.** The cuff is inflated. The catheter is then pulled until resistance is met to occlude the urethra with the cuff.

ASSESSMENT

In a normal retrograde urethrogram, the entire urethra should be visible. Some of the contrast material should also be seen within the bladder. Extravasation of contrast from the urethra will appear as a flame-like density outside the urethra. A partial urethral disruption will show extravasation of contrast as well as contrast within the bladder. In a complete urethral disruption, no contrast material will be visible within the bladder. Occasionally, contrast material may be seen in the venous plexus of the penis due to forceful injection of contrast into the urethra. This is a common phenomenon and should not be mistaken for extravasation. The venous flush will clear spontaneously on a postvoid film.

In the evaluation of the retrograde cystogram, intraperitoneal and extraperitoneal bladder injuries can be differentiated. The extravasation of the contrast material that appears as a flame-like projection confined to the pelvis constitutes the extraperitoneal injury. In patients with intraperitoneal injuries, the contrast tends to outline the intraperitoneal organs. This differentiation is important because each requires a different treatment. All intraperitoneal injuries are managed surgically whereas some extraperitoneal injuries can be managed with Foley catheter drainage or suprapubic cystostomy (Chapter 144).[7]

AFTERCARE

Because of the hypertonicity of the contrast material and urethral stretching, patients may experience burning and dysuria. After a normal study, ensure that the patient is well hydrated. The flow of urine will wash the contrast out of the bladder and urethra.

COMPLICATIONS

Several complications can result from retrograde urethrography and cystography. Mechanical trauma from the catheter or balloon can result in bleeding, urethral injury, bladder perforation, and the conversion of a partial urethral disruption into a complete urethral disruption. Adverse reactions to the contrast agents can occur.[17–20] These may be due to local reactions or absorption of contrast into the blood. These reactions can range from itching and skin rashes to anaphylaxis and Stevens–Johnson syndrome. Treat any adverse reactions as any other allergic or hypersensitivity reaction.

SUMMARY

The retrograde urethrogram should be performed in any male with a pelvic fracture, lower abdominal trauma with gross hematuria, inability to void, hematoma of the perineum, or a high riding or boggy prostate on physical examination. The cystogram should follow to evaluate potential bladder injuries. The cystogram is used to evaluate and differentiate intraperitoneal and extraperitoneal bladder injuries.

Retrograde urethrography and cystography are diagnostic procedures that are easy to perform and have the potential to avoid major complications related to urine leakage. Both of these procedures are safe and simple to perform. With basic equipment, invaluable information can be collected with very little time investment. The early recognition of disruption of the lower genitourinary tract can prevent significant morbidity.

146 Anesthesia of the Penis, Testicle, and Epididymis

Eric F. Reichman

INTRODUCTION

A wide range of urologic procedures are performed using local or regional anesthesia. This includes an orchiectomy, inspection of the painful testis, release of a paraphimosis, dorsal slit, circumcision, and even a hydrocelectomy or varicocelectomy done in the Operating Room. Emergency Physicians can utilize some of the same anesthetic techniques, namely the penile or spermatic cord blocks, to safely and painlessly perform many procedures in the Emergency Department. These techniques are easy to learn, simple to perform, and have a low risk of serious complications.

ANATOMY AND PATHOPHYSIOLOGY

Innervation of the penis arises from the pudendal nerve that is derived from sacral levels 2 to 4. The pudendal nerve divides into the perineal and the inferior rectal nerves. The perineal nerve further divides into the right and left dorsal nerves of the penis. The dorsal nerves of the penis pass under the pubic symphysis to penetrate the suspensory ligament of the penis.[1] They travel under Buck's fascia to supply sensory innervation to the entire penis (**Figure 146-1**).

The primary nerve supply of the testis and epididymis are from the ilioinguinal and genitofemoral nerves. The ilioinguinal nerve is derived from the first lumbar spinal nerve. It arises slightly inferior and medial to the anterior superior iliac spine and courses toward the pubic tubercle, between the internal and external oblique muscles.[1,2] It enters the inguinal canal on the anterior surface of the spermatic cord. The ilioinguinal nerve provides sensory innervation to the skin of the upper thigh, base of the penis, and the upper scrotum.[3] It also provides sensory innervation to the spermatic cord and testicle. The genitofemoral nerve is derived from the first two lumbar spinal nerves. It divides into the genital branch and the femoral branch. The genital branch enters the inguinal canal at the external inguinal ring and travels with the spermatic cord. It provides sensory innervation to the lower scrotum, cremaster muscle, spermatic cord, and scrotum. The femoral branch supplies the skin of the anteromedial thigh.[3]

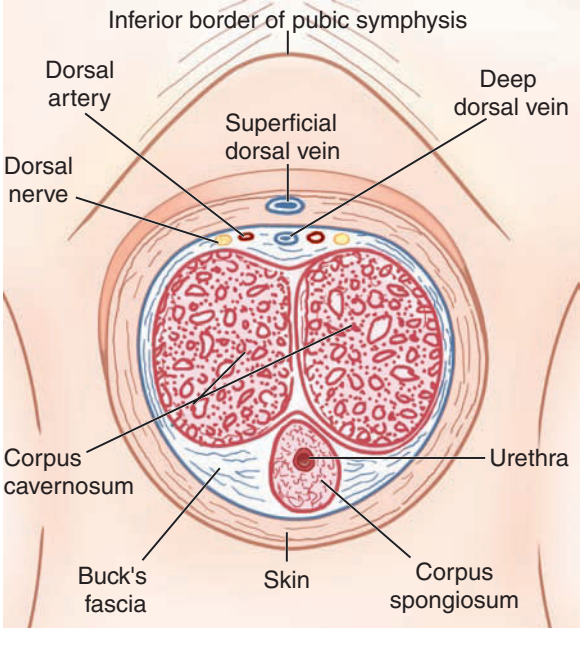

FIGURE 146-1. Transverse section through the base of the penis.

INDICATIONS

Emergency Department procedures that are facilitated by local anesthesia of the penis include a dorsal slit of the foreskin, release of a phimosis or paraphimosis, repair of penile lacerations, and the release of penile skin entrapped in zippers. Local anesthesia can also be used before performing a circumcision. However, this procedure is usually not performed in the Emergency Department.

The Emergency Department indications for a spermatic cord block include the relief of epididymal pain, the facilitation of a manual or ultrasound examination when differentiating between torsion and epididymitis, and to inspect the testis following trauma. Manual detorsion of a testis may be enabled by local anesthesia when a patient cannot tolerate the pain of palpation. **This should be performed only if the patient will be taken immediately to the operating room for confirmation of detorsion and an orchiopexy.** However, the risk of compromising the blood supply to the testis and the loss of patient assessment of pain in determining the success of detorsion are often cited as contraindications to spermatic cord blockade when testicular torsion is suspected.

CONTRAINDICATIONS

Local anesthesia is contraindicated in testicular torsion, as there is a risk of compromising the testicular blood supply. The anesthetic effect will also eliminate the patient's assessment of pain that is needed to determine the success of manual detorsion. Agents containing epinephrine are not to be used in or around the penis.[4] The arteries of the penis are end arteries and vasoconstriction can result in tissue ischemia and sloughing. To minimize the spread of infection, local anesthetic should not be directly injected into an area of local infection.

EQUIPMENT

- 25 and 27 gauge needles
- Syringes (3, 5, and 10 mL)
- Povidone iodine or chlorhexidine solution
- Alcohol pads
- 4 × 4 gauze squares
- Local anesthetic solution without epinephrine

Several local anesthetic agents are commonly used for genitourinary anesthesia. These include lidocaine, bupivacaine, mepivacaine, and chloroprocaine (**Table 146-1**). **The anesthetic agent, concentration, and technique must be chosen so that the maximum safe dose is not exceeded. This is especially important when performing anesthesia in children.**

TABLE 146-1 Local Anesthetic Agents Commonly used for Genitourinary Anesthesia

Anesthetic agent	Strength (%)	Onset of action (min)	Duration of action (min)	Maximum dose (mg/kg)
Lidocaine	0.5, 1.0, 1.5, 2.0	5–15	45–90	4.5
Bupivacaine	0.25, 0.50	10–15	120–240	2.5
Mepivacaine	1.0, 1.5	10–15	120–240	4.0
Chloroprocaine	2.0, 3.0	10–15	20–40	11.0

PATIENT PREPARATION

The patient must be informed of the procedure, including its risks and benefits. The explanation must include the risks of local anesthetic injection and the possibility that the anesthetic may not effectively eliminate pain. The risks associated with the injection include pain, hematoma formation, and bleeding. Infection is a late risk that can be reduced by prepping the skin and using sterile technique. Obtain an informed consent for the anesthetic procedure in addition to the consent for the procedure that will be performed under anesthesia.

The patient's ability to cooperate with the planned procedures must be assessed. Consider oral or parenteral sedation, especially in anxious patients or children. Midazolam (0.02 to 0.04 mg/kg IV) or diazepam (2.5 to 5 mg IV) are often good choices in adults. Children may benefit from midazolam parenterally (0.05 to 0.15 mg/kg IV) or orally (0.5 to 0.7 mg/kg). Ketamine (1.0 to 1.5 mg/ kg IV or 2 to 5 mg/kg IM) combined with atropine (0.01 mg/kg) to reduce respiratory secretions is an alternative, especially in children younger than 10.

Clean any dirt and debris from the skin. Identify the anatomic landmarks required to perform the anesthetic injection. Apply povidone iodine or chlorhexidine solution to the area where the anesthetic is to be injected. The povidone iodine or chlorhexidine may also be applied to the penis and scrotum if an invasive procedure is subsequently to be performed. Apply sterile drapes to delineate a surgical field. Allow the povidone iodine or chlorhexidine to dry. Put on sterile gloves and reidentify the anatomic landmarks. Infiltrate with local anesthetic solution using sterile technique.

TECHNIQUES

LOCAL INFILTRATION

Local anesthetic infiltration of the skin of the penis is useful for the repair of superficial lacerations, dorsal slits of the foreskin, or freeing entrapped skin from a zipper. Local infiltration circumferentially around the penis will provide adequate anesthesia distal to the anesthetic injection site. The circumferential subcutaneous injections can be performed directly on the penis or on the abdominal wall and scrotum surrounding the penis. While not contraindicated, some authors avoid direct infiltration of the foreskin as tissue sloughing may result.[2] **Local infiltration of anesthetic agents is often extremely painful for the patient. Consider premedicating the patient with parenteral benzodiazepines and/or narcotic agents**.

Local anesthetic agents can be injected subcutaneously into the penis to provide distal anesthesia. If performing a dorsal slit of the foreskin, raise a skin wheal of local anesthetic solution at the base of the foreskin in the 12 o'clock position (**Figure 146-2A**). Insert the needle through the skin wheal aimed distally. Inject local anesthetic solution subcutaneously as the needle is advanced to the distal edge of the foreskin. Alternatively, local anesthetic solution can be circumferentially infiltrated around the penis (**Figure 146-2B**). This block usually requires 6 to 10 mL of local anesthetic solution in the adolescent or adult and 2 to 3 mL in a child.

PENILE BLOCK

The objective of a penile block is to anesthetize the right and left dorsal nerves of the penis that provide sensation to the penis (**Figure 146-1**). **The dorsal nerves should be blocked as close to the base of the penis as possible. If the block is performed too distal to the pubic bone, the posterior branches of the dorsal nerves will not be anesthetized and the ventral surface of the penis will retain sensation.**[5,6] Multiple effective techniques will be described to perform a penile block. The technique chosen should depend on the specific procedure to be performed, the level of patient cooperation, and the preference of the Emergency Physician.

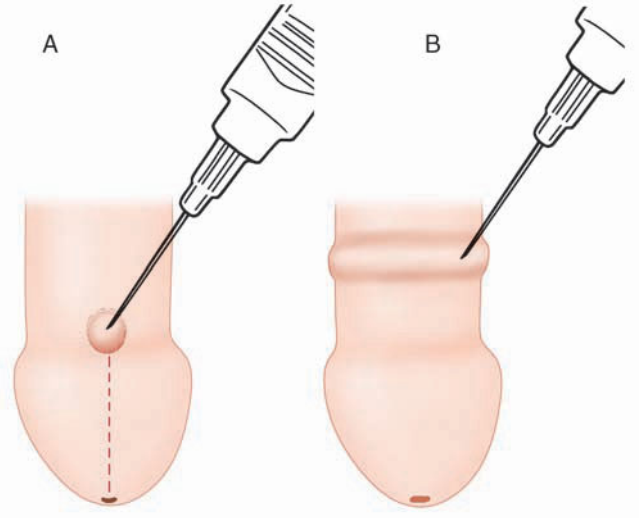

FIGURE 146-2. Local anesthetic infiltration into the penis. **A.** A skin wheal is raised and local anesthetic is injected distally (*dotted line*). **B.** Circumferential infiltration of local anesthetic solution.

The penis may be anesthetized where it forms along the abdominal wall.[2] This block anesthetizes the nerves to the penis before they reach the penis. Form three skin wheals using local anesthetic solution on the abdominal and scrotal skin, 0.5 to 1.0 cm from the base of the penis, at the 2 o'clock, 6 o'clock, and 10 o'clock positions (**Figure 146-3**). Infiltrate subcutaneously with local anesthetic solution between the skin wheals to form a triangle of local anesthetic that surrounds the base of the penis. This block usually requires 8 to 12 mL of local anesthetic solution in the adolescent or adult and 3 to 5 mL in a child.

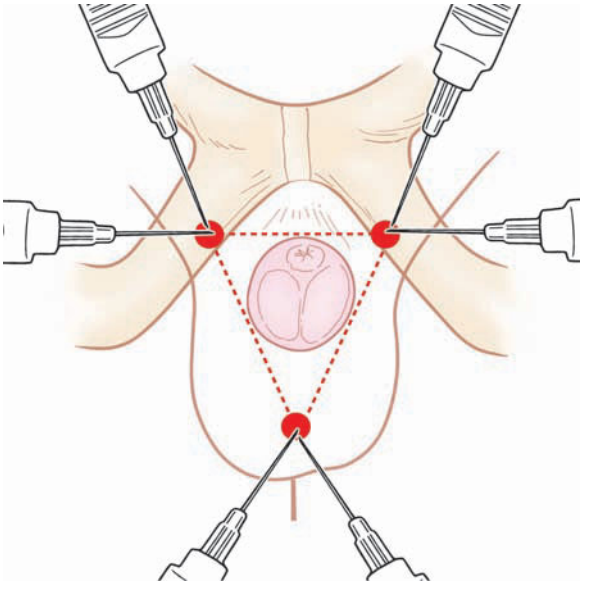

FIGURE 146-3. Local anesthetic infiltration around the base of the penis. Black dots represent the locations of the skin wheals.

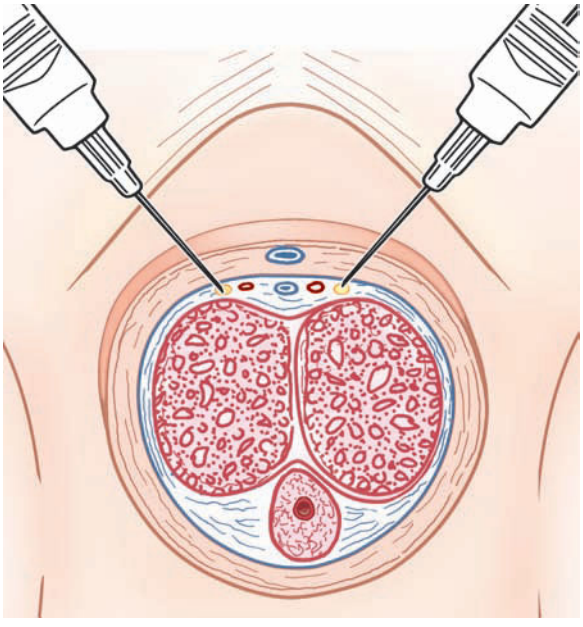

FIGURE 146-4. The penile block anesthetizes the left and right deep dorsal nerves of the penis.

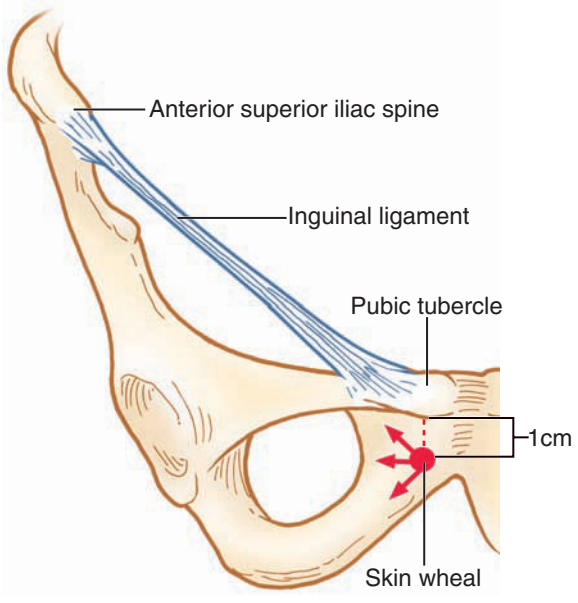

FIGURE 146-5. The spermatic cord can be anesthetized just below the pubic tubercle, if the tubercle is palpable. The arrows represent the three different directions required to inject local anesthetic solution.

The dorsal nerves of the penis can be anesthetized as they course onto the penis. Place a skin wheal of local anesthetic solution at the 1 o'clock and 11 o'clock positions. Slowly insert a 27 gauge needle through the skin wheals until there is a slight loss of resistance indicating penetration of Buck's fascia (**Figure 146-4**). Aspirate to ensure that the needle is not within a blood vessel. Inject 1 mL of local anesthetic solution at each site in the adolescent or adult and 0.3 to 0.5 mL in a child.[1]

Another technique blocks the dorsal nerves as they pass through the triangular space bordered by the pubic symphysis, the corpora cavernosa, and Buck's fascia. Place a skin wheal of local anesthetic solution at the dorsal base of the penis. Insert the needle through the skin wheal and to the pubic symphysis. Withdraw the needle slightly and advance it caudally until a loss of resistance is felt, indicating that it has penetrated Buck's fascia. Aspirate to ensure that the needle is not within a blood vessel. Inject 10 mL of local anesthetic solution on each side of the suspensory ligament (midline) in the adolescent or adult and 2 to 3 mL in a child. Alternatively, the same block can be accomplished with a separate injection on each side of the midline.[1,7]

SPERMATIC CORD BLOCK

As the spermatic cord exits the external inguinal ring, it passes over the pubic tubercle and continues medially toward the scrotum. In this same location, the ilioinguinal nerve travels on the anterior surface of the spermatic cord and the genital branch of the genitofemoral nerve on the posterior surface. These two nerves supply sensation to the spermatic cord, epididymis, and testicle. Anesthesia of the spermatic cord in the region of the pubic tubercle will provide anesthesia to the testis and its covering, the epididymis, and the vas deferens.[6] **The spermatic cord block does not provide anesthesia to the skin of the scrotum.** Additional subcutaneous infiltration is necessary for an incision of the scrotal skin.

This first spermatic cord block technique is useful in thin patients with a palpable pubic tubercle. Identify the pubic tubercle by palpation. Inject local anesthetic solution to make a skin wheal just medial and 1 cm below the pubic tubercle (**Figure 146-5**). Gently advance a 25 gauge needle laterally through the skin wheal and spermatic cord until bone is contacted. Aspirate to ensure that the needle is not within a blood vessel. Inject 3 to 4 mL of local anesthetic solution as the needle is slowly withdrawn in the adolescent or adult and 1 to 2 mL in a child. Repeat the procedure two more times using the same skin puncture site, each time passing through the cord at a slightly different angle. This block requires a total of 10 to 12 mL of local anesthetic solution in the adolescent or adult and 3 to 5 mL in a child.[6]

A modified technique is used for the patient in whom the pubic tubercle is difficult to palpate. Grasp the spermatic cord between the nondominant thumb and index finger as it enters the scrotum (**Figure 146-6**). Place a wheal of local anesthetic solution between the fingers and above the spermatic cord. Insert a 25 gauge needle through the skin wheal. Direct the needle anterior to the spermatic cord. Aspirate to ensure that the needle is not within a blood vessel. Inject 3 to 4 mL of local anesthetic solution in the adolescent or adult and 1 to 2 mL in a child. Repeat the process on the medial and lateral side of the spermatic cord.

Alternatively, palpate the spermatic cord as it enters the scrotum.[8] Trace the spermatic cord superiorly to the pubic tubercle where it exits the external inguinal ring. Trap the spermatic cord between the second and third fingers of the nondominant hand and the pubic tubercle. Place a wheal of local anesthetic solution between the fingers and above the spermatic cord. Insert a 25 gauge needle through the skin wheal. Aspirate to ensure that the needle is not within a blood vessel. Inject local anesthetic solution anteriorly, medially, and laterally to the spermatic cord as described above. Injection of local anesthetic solution around the spermatic cord as it exits the inguinal canal may be less painful than injection as it enters the scrotum.

ASSESSMENT

Allow 10 to 15 minutes for the local anesthetic solution to take effect for a penile block. Test the level of anesthesia by pinching the skin with a forceps or by pin-prick with a needle. The patient

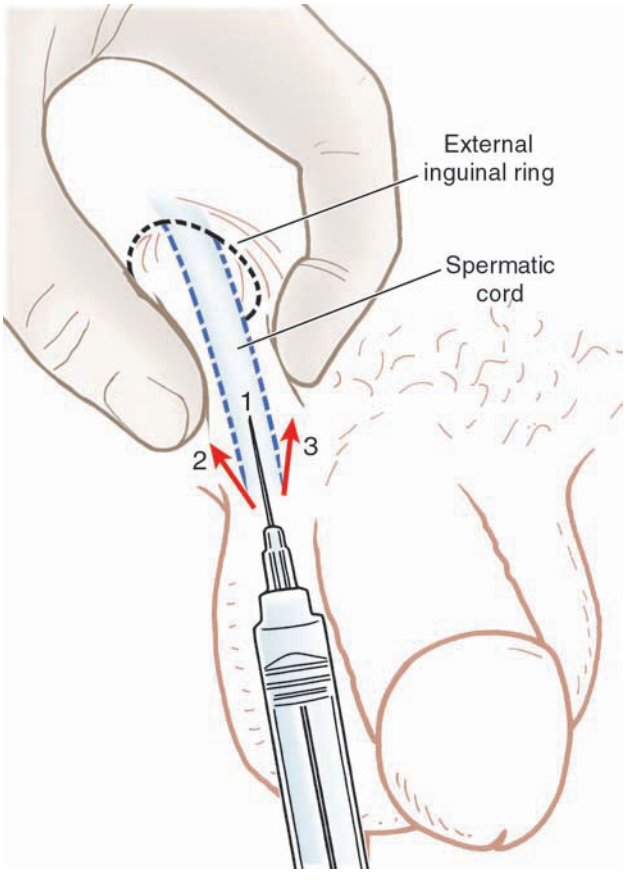

FIGURE 146-6. The spermatic cord block at the base of the scrotum. Local anesthetic solution is injected anteriorly (1), laterally (2), and medially (3) to the spermatic cord.

may feel a pressure sensation, but should not feel pain. If the test stimulus is painful, repeat the block or use additional anesthetic techniques prior to performing the procedure.

Spermatic cord blocks require 10 to 15 minutes for maximal effectiveness. The patient should be warned that, despite an effective block, traction on the spermatic cord might cause nausea and a tugging sensation. These will resolve upon release of the traction.[6] Additional anesthesia must be applied to the scrotal skin for any incisions or procedures as a spermatic cord block does not anesthetize the scrotal skin.

AFTERCARE

Minimal aftercare is required for these local anesthetic techniques. Depending on the agent used, sensation may return in as little as 1 to 2 hours with lidocaine and chloroprocaine or up to 4 hours with bupivacaine. The skin may reawaken with a pins-and-needles sensation. Patients should use caution when zipping their pants so as not to catch the penis, foreskin, or scrotum as they will not feel the injury. Patients should be warned that the site of a spermatic cord block might remain tender for as long as 10 days.[6] The application of cool compresses to the injection site and oral nonsteroidal anti-inflammatory drugs will provide adequate analgesia for injection site pain. Patients should inspect the injection site and surrounding area three to four times a day for any signs of infection. They should return to the Emergency Department immediately if any problems or concerns arise.

COMPLICATIONS

The most procedure-specific complication of a penile block is sloughing of the penile skin. This is more common in the region of the glans. Performing the penile block at the base of the penis and using solutions without epinephrine minimizes this risk.

Hematomas can be quite large in spermatic cord blocks because the venous plexus is usually pierced. The use of a smaller needle and careful application of pressure can help prevent hematomas. Blood loss from puncturing a vascular structure is easily controlled with direct pressure. A Urologist should be consulted urgently in the rare occasion that bleeding does not resolve with pressure. Most hematomas will resolve within 1 to 2 weeks. The application of warm compresses to the hematoma several times a day may result in quicker resorption.

Local infection at the injection site is possible. Patients should be warned about the signs of infection including fever, erythema, warmth, induration, increased pain, and purulent drainage. Patients should seek immediate medical attention for any of these symptoms.

Toxic levels of anesthetic agents can affect multiple organ systems, most notably the central nervous and cardiovascular systems. Anesthetic agents block the inhibitory neurons of the brain producing a state of neuroexcitation. Initial symptoms may include tinnitus, premolar numbness, disorientation, lightheadedness, or nystagmus. This may progress to seizures that can be accompanied by slow or absent breathing, acidosis, aspiration, and cardiovascular instability. Intravenous diazepam (2.5 to 5 mg) at the first sign of symptoms may stop the cascade.[2] Significantly higher doses of diazepam are required to treat seizures. Very high levels of local anesthetics are cardiotoxic and may result in heart block. Heart block from bupivacaine toxicity is associated with resistance to resuscitative maneuvers. The onset of all local anesthetic toxicities is faster with intravascular injection versus toxic tissue concentrations.

SUMMARY

Local anesthesia allows many painful genitourinary procedures to be performed in the Emergency Department. The techniques are simple and easy to perform with little to no experience. Local anesthetic solutions containing epinephrine should never be used to anesthetize the penis, scrotum, or spermatic cord.

147 Priapism Management

Steven Go

INTRODUCTION

Priapism was first described in the English literature in an 1824 case report by Callaway.[1,2] It is defined as a prolonged engorgement or erection of the penis or clitoris that lasts greater than 4 hours and occurs beyond or apart from sexual stimulation or arousal.[3,4] The term "priapism" derives its origin from the name of a minor Greek god of fertility and luck named Priapus.[5] He was said to have been cursed by Hera by having out of proportion genitals, ugliness, salaciousness, and ironically, impotence. A famous Pompeiian fresco graphically illustrates Priapus' plight as he weighs his massive phallus with a hanging scale.[5] Male priapism is far more common than the extremely rare female form. This chapter will focus on the male priapism.

TABLE 147-1 The Etiologies of Ischemic Priapism[9–17]

Etiology	Incidence	Specific conditions or substances
Drug induced	Uncommon	Androgens Anticoagulants Antihypertensives Antipsychotics Erectile dysfunction agents Ethanol Sympathomimetics
Hematologic disorders	Common	Anemia Leukemia Multiple myeloma Polycythemia Sickle cell disease
Iatrogenic	Common	Intracavernous erectile dysfunction drug therapy Surgery
Idiopathic	Common	
Malignancies	Rare	Metastatic cancer to penis Primary penile cancer Prostate cancer
Miscellaneous	Rare	Amyloidosis Fabry's disease G6PD deficiency Gout Hemodialysis Total parenteral nutrition
Neurologic	Rare	Spinal cord lesions or stenosis
Traumatic	Uncommon	Usually causes high-flow priapism

TABLE 147-2 The Etiologies of Nonischemic Priapism[19,20]

Drug-induced: cocaine, androgens
Idiopathic
Metastatic malignancies
Miscellaneous causes: Fabry's disease, neurological conditions
Traumatic:
Iatrogenic (e.g., postsurgical)
Incidental

Priapism affects an estimated 1.5 cases per 100,000 person-years in the general population and 29% to 42% of sickle cell patients during their lifetimes.[6–8] The most common form of priapism is often an excruciatingly painful and prolonged erection. This is frequently embarrassing to the patient and results in delays in seeking medical attention. Without swift and expert intervention, priapism can sometimes lead to permanent scarring and impotence.

Priapism is generally classified into two major subtypes, ischemic and nonischemic, although other less common subtypes exist.[3] It is critical that the Emergency Physician determines which subtype the patient is presenting with because emergent management and prognosis differs considerably between them.

The most common priapism subtype is ischemic priapism. This condition is also known as low flow or vaso-occlusive priapism. This subtype of priapism poses the greatest risk of permanent penile dysfunction. It is generally thought to result primarily from an impediment to blood emptying from the penis and has a large number of associated etiologies (**Table 147-1**). These patients present with a very painful, rigid penis, with engorgement of both corpora cavernosa. The corpus spongiosum and the glans are usually spared, although those structures also may be involved in rare instances[18] If left untreated, this condition forms a type of compartment syndrome which results in fibrosis and scarring, loss of function, and in extreme cases tissue necrosis. Even with treatment, the outcomes are often poor. Reported rates of complete erectile dysfunction after ischemic priapism range from 30% to 90%.[3,7]

Stuttering or intermittent priapism is a variant of ischemic priapism in which the patient suffers intermittent priapism episodes over time. This particular variant is difficult to definitively treat in the long term as the episodes tend to reoccur. This condition sometimes resolves prior to the patient's arrival at the Emergency Department and can fool the Emergency Physician into making a misdiagnosis of malingering.

The second subtype of priapism is known as nonischemic, high flow, or arterial priapism. This subtype is far less common than the ischemic subtype. It is thought to result from penile arterial blood flow being unregulated, often secondary to genital trauma. The number of etiologies is far fewer than in ischemic priapism (**Table 147-2**). Because arterial blood is freely flowing through the penis, the outcomes of nonischemic priapism tend to be more favorable than those of ischemic priapism, although subsequent erectile dysfunction can occur.[21] The Emergency Department management of this subtype is generally supportive and requires no procedural intervention in most cases.

ANATOMY AND PATHOPHYSIOLOGY

RELEVANT ANATOMY

The penis is primarily composed of the dual dorsal corpora cavernosa and a single ventral corpus spongiosum (**Figure 147-1**). The corpora cavernosa surround the cavernous and helicine arteries and are the structures engorged during most cases of priapism. The corpus spongiosum surrounds the urethra and forms the glans of the penis distally. The cavernosa and spongiosum are encased by Buck's fascia, a fibrous sheath that constricts to limit venous outflow during an erection. A superficial and deep neurovascular bundle is located on the dorsal surface of the penis.

The corpora of the penis consist of spongy sinusoidal networks of smooth muscle, collagen, nerves, vascular structures, and endothelial tissue.[22] The primary arterial supply to the penis arises from the internal pudendal artery, which gives rise to the cavernous artery, which supplies the lacunar spaces in the cavernosa. Another two other branches of the internal pudendal artery, the bulbourethral and dorsal arteries mainly supply blood to the corpus spongiosum, glans, and related structures. The dilation of the cavernous artery and its branches is primarily responsible for engorging the penis during an erection. During an erection, the sinusoidal spaces in the corpora fill with blood and the corpora expand. The corpora are covered by a strong fibrotic outer layer, the tunica albuginea, that produces a rigid penis when engorged. An important functional anatomic feature is that blood flows freely between both corpora cavernosa due to the incomplete septum between them.

Venous outflow regulation plays an equally important role in maintaining an erection. The venous drainage is complex, with paired branches running with the arteries. An additional major drainage system enters into the deep dorsal vein via multiple emissary veins and circumflex veins. The extensive subtunical plexus of veins feeds into the emissary veins that perforate the tunica albuginea and drain into the circumflex veins. During an erection, the increasing distention of the corpora with arterial blood causes the compression of the subtunical venous plexus and obstructs drainage

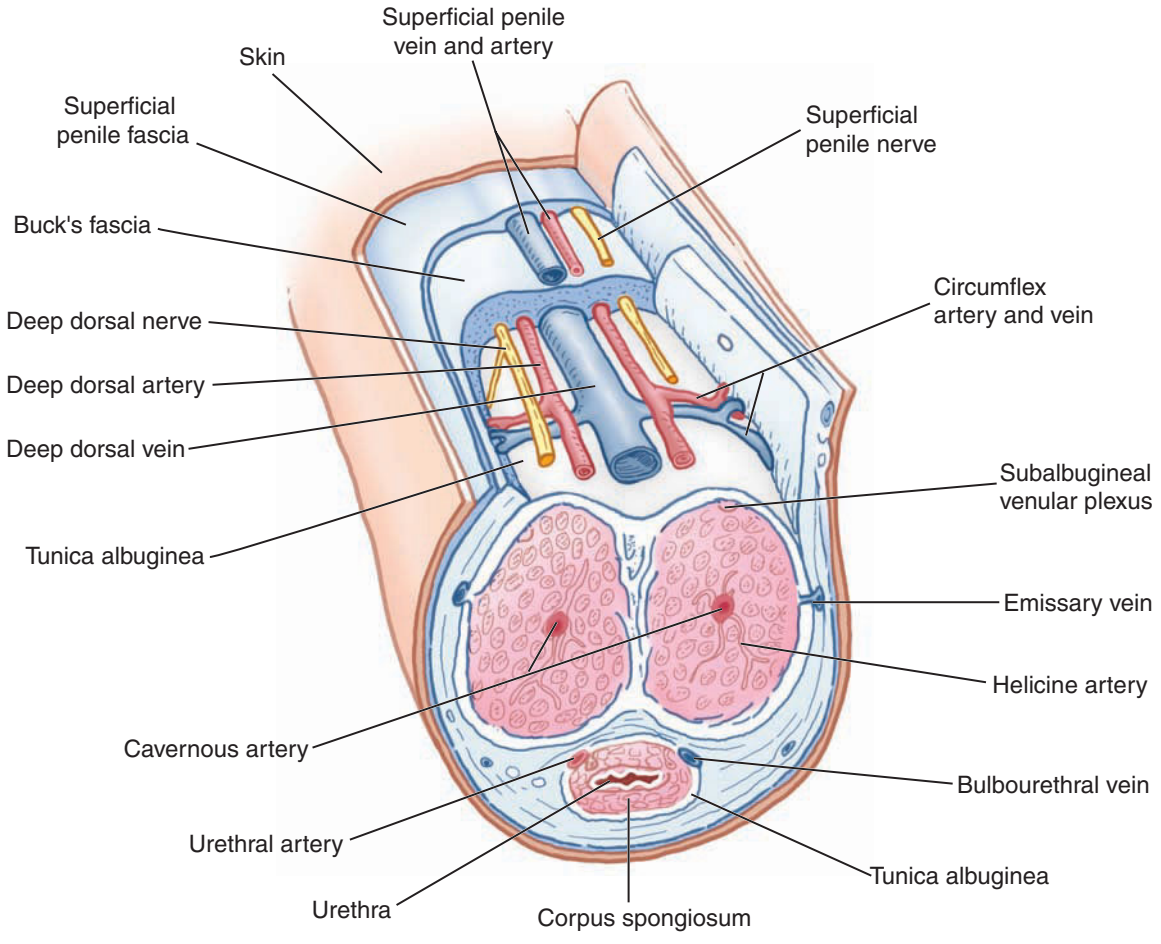

FIGURE 147-1. Cross section of the penis demonstrating the anatomy.

through the emissary veins with both in-flow and out-flow decreasing. There is no obstruction to the glans and corpus spongiosum drainage and this system does not typically develop the higher pressure of the corpora cavernosa.

NORMAL ERECTION PHYSIOLOGY

The relative simplicity of the function anatomy belies the complexity of the physiology underlying tumescence.[22–24] In the last decade, much research has emerged to shed light on the mechanisms of both a normal erection and priapism. An erection begins when the parasympathetic nervous system releases acetylcholine and nitric oxide. This begins a multifaceted cascade of neurotransmitter events that culminates in the efflux of calcium from smooth muscle cells and results in the relaxation of the smooth muscle in the corpora and the arterial walls of the penis.[24] Detumescence occurs when the sympathetic nervous system releases norepinephrine. This eventually results in the constriction of smooth muscle which reduces arterial inflow, reduces corpora volume, and promotes venous outflow. In addition, α_1-adrenergic receptors play an important role in keeping the smooth muscle relaxed by promoting the accumulation of calcium ions within the cells.[22]

ISCHEMIC PRIAPISM PATHOPHYSIOLOGY

The pathophysiology of ischemic priapism can be separated into peripheral pharmaceutical-induced ischemic priapism and nonpharmaceutical-induced ischemic priapism.[24] The three major underlying processes that characterize both mechanisms are hypoxia, glucopenia, and acidosis.[23]

Pharmaceutical-induced ischemic priapism is secondary to the offending pharmaceutical altering the physiological balance of the penile smooth muscle toward relaxation.[24] This prolongs the erection, which over time, causes the oxygen partial-pressure in the trapped blood to decrease resulting in local hypoxia. The hypoxia induces arterial relaxation and venous contraction by an endothelin-1 mediated mechanism. Hypoxia also decreases α_1-adrenergic receptor ability to induce smooth muscle contraction. This helps explain why α-agonists become less efficacious in prolonged priapism. Anaerobic metabolism ensues, causing local glucopenia. Metabolic byproducts build up in the penis causing acidosis. These processes work together to cause the tissue edema, fibrosis, and eventually erectile dysfunction with prolonged priapism.

Nonpharmaceutical-induced ischemic priapism occurs secondary to a derangement in vascular homeostasis, such as blood dyscrasias (e.g., sickle cell disease, leukemia), by a mechanism that has not yet been fully delineated.[24] It is thought that a deficiency in endothelial nitric oxide in the penis decreases the activity of a RhoA/Rho-kinase mediated vasoconstrictive pathway.[24] This malfunction causes the smooth muscle contraction system to respond in an exaggerated manner and prolong the erection. This results in the hypoxia, glucopenia, and acidosis. The presence of these three processes worsens the conditions that led to the priapism in the first place. For example, the resultant penile hypoxia tends to worsen the sickling of erythrocytes which worsens the

compromised vascular outflow, which worsens the hypoxia. Thus, a vicious cycle occurs that exacerbates the overall disease process.

NONISCHEMIC PRIAPISM PATHOPHYSIOLOGY

In contrast, nonischemic priapism generally results from a trauma-induced arteriovenous communication between the cavernous artery and the sinusoidal spaces, bypassing the high resistance helicine arteries. This results in unrestrained arterial flow. Because there is no increased venous constriction in this form of priapism, the penis is not at risk for ischemia. The penis is generally without pain or tenderness and is softer than in low-flow priapism.

DETERMINING THE PRIAPISM SUBTYPE

The initial evaluation by the Emergency Physician must be quick, aggressive, and accurate. There are several differences in the presentation of ischemic and nonischemic priapism that differentiate these subtypes (**Table 147-3**). The clinical features that characterize ischemic priapism are generally detected with a careful history and physical examination. **However, it is recommended that clinical impression be confirmed on every priapism patient by either sampling the penile blood for arterial blood gas analysis or by a color Doppler ultrasound.** Penile blood can be readily sampled at the same time therapy is initiated. The sampling is somewhat invasive and can be painful. Color Doppler ultrasound is less invasive but can delay definitive therapy if it is not readily available. Ultimately, the choice of a confirmatory test must be driven by the clinical situation and setting.

Some authors have recommended beginning treatment of ischemic priapism medically with agents such as terbutaline and pseudoephedrine.[27–30] The data to support such strategies are not very copious and are sometimes contradictory.[30,31] The most current American Urological Association priapism guideline recommends that cases of ischemic priapism require emergent aspiration and irrigation of the corpora cavernosa and this should not be delayed by ancillary treatments.[3]

This general recommendation is true even in the modern management of sickle cell patients with ischemic priapism. Traditionally, sickle cell-related priapism was treated only with conservative treatment. This included aggressive hydration, alkalization, analgesics, blood transfusion, and occasionally exchange transfusion. These systemic treatments have resulted in 35% of these patients developing subsequent erectile dysfunction.[3,8] These ancillary treatments should only be given in sickle cell patients while quickly and simultaneously gathering the materials for the intracavernous treatment described in the techniques section of this chapter.

TABLE 147-3 Features that Distinguish Ischemic Versus Nonischemic Priapism[3,7,23]

	Ischemic priapism	Nonischemic priapism
Clinical features	Usually atraumatic	Often traumatic
	Very painful	Minimal pain if any
	Rigid penis	Less tense penis
Penile blood characteristics	Dark appearance	Bright red appearance
	Thick consistency	Thin consistency
	pH < 7.25	pH > 7.25
	paO_2 < 30 mmHg	paO_2 > 30 mmHg
	$paCO_2$ > 60 mmHg	$paCO_2$ < 60 mmHg
Color Doppler flow pattern	Low arterial flow	High arterial flow

Some authors have recommended various additional diagnostic tests in patients who present with first time priapism.[3,7,32] This includes such as a CBC with manual differential to diagnose blood dyscrasias, urinalysis as an infection screen, and various drug screens if indicated. These studies should not delay seeking definitive diagnosis and treatment of ischemic priapism.

INDICATIONS

The key diagnostic decision to be made in a patient presenting with priapism is to determine whether the priapism is ischemic or nonischemic.[3] This salient point cannot be overemphasized. Ischemic priapism is the only subtype where emergent interventional treatment is indicated.[25,26]

CONTRAINDICATIONS

If a patient has trauma-induced priapism and has concurrent serious life-threatening injuries, the patient must be stabilized prior to dealing with the priapism. The medical risks making priapism therapy inappropriate will occasionally occur and have to be weighed against the fact that the natural course of priapism does not cause mortality. Patients with significant hypertension, unstable angina, dysrhythmias, and other high-risk cardiac conditions should not receive α-adrenergic agonists. They are also contraindicated if the patient is taking β-blockers or monoamine oxidase inhibitors.

EQUIPMENT

- 19 gauge butterfly or straight needles
- 21 gauge butterfly or straight needles
- Arterial blood gas syringe
- Syringes (1, 3, 10, and 20 cc)
- Povidone iodine or chlorhexidine solution
- 4 × 4 gauze squares
- Sterile drapes
- Sterile basin
- Three-way stopcock (optional)
- Phenylephrine, 10 mg/mL in 1 mL vials
- 1% lidocaine without epinephrine
- Sterile normal saline, 1 L bottle
- Sterile normal saline, 10 mL vial
- Blood pressure monitoring equipment
- Cardiac monitoring equipment

PATIENT PREPARATION

Informed consent is extremely crucial in the treatment of ischemic priapism. Even with appropriate treatment, the outcomes can be poor. There are recommendations in the literature that the procedures described below should only be performed by a Urologist.[33] There is no literature to support this recommendation. To help mitigate these legal risks, discuss the procedural risks and benefits, any alternatives, and being treated by an Emergency Physician versus a Urologist in the Emergency Department or being transferred to a facility with a Urologist if one is not immediately available. Allow time for questions so that the patient can make an informed and voluntary decision. An emergency consult by a Urologist should be obtained immediately when the presence of ischemic priapism is determined. Delays in the Urologists arrival should not delay the procedure if the Emergency Physician

is comfortable performing the procedure. The informed consent process including the patient's capacity to consent, the potential risks and benefits, alternatives discussed, and the medical decision making should be thoroughly documented in the patient's chart and a signed consent obtained.

Prepare the patient. Intravenous access should be obtained for pain control. The patient should have vital signs and cardiac rhythm monitoring before, during, and after the procedure as adverse events have been reported. This is especially true in patients with a history of hypertension, coronary artery disease, or cardiac dysfunction. These procedures can be extremely painful. Perform a penile nerve block if there are no contraindications (Chapter 146). Alternatively, consider the use of parenteral analgesics, sedatives, and/or procedural sedation (Chapter 129). After adequate analgesia has been achieved, gently clean the penis, scrotum, and surrounding area of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the shaft of the penis and scrotum and allow it to dry. Apply sterile drapes to delineate a sterile field.

TECHNIQUES

PENILE ASPIRATION AND IRRIGATION

Insert a 19 gauge butterfly needle into the lateral mid-shaft of the penis at the 3 o'clock or 9 o'clock position (**Figure 147-2**). This will be used for draining or aspirating the penis. The tubing can be capped with a syringe or three-way stopcock. The 19 gauge needle usually provides free drainage with no aspirating being necessary. **The needle should always be inserted straight in and directed toward the center of the corpora.** If a difficult procedure is anticipated (priapism duration > 24 hours), a 21 gauge butterfly needle can also be inserted in the base of the penis and left in place for either injection or irrigation. **The fewer the injections, the less the chance for a hematoma formation.** Send a sample of the initial aspirated blood for blood gas analysis. This may be accomplished by attaching an arterial blood gas syringe to the tubing of the butterfly needle.

Place the catheter end of the butterfly into a sterile basin and allow the blood to drain from the penis. If blood does not spontaneously drain, attach a 10 or 20 mL syringe to the catheter end and aspirate blood from the penis. Cap the butterfly catheter after draining enough blood to significantly soften the penis. Since the cavernosa communicate across the incomplete septum, both cavernosa will decompress through the single drainage needle. It has been reported that aspiration alone is effective in inducing detumescence in approximately 30% of cases.[3]

If there is difficulty with the drainage, a 21 gauge butterfly needle should be inserted in the proximal shaft area. Begin gentle irrigation with normal saline through the 21 gauge needle with outflow through the 19 gauge needle. This will help to irrigate out the old blood. **Only normal saline should be used because the endothelium can be damaged if the solution is not isotonic**. Massaging the penis to "milk out" sludge can be helpful. Placement of additional 19 gauge butterfly needles may be used to improve drainage in difficult cases.

INTRACAVERNOUS SYMPATHOMIMETIC INJECTION

Intracavernous injection is recommended if aspiration and irrigation fail to resolve the priapism. Phenylephrine is the agent most commonly recommended.[3] Although other agents for this purpose do appear in the literature, such as epinephrine, no adequate controlled data yet exist comparing one agent to another.[29] Untoward side effects with some agents, such as epinephrine, have been reported.[34]

Prepare the phenylephrine. It is purchased in sterile 1 mL glass vials with a concentration of 10 mg/mL. Place 10 mg (1 mL) of phenylephrine into a syringe containing 9 mL of sterile normal saline. This provides a solution of 1 mg/mL that allows easy calculation of the doses. Other dilutions can be used, as this is physician-dependent, and the concentration should be clearly marked on the syringe.

Inject 0.25 to 0.5 mL (250 to 500 μg) of the phenylephrine solution with an insulin syringe through the butterfly catheter and into the penis. Observe the penis for up to 10 minutes. Repeat the procedure if the erection returns or does not resolve. There is no definite limit to the amount of phenylephrine used. Most

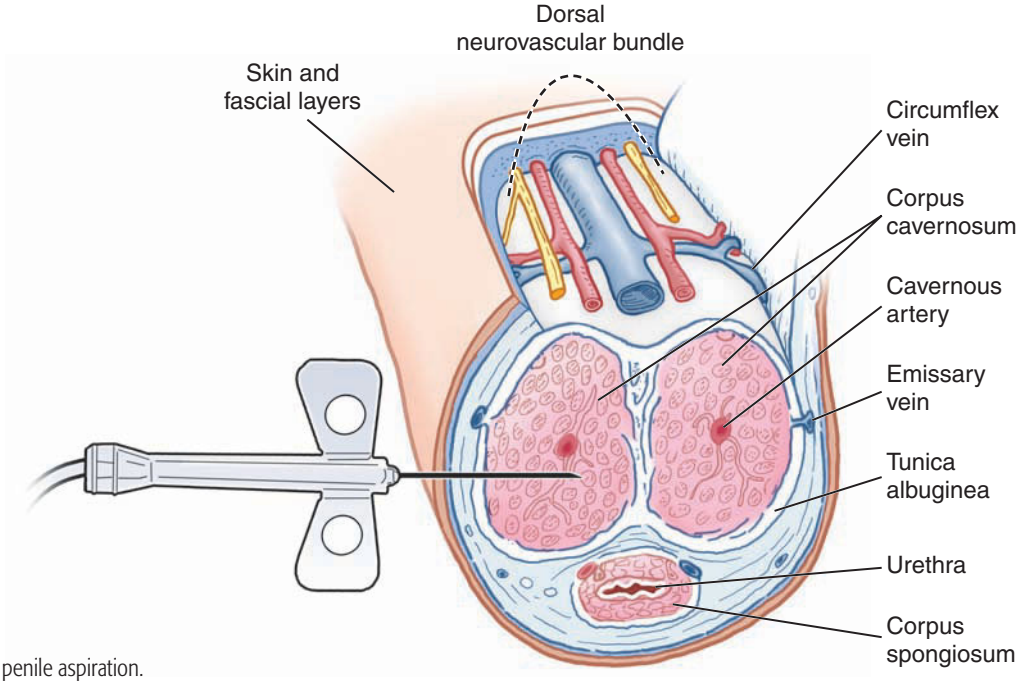

FIGURE 147-2. The technique of penile aspiration.

physicians inject up to 1 mg of phenylephrine, but up to 2.5 mg has been suggested.[2] Current recommendations suggest not concluding intracavernous injections have failed until the patient has been treated for 1 hour as long as no untoward cardiovascular effects have occurred.[3]

Compression of a puncture site must be done every time a needle is withdrawn from the penis to avoid a hematoma. The penis should resume a soft state. Partial detumescence might occur in some patients. If in doubt and pressure equipment is available, a cavernous pressure below 40 mmHg is considered acceptable. If this has been unsuccessful, venous shunting has to be considered. A Winter procedure using a Tru-Cut biopsy needle through the glans to remove a piece of corporal tissue can be performed in the Emergency Department by a Urologist. Familiarity with this procedure is necessary in order to establish an effective shunt. Other venous types of shunts are performed in the Operating Room to decompress the corpora cavernosa.

AFTERCARE

The patient should be observed for at least 30 minutes before assuming successful detumescence. **Do not apply a compression dressing to the penis.** A pressure or circumferential dressing can result in ischemia and pressure necrosis. Referral to an appropriate specialist depends upon the cause of the priapism. If an underlying condition or medication is the suspected cause, the offending mechanism should be treated (or medication discontinued), the treating physician notified, and an appropriate disposition and follow-up ensured. Follow-up with a Urologist within 24 hours is necessary for all patients. A detailed procedure note as well as a precise statement of the discharge information given to the patient should be meticulously documented in the chart.

There are no randomized controlled data to support the use of prophylactic antibiotics after aspiration, irrigation, and/or intracavernous therapy. Some physicians will prescribe an antibiotic whose spectrum covers skin flora, such as cephalexin. The benefits of the antibiotic must be weighed against the possible adverse effects of the antibiotic such as allergic reactions, diarrhea, and clostridium difficile colitis to name just a few. The decision to prescribe or not prescribe an antibiotic should be based on the particular patient circumstances, Emergency Physician preference, and the consulting Urologists preference.

COMPLICATIONS

The long-term sequelae to unresolved priapism are fibrosis of the corporal tissue and loss of erectile function. Erectile dysfunction may still occur in patients despite successful detumescence. Varying degrees of fibrosis may be found on physical examination at a later date. Treatment by aspiration and irrigation can be associated with hematoma formation, urethral or vascular injury, and infection. The use of alpha-adrenergic agonists can have the systemic effects of headache, hypertension, flushing, reflex bradycardia, tachycardia, and other dysrhythmias. Deaths have been recorded with agents other than phenylephrine. The use of phenylephrine has not been reported to give rise to serious complications and is the agent of choice.

A prophylactic antibiotic, compression of needle puncture sites, care in alpha-adrenergic agonist dosing, observing the patient, and monitoring the blood pressure and pulse can help prevent untoward outcomes. The patient needs to be fully informed of the long-term risk of sexual dysfunction, even if detumescence is successful. Recurrence of the priapism is common and the patient should be warned to seek immediate care.

SUMMARY

Priapism is an uncommon but vexing complaint in the Emergency Department. The two major subtypes of priapism are ischemic (low flow) and nonischemic (high flow). The key decision for the Emergency Physician is to determine what type of priapism is present. Ischemic priapism requires prompt treatment to reduce the possibility of permanent damage to the penile tissue and subsequent erectile dysfunction. It is imperative to confirm the diagnosis with either color Doppler flow ultrasound or penile aspiration. Ischemic priapism, suspected or confirmed, requires an emergent Urology evaluation. Treatment should be performed in a stepwise fashion beginning with penile aspiration followed by irrigation if necessary. If unsuccessful, the intracavernous injection of phenylephrine should be attempted if no contraindications exist. If these bedside strategies fail, a Urologist should perform more invasive surgical procedures.

148 Paraphimosis Reduction

Ann P. Nguyen

INTRODUCTION

A paraphimosis is defined as the inability to reduce a proximally positioned foreskin over the glans penis and back to its normal anatomic position. The most common causes for a paraphimosis are iatrogenic. Following examination or instrumentation of the penis, medical personnel may forget to reduce the foreskin over the glans. This is particularly true of patients who are sedated, confused, demented, delirious, or in a nursing home. Patients may fail to reduce their foreskin after intercourse or urination. In infants and toddlers, the foreskin does not become fully mobile until after 3 years of age. This predisposes them to a paraphimosis when well-meaning caregivers forcibly retract the foreskin during cleaning. A paraphimosis may also occur when a narrowed (phimotic) foreskin is retracted and unable to be reduced.

A patient with a paraphimosis usually presents with severe pain in the distal penis. The process may have a more indolent presentation in persons with impaired pain sensation, such as the elderly or diabetics. As they are often unable to complain of pain, patients with altered mental status are at risk for complications of a paraphimosis. This includes penile ulceration, infection, gangrene, and partial penile autoamputation.[1] A careful and complete physical examination is mandatory in these patients. Penile edema secondary to a paraphimosis must be differentiated from edema due to infection, trauma, or allergic reactions.

ANATOMY AND PATHOPHYSIOLOGY

The foreskin is composed of a double layer of epidermis overlying subcutaneous tissue. It is attached to the skin at the base of the glans penis. The foreskin covers the glans to a variable degree and can usually be completely pulled over the glans. In a paraphimosis, the foreskin is retracted behind the glans and becomes edematous. The base of the foreskin is the location of the constricting or phimotic ring (**Figures 148-1 & 148-2**).

Arterial supply to the foreskin is derived from superficial branches of the external pudendal artery, which originates from the femoral artery. These superficial arteries do not communicate with the deep

FIGURE 148-1. The anatomy of a paraphimosis.

arteries of the penis. Arterial supply to the glans penis is derived from the paired dorsal arteries of the penis, which originate from the penile artery. These dorsal penile arteries run deep to Buck's fascia to enter the glans at the coronal sulcus. Arterial supply to the glans penis is thus entirely separate from that of the foreskin.

A retracted foreskin will block lymphatic drainage from the distal penis. As arterial inflow continues, lack of lymphatic drainage will cause a progressive edema of the penis distal to the retracted foreskin. As the foreskin continues to swell the phimotic ring becomes progressively tighter, and if not reduced, will eventually obstruct venous outflow. The distal penis will become painful and hyperemic. The edema will progress to ultimately obstruct arterial inflow resulting in penile ischemia, necrosis, and gangrene. This series of events, from retraction of the foreskin to arterial inflow obstruction, can occur over a few hours to 1 to 2 days. To relieve the obstruction, the phimotic ring must be advanced (reduced) over the glans of the penis.

FIGURE 148-2. A paraphimosis. **A.** Superior view. **B.** Inferior view.

INDICATIONS

All paraphimoses require reduction. The earlier a reduction is attempted, the less edematous the tissues will be and the easier it will be to perform the reduction. **Nonsurgical techniques should be attempted first. Surgical techniques are indicated if nonsurgical techniques are unsuccessful or the skin is compromised by infection, ulceration, or gangrene.**[2]

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a paraphimosis. While all paraphimoses must be reduced, certain techniques are contraindicated in specific patient subgroups. Nonsurgical techniques are contraindicated in patients with ulcerated or necrotic foreskins as they may cause iatrogenic injury.[2] Some authors feel that surgical reductions in children should be reserved for Pediatric Urologists.[3,4] **A surgical reduction should not be performed until noninvasive and lesser invasive techniques have been attempted.** The hyaluronidase technique is contraindicated in penile cancers or infections due to the possibility of spreading infected or malignant cells through the tissue planes.[5]

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Lidocaine jelly
- Water-soluble lubricant
- Local anesthetic solution (1% lidocaine or 0.5% bupivacaine) without epinephrine
- 18 gauge needles
- 27 gauge needles
- 10 mL syringe
- 4 × 4 gauze squares
- Crushed ice
- Surgical gloves
- Babcock clamps (6 to 8)
- 2-inch wide roll of elastic bandage (Ace Wrap or Elastoplast)
- Sterile drapes
- Sterile surgical gloves
- Suture scissors
- Two straight hemostats
- #15 surgical blade with handle
- Needle driver
- 3-0 synthetic absorbable suture or chromic catgut suture
- Granulated (table) sugar
- Hyaluronidase, 150 units or 1 cc
- Tuberculin syringe
- Antibiotic ointment, topical
- Petrolatum gauze

PATIENT PREPARATION

Reduction of a paraphimosis can be painful and somewhat distressing to patients. Explain to the patient and/or their representative the risks and benefits of the procedure. Also explain that the progression from nonsurgical to surgical techniques may be required. Obtain an informed consent from the patient. If the patient has an indwelling urinary catheter, it should be left in place during the reduction.

While premedication is rarely necessary, some patients may benefit from mild sedation. Procedural sedation (Chapter 129) and general anesthesia may be required in children.[3,4] Analgesia can sometimes be achieved with the topical application of lidocaine jelly or EMLA cream (2.5% prilocaine and 2.5% lidocaine) applied liberally and held in place for 45 to 60 minutes by a biofilm dressing. If this does not provide adequate patient comfort, a ring block or dorsal penile nerve block can be performed with 0.5% bupivacaine and/or 1% lidocaine.[6] Refer to Chapter 146 for the complete details regarding penile anesthesia.

TECHNIQUES

The techniques described below to reduce a paraphimosis begin with manual compression and progress to incision of the phimotic ring. They should be attempted in a stepwise manner from least invasive to most invasive in the order presented below.

MANUAL REDUCTION

This method has been extensively described.[3,7–10] Liberally apply an anesthetic jelly or water-soluble lubricant to the glans and foreskin. Do not coat the penile shaft or else it will be too slippery to facilitate an easy reduction.

Apply manual compression directly to the glans and edematous foreskin by grasping them with the palm of a gloved hand (**Figure 148-3**). Apply slow and steady pressure for 5 to 10 minutes. Many physicians do not have the time or the strength to apply pressure to a patient's penis for 5 to 10 minutes. In children, the parent may be asked to provide the manual compression. Compression may also be provided by circumferentially wrapping a bandage around the penis beginning at the glans and working toward the base of the penis. Apply the bandage so that it places more pressure distally and less proximally. This will mobilize the edematous fluid from distal to proximal. The bandage can be an Ace Wrap or Elastoplast,[10] a gauze sponge soaked in lidocaine jelly, or a gauze sponge soaked in cold water.[7]

FIGURE 148-3. Manual compression of the glans and foreskin to reduce the edema of the foreskin.

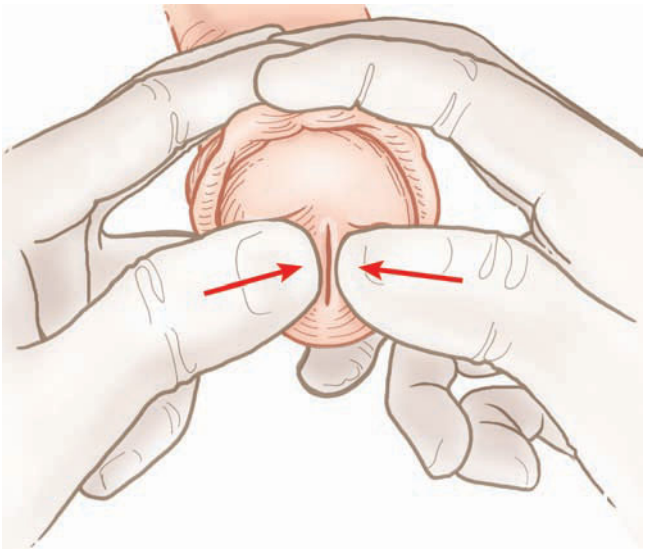

FIGURE 148-4. Manual reduction of a paraphimosis. The thumbs push the glans proximally (*arrows*) while the fingers provide countertraction to slip the phimotic ring over the glans.

Remove the bandage or release manual compression after it has been applied for 5 to 10 minutes. Apply the index and middle fingers of both hands to surround the top of the penile shaft proximal to the phimotic ring and the ring fingers underneath the penile shaft (**Figure 148-4**). Place both thumbs adjacent to the urethral meatus (**Figure 150-3**). Push the glans proximally with the thumbs while the fingers simultaneously provide countertraction to pull the phimotic band over the glans. Apply continuous force until the phimotic band moves distal to the glans. This same technique can be applied if the patient has an indwelling urinary catheter (**Figure 148-5**).

Alternatively, encircle the entire foreskin in one hand and pull distally while simultaneously pushing the glans proximally with the thumb of the opposite hand.[8] It is important to be very deliberate in the first attempt as the patient will become more anxious on subsequent attempts. This same technique can be applied if the patient has an indwelling urinary catheter.

ICED GLOVE TECHNIQUE

This technique combines cold to induce vasoconstriction and compression to reduce swelling.[2,8] It uses a glove to provide a circumferential ice pack to the foreskin to reduce edema. Half-fill a size 8 surgical glove with crushed ice and cold water. Squeeze the air from the glove and tie a knot in the wrist of the glove. Invaginate the thumb into the body of the glove. Liberally lubricate the glans and foreskin. Insert the penis into the invaginated thumb of the glove. Apply manual pressure with a clenched fist or bandage for 5 to 10 minutes. Attempt manual reduction as described previously.[2,3,4,8]

BABCOCK CLAMP TECHNIQUE

This technique can be used when manual reduction has been unsuccessful. It has a high rate of success in reducing a paraphimosis.[3,8,11] **This technique requires penile anesthesia (Chapter 146). Use only Babcock clamps. All other surgical clamps will crush and devitalize tissue.**

Apply 6 to 8 Babcock clamps circumferentially around the phimotic ring (**Figure 148-6A**). Place one edge of each clamp just proximal to the phimotic ring and the other edge just distal to the phimotic ring. **It is important to grasp a sufficient amount of**

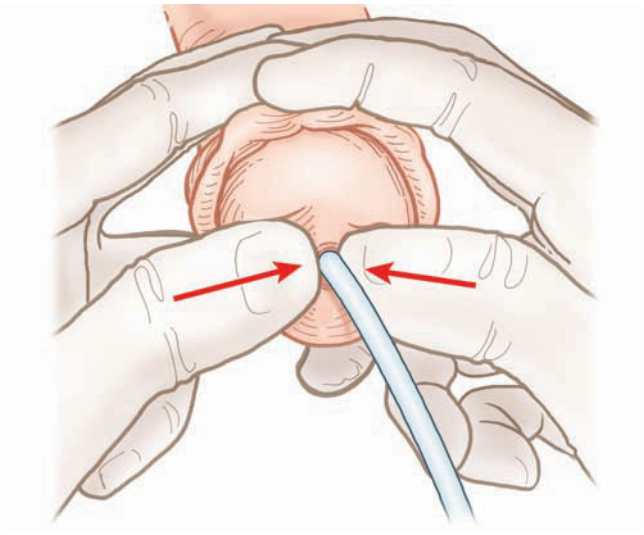

FIGURE 148-5. Manual reduction of a paraphimosis in the patient with an indwelling urinary catheter.

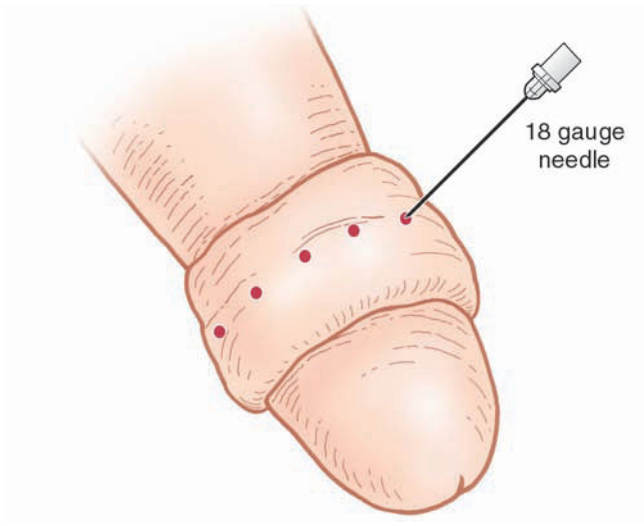

FIGURE 148-7. The needle decompression technique. An 18 gauge needle is used to circumferentially puncture the edematous foreskin 8 to 12 times.

the constricting ring to avoid tearing the skin once traction is applied. Space the clamps evenly around the circumference of the penis. Grasp all of the Babcock clamps in one hand. Simultaneously and slowly apply distal traction to the clamps to pull the phimotic ring over the glans (**Figure 148-6B**). After reduction, remove the Babcock clamps. Examine the foreskin for any signs of traumatic injury from the clamps.

A variation of this technique uses two operators and two Adson forceps in place of Babcock clamps.[12,13] This method is briefly described for completeness but is not recommended even though it is described in the medical literature. Adson forceps are toothed forceps. Traction with an Adson forceps can result in the teeth pulling through the phimotic ring and tearing the foreskin. One operator applies an Adson forceps to the phimotic ring at the 3 o'clock position and a second at the 9 o'clock position. The first operator pulls the foreskin distally via the forceps, while a second operator compresses the glans and pushes it proximally.

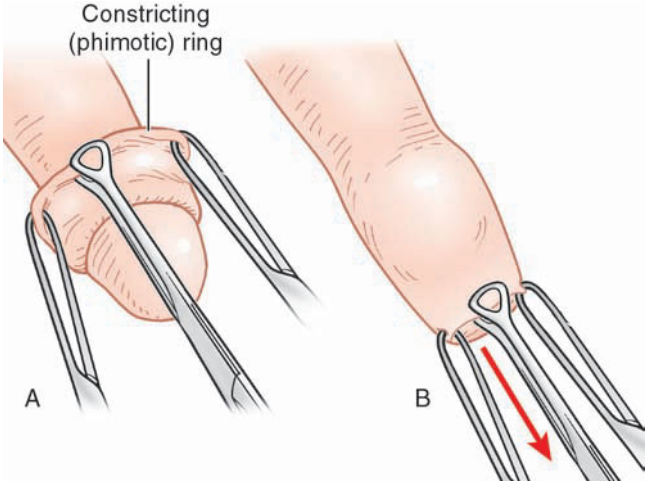

FIGURE 148-6. The Babcock clamp technique. **A.** Place six to eight Babcock clamps along the phimotic ring. Note that only three Babcock clamps are seen in the illustration for the sake of clarity. **B.** Gentle traction is simultaneously placed on all the clamps to advance the phimotic ring over the glans.

NEEDLE DECOMPRESSION TECHNIQUE

This technique mechanically expresses fluid from the edematous foreskin via a series of puncture holes in the foreskin.[3,9,14–17] Penile anesthesia is required with this technique. Clean the penis of any dirt or debris. Drape and isolate a sterile field around the penis. Apply povidone iodine or chlorhexidine solution to the penis and allow it to dry. Perform a penile block (Chapter 146).

Insert a sterile, hollow-bore 18 gauge needle 3 to 5 mm deep into the edematous foreskin. The use of needles as large as 18 gauge to as small as 26 gauge have been described. An 18 gauge is preferred as it makes a hole large enough to allow blood and fluid to escape from the tissues and not close or clot closed. Continue to puncture holes circumferentially around the edematous foreskin (**Figure 148-7**). An average of 8 to 12 holes are required. Different recommendations to use as few as 1 to as many as 20 punctures have been made.[15,16] Wrap a gauze square around the foreskin and glans. Grasp the glans and foreskin in the palm of a gloved hand and apply manual compression. Edema fluid and blood will be expressed from the puncture holes allowing the foreskin to decompress. The gauze square will allow the Emergency Physician to maintain a grasp as the penis becomes slippery with blood and edema fluid. After the foreskin is decompressed, reduce it manually or with Babcock clamps.

DORSAL SLIT OF THE FORESKIN

The Emergency Physician must always be prepared to perform surgical techniques if nonsurgical reduction is unsuccessful. This technique involves the incision of the phimotic ring under strict aseptic technique.[2,6,8] Place the patient supine and anesthetize the penis (Chapter 146), if it has not been done previously. Apply povidone iodine or chlorhexidine solution to the penis and let it dry. Apply sterile drapes to isolate a surgical field. Consider the administration of parenteral sedation prior to performing this procedure to alleviate the patient's anxiety.

Clamp a straight-blade hemostat over the foreskin and phimotic ring at the 11 o'clock and 1 o'clock positions. Place one jaw of each hemostat beneath the phimotic ring and the other jaw on top of it. **Be careful not to clamp the skin on the shaft of the penis.** Pull the foreskin taut between the hemostats. Grasp the hemostats with the nondominant hand or have an assistant hold them. Incise the

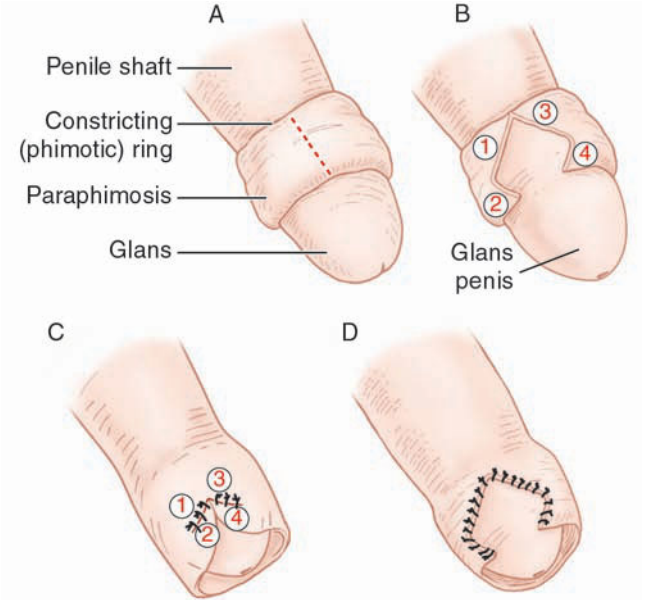

FIGURE 148-8. The dorsal slit of the foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut. A small gap should remain in the midline that is free of sutures. **D.** Alternatively, sew the edges closed with a simple running stitch.

foreskin and phimotic ring at the 12 o'clock position with a scissors or a #15 scalpel blade (**Figure 148-8A**). **Be careful not to cut the skin on the shaft of the penis.** Remove the hemostats. The incision will open into a pentagonal shape (**Figure 148-8B**). Reduce the foreskin over the glans. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes.

This technique can be technically difficult for the non-Surgeon. As an alternative to the two-hemostat technique, a one-hemostat technique may be performed. Place one hemostat over the foreskin and phimotic ring at the 12 o'clock position (**Figure 148-8A**). Remove the clamp after 1 to 2 minutes. Cut the crushed tissue with scissors through the phimotic ring. **Be careful not to cut the skin on the shaft of the penis.** The foreskin will then open up as described above (**Figure 148-8B**).

After the foreskin has been incised and reduced over the glans, approximate the cut edges with 3-0 chromic suture using a simple interrupted stitch (**Figure 148-8C**). Sew edge 1 and edge 2, on the illustration, together. Sew edge 3 and edge 4, on the illustration, together. A gap will remain at the 12 o'clock position that corresponds to the area of the initial incision. Alternatively, sew the cut edges with a simple running stitch (**Figure 148-8D**). Loosely apply petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **Do not apply the tape circumferentially as this can result in penile ischemia.**

MODIFIED DORSAL SLIT OF THE FORESKIN

A modified dorsal slit technique has been described where only the phimotic ring is cut rather than the entire foreskin.[4,8] Clean, prep, anesthetize, and drape the penis as above. A penile block is the preferred method of anesthesia as injection onto the distal penis is extremely painful (Chapter 146). As an alternative to a penile block, infiltrate immediately under the phimotic ring at the 12 o'clock position with local anesthetic solution without epinephrine using a 27 gauge needle. Be sure to raise a wheal both proximally and distally to the phimotic ring (along the dotted line in **Figure 148-9A**).

Incise the phimotic ring with a #15 scalpel blade. **Incise only the phimotic ring. Do not extend the cut more than 3 mm proximally or distally to the phimotic ring.** Once incised, the foreskin will spring open into a diamond-shaped defect (**Figure 148-9B**). Reduce the foreskin. Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes to decompress the foreskin. Approximate the edges of the wound with 3-0 chromic suture in a running pattern (**Figure 148-9C**). Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

ALTERNATIVE TECHNIQUES

A variety of alternative techniques have been described in the literature.[5,9,14,18,19,21] These techniques are variations on the basic principles previously discussed. We will briefly review the osmotic (sugar), hyaluronidase, and glans aspiration techniques.

OSMOTIC (SUGAR) TECHNIQUE

An alternative to surgical techniques is the osmotic technique.[9,18,19,21] It is an innovative, painless, but time-consuming method. The glans and foreskin are immersed in sugar. An osmotic gradient is formed between the edematous foreskin and the sugar. The hypertonicity of the sugar draws the edema fluid out of the foreskin. The deflated foreskin can then be manually reduced over

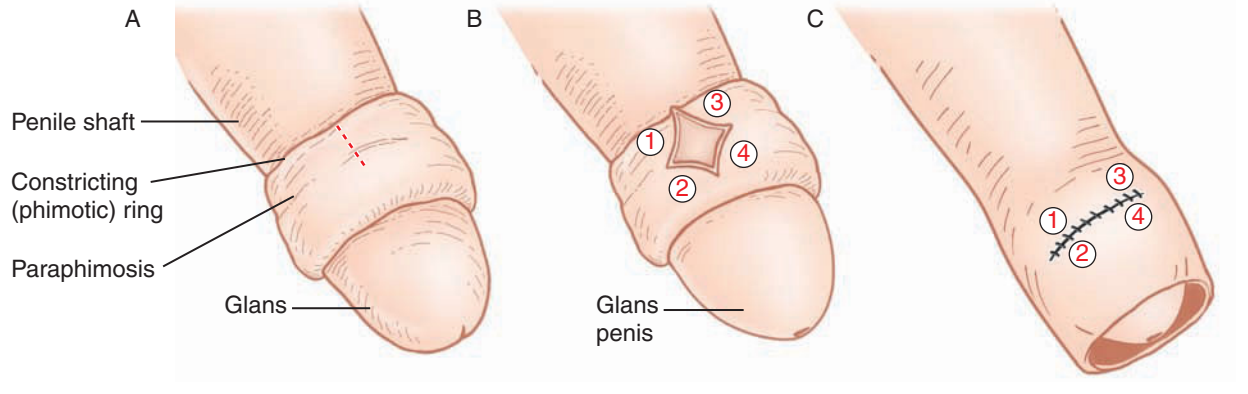

FIGURE 148-9. The modified dorsal slit of the foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut.

the glans. This technique should not be performed if the foreskin or the glans is infected, gangrenous, or ulcerated.

Place ordinary table sugar into the invaginated thumb of a large surgical glove. Insert the penis into the thumb of the glove, like in the iced glove method described above.[17] The penis may also be wrapped distally to proximally in a gauze square saturated with a 50% dextrose solution.[9,19] In all reports, the sugar was left on the penis for 1 to 2 hours before manual reduction was successful. The maximum time reported before successful reduction was 4 hours.[18]

HYALURONIDASE METHOD

Hyaluronidase (Amphadase, Amphastar Pharmaceuticals Inc., Rancho Cucamonga, CA; Hydase, PrimaPharm Inc., San Diego, CA; Hylenex, Halozyme Therapeutics, San Diego, CA; Vitrase, Ista Pharmaceuticals Inc., Irvine, CA) is a commercially available mammalian enzyme that degrades the intercellular ground substance of connective tissue. It is widely used in ophthalmologic and plastic surgery as a spreading agent. When injected into an edematous foreskin, hyaluronidase disperses the extracellular edema fluid, facilitating reduction of the paraphimosis.[5,14]

Clean, prep, drape, and anesthetize the penis. Inject hyaluronidase subcutaneously using a tuberculin syringe at various points around the circumference of the edematous foreskin. A total of 150 units, or 1 cc, of hyaluronidase should be used. An alternative is to inject the hyaluronidase into the puncture holes previously made from the needle decompression technique.[9,14] The edema should resolve almost immediately. Manual compression may be applied to the foreskin for 1 to 2 minutes to help mobilize the fluid. After the edema has decreased, manually reduce the foreskin.

The advantage of this technique is the rapidity with which the edema resolves. However, hyaluronidase is contraindicated in patients with penile infections or cancer as it may spread bacteria or malignant cells through the tissue planes. It is also contraindicated if the foreskin or glans is gangrenous or ulcerated.

GLANS ASPIRATION TECHNIQUE

This method is based on techniques used to treat priapism.[20] The author reports using this technique on four patients with paraphimoses with a 100% success rate and no complications. He recommended it for use when the foreskin is very friable and not amenable to vigorous manipulation. This technique is described for the sake of completeness but is not recommended.

Clean, prep, drape, and anesthetize the penis. Apply a sterile tourniquet to the penile shaft proximal to the phimotic ring. Use either umbilical tape or a Penrose drain. Insert a 20 gauge needle on a 10 mL syringe into the midline of the glans, halfway between the meatus and the corona. Keep the needle and syringe parallel to the urethra. Advance the needle while aspirating with the syringe. Once blood is encountered, stop advancing the needle. Continue to aspirate blood until the glans collapses completely. It is estimated that approximately 3 to 12 mL of blood will need to be aspirated, depending on the size of the glans. Remove the needle. Grasp and firmly squeeze the glans with the nondominant hand. While maintaining this pressure, release the tourniquet and manually reduce the foreskin over the collapsed glans with the dominant hand.

ASSESSMENT

The successfully reduced paraphimosis should have the general appearance of a normal uncircumcised penis. The patient usually notes immediate pain relief. It is normal for residual edema to be present. Reassure the patient that the edema will spontaneously resolve over hours to days.[3,8] If invasive techniques were utilized, observe the patient in the Emergency Department for 45 to 60 minutes to confirm hemostasis. Observe the patient for full recovery from any sedation or procedural sedation techniques as per hospital policy.

AFTERCARE

Wound care following a surgical reduction is the same as that for any sutured laceration. Many physicians do not dress the site at all. But if desired, the site may be covered with antibiotic ointment or petrolatum gauze followed by a dry sterile gauze.[6] The patient should be counseled on proper wound care. The patient should inspect the glans and foreskin three to four times a day if Babcock clamps, needle decompression, or surgical techniques were used to reduce the paraphimosis. They should return immediately to the Emergency Department if any signs of infection develop. Advise them to avoid intercourse or masturbation for 4 to 6 weeks.[6]

Antibiotics should be prescribed if the foreskin is abraded, infected, ulcerated, or torn by the Babcock clamp technique. They should also be prescribed if the foreskin was reduced by an invasive technique (e.g., needle decompression, dorsal slit, modified dorsal slit, hyaluronidase, or glans aspiration). Oral antibiotics whose spectrum covers skin flora should be prescribed. Cephalexin, 500 mg orally four times a day, is usually adequate.

All patients must follow up with a Urologist in 1 to 2 days. The definitive treatment is circumcision. This is typically delayed 7 to 10 days until any edema, inflammation, or ulceration has resolved.[7,8]

COMPLICATIONS

Incomplete reduction and pain are possible complications of manual reduction. With that in mind, it is important to allow enough time for adequate dispersion of edema. Manual reduction may also be associated with glans contusion and even glans ischemia if manual pressure is too great.[4] The iced glove method may produce cold injury if not properly monitored during use.[3] Compromised penile skin may be torn during manual or Babcock clamp reduction. The treatment is to suture any tears that occur.[8]

If surgical techniques are performed, bleeding is a common complication in this very vascular tissue. Venous bleeding can be profuse. It is important to have good control of the tissue edges so that adequate hemostatic stitches can be placed. A compressive dressing may aid in hemostasis. If the penile shaft is lacerated during a surgical reduction, it too should be sutured. And as with all invasive procedures, infection may be a complication of the needle decompression, dorsal slit, modified dorsal slit, hyaluronidase, and glans aspiration techniques.

The glans aspiration method runs the risk of transecting the urethra if the needle is not advanced parallel to the urethra. Complications of the hyaluronidase method may range from minor ecchymoses at the injection site to anaphylaxis and shock if the hyaluronidase is inadvertently injected intravascularly.[5,14]

SUMMARY

A paraphimosis is a problem that is best prevented. Replacement of the foreskin after urethral catheterization or glans cleaning is important. Early intervention is necessary and can prevent disastrous tissue loss. The reduction techniques should be attempted in a stepwise manner beginning with noninvasive techniques and progressing to increasingly invasive techniques.

149 Phimosis Reduction

Eric F. Reichman and Natana Peres

INTRODUCTION

A phimosis is a condition in which the foreskin cannot be retracted behind the glans of the penis.[1–19] It interferes with cleaning under the foreskin, allows the accumulation of secretions and debris (i.e., smegma) under the foreskin, and may predispose the patient to infections and possible malignancy.[18] It is classified into two subgroups: physiologic and pathologic. Physiologic phimoses occurs naturally in newborns. In males younger than 4 years of age, it is normal for the foreskin to not be retractable. In older boys and adults, the foreskin can usually be retracted without difficulty.[1] Pathologic phimoses is the inability to retract the foreskin after it was previously retractable or after puberty, usually secondary to scarring of the foreskin. Surgical treatment for a phimosis has been known for hundreds of years.[2] A Byzantine surgeon by the name of Oribasius, in the fourth century AD, gave a seemingly well-acquainted description of a technique involving forced dilation of the constrictive foreskin, scalloping out of its inner surface, then stretching it over a parchment-wrapped lead tube placed between the filleted skin and the glans.[2] Current techniques for the management of a phimosis in the Emergency Department are simple and remain an important intervention directed to relieving urinary obstruction.

ANATOMY AND PATHOPHYSIOLOGY

At birth there is a physiologic phimosis in the majority of male neonates. This is due to natural adhesions that exist between the foreskin and the glans of the penis. During the first 3 to 4 years of life, as the penis grows, epithelial debris (i.e., smegma) accumulates under the foreskin and gradually separates the foreskin from the glans. Intermittent penile erections aid in allowing the foreskin to eventually become retractable. The foreskin of most males will retract easily by the age of four. Forcible retraction should be categorically discouraged as this can result in scarring and constriction.[1] For a nonobstructive phimosis in children, topical steroids and topical conjugated equine estrogen have shown excellent results in releasing the stubborn physiologic adhesions between the foreskin and the glans.[3,4]

A phimosis can be the cause of other problems or be a result of other medical conditions. Recurrent infections such as balanitis or balanoposthitis, repeated urinary catheterization, forceful foreskin retraction, and poor hygiene can lead to scarring of preputial orifices causing a pathologic phimosis. Pathologic phimosis may also arise in diabetics due to the presence of glucose in their urine giving rise to an infection of the foreskin. Once acquired, a phimosis can become a paraphimosis if the foreskin is retracted and not promptly reduced. It can result in urinary tract infections from bacterial colonization of the phimosis or secondary to urinary obstruction. Some males may report painful erections, hematuria, preputial pain, or a weakened urinary stream. Other complications of a phimosis include recurrent balanitis, other local infections, urinary retention, carcinoma of the penis, and easy growth of venereal warts and other sexually transmitted diseases. It may also be due to local trauma (known as Tristram Shandy syndrome) or the congenital lack of conversion to a mobile foreskin.[5] Penile carcinoma deserves special mention. Coexistent phimosis is seen in up to 52% of cases of penile carcinoma. The need for timely follow-up should be impressed upon the patient regardless of the intervention required in the Emergency Department.[6]

INDICATIONS

The sole indication for the surgical release of a phimosis is urinary obstruction that cannot be relieved by passing a urethral catheter. A dorsal slit of the foreskin should be performed only after failure of noninvasive techniques. Most patients with a phimosis rarely require any emergency intervention and should be referred to a Urologist on an outpatient basis.

CONTRAINDICATIONS

The ability to pass a urinary catheter (Foley or coudé) into the bladder eliminates the acute need for the reduction of a phimosis. Patients with bleeding disorders, gross infections of the foreskin, who are immunocompromised, or who have lesions of the foreskin should have a urinary catheter placed into the bladder rather than an incision of the phimotic foreskin. If a catheter cannot be inserted into the urethra in these patients, a Urologist should be consulted prior to any invasive procedures. Patients with a nonobstructing phimosis should be referred for an elective circumcision and not have a dorsal slit procedure.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Gauze squares
- Sterile drapes
- 1% lidocaine without epinephrine
- Lidocaine Uro-jet
- 27 gauge needle
- 5 mL syringes
- Hemostats, straight or straight Kelly clamps
- Urinary catheters (Foley, coudé)
- Sterile gloves
- Sterile drapes
- Scissors
- #15 scalpel blade on a handle
- 3-0 or 4-0 chromic catgut or Vicryl on a noncutting needle
- Needle driver
- Petrolatum gauze
- 1 to 2 inch bandage
- Topical antibacterial ointment

The use of tissue glue of the type normally found in Emergency Departments has been studied in children undergoing circumcision.[7] It was shown to increase infection, bleeding, and wound dehiscence when compared to suture. The use of suture must be recommended at this time to close the wound edges.

PATIENT PREPARATION

Explain the benefits, risks, potential complications, and aftercare of the procedure to the patient and/or their representative. An informed consent should be obtained and placed in the medical record.

Place the patient supine with their genitalia exposed. Prepare the penis for any intervention. Clean the penis of any dirt, debris, and discharge. Apply drapes to isolate the penis. Apply povidone iodine or chlorhexidine solution onto the penis. If possible, apply the solution under the foreskin using a cotton-tipped applicator if necessary. If the patient has pain in the area of the foreskin, or if

a procedure other than catheter insertion is to be performed, the penis should be anesthetized. Refer to Chapter 146 for the complete details regarding penile anesthesia. Alternatively, infiltration of local anesthetic solution can be used to anesthetize the foreskin. Draw up 5 mL of local anesthetic solution without epinephrine into a syringe armed with a 27 gauge needle. Inject a subcutaneous wheal of local anesthetic solution 2 cm proximal to the distal end of the foreskin. Continue subcutaneous infiltration circumferentially around the penis with the local anesthetic solution. The patient may require intravenous sedation or procedural sedation prior to the injection of local anesthetic solution into the penis.

The use of topical anesthetics such as lidocaine jelly, prilocaine creams, or combinations (EMLA, LET, and LAT) is not recommended.[8] The application of these mixtures requires an occlusive dressing and 60 to 90 minutes for the anesthetic effect, which may then be inadequate.

TECHNIQUES

TOPICAL CORTICOSTEROIDS

Up to 85% of pathologic phimoses that are mild to moderate will respond to the application of topical steroids to the preputial orifice. It is reasonable for the Emergency Physician to prescribe 0.1% to 0.05% betamethasone dipropionate applied twice daily for 4 to 6 weeks with appropriate Urologic follow-up if there is no urinary obstruction or a urinary catheter can be placed.[11] The application of topical corticosteroids is the most cost-effective treatment if the circumstances permit.[19]

URETHRAL CATHETERIZATION

Attempt to pass a size 16 or 18 French Foley or coudé catheter into the bladder. If this is too large, attempt to pass the largest possible catheter. Please refer to **Table 145-1** for an age-based list of proper catheter sizes. **Care should be taken to avoid forceful placement of the catheter between the foreskin and the glans.** Correct catheter placement will be confirmed by an outflow of urine. Refer to Chapter 142 for a complete discussion of urethral catheterization.

FORESKIN DILATION

Most simply, the opening of the prepuce can be stretched. The patient's penis should be thoroughly anesthetized prior to performing this procedure (Chapter 146). Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation (Chapter 129).

Insert the jaws of a closed hemostat just inside the foreskin. Slowly open the arms of the hemostat 2 to 3 mm. **Palpate the foreskin to feel both jaws of the hemostat. If the jaws are not palpable, immediately remove the instrument as one of the jaws may be in the urethra.** If both jaws of the hemostat are palpable, open the arms to dilate the opening of the foreskin. Remove the hemostat. Clean the glans and undersurface of the foreskin with povidone iodine or chlorhexidine solution. Insert, using strict aseptic technique, a urinary catheter if required (Chapter 142).

This approach is not the ideal technique as it carries significant risk of injury to the patient. Inadvertent placement of the hemostat jaw in the urethra can lacerate the urethra and glans of the penis. Dilating the foreskin can cause irregular tears. Injury may require operative intervention and circumcision to correct any iatrogenic trauma.

DORSAL SLIT OF THE FORESKIN

The preferred method to correct an obstructing phimosis in the Emergency Department is the dorsal slit procedure. The patient's penis should be thoroughly anesthetized prior to performing this procedure (Chapter 146). Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation (Chapter 129).

Insert the bottom jaw of a straight hemostat between the foreskin and glans at the 12 o'clock position (**Figure 149-1A**). For those individual patients or cultural situations where dorsal incision of the foreskin, much less excision, is cosmetically unacceptable, a ventral approach may be substituted which will yield an apparently uncircumcised penis without obstructive symptoms.[9] Advance the hemostat until the tip of the jaw is at the coronal sulcus (**Figure 149-1A**). The coronal sulcus is where the foreskin attaches to the penis. Depending on the etiology of the phimosis, adhesions may be encountered. These should be gently broken as the hemostat is advanced. The skin of the foreskin is relatively thin and the jaw of the hemostat should be easily palpated. The tip of the jaw should be seen to tent the skin at the coronal sulcus when properly placed (**Figure 149-1B**). **It cannot be overemphasized that the Emergency Physician must be confident that the instrument has not been inadvertently placed in the urethra. If the jaw of the hemostat cannot be felt and cannot be seen tenting the skin of the foreskin, remove the hemostat and reinsert it.**

Once properly placed, close the hemostat to crush the foreskin at the 12 o'clock position. Allow the hemostat to remain closed for 2 to 3 minutes to thoroughly crush the foreskin. Remove the

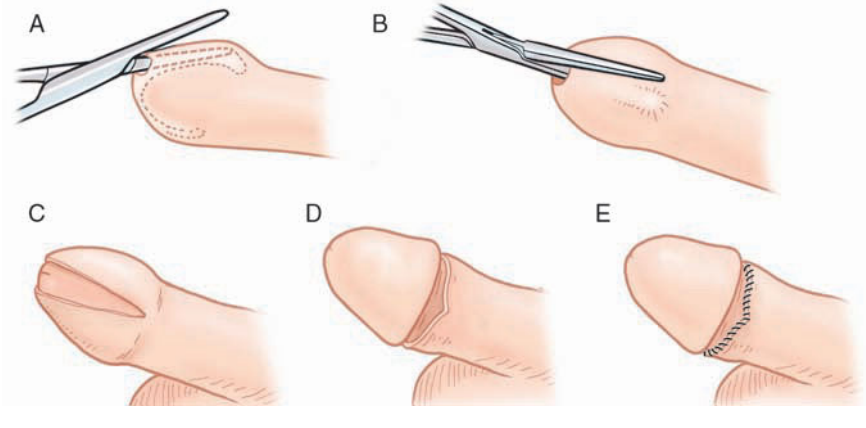

FIGURE 149-1. Dorsal slit of the foreskin. **A.** A hemostat is inserted under the foreskin and advanced to the coronal sulcus. **B.** The hemostat is elevated to tent the skin and confirm it is properly placed. **C.** The dorsal slit has been made. **D.** The foreskin is retracted. **E.** Interrupted sutures are placed in the cut edge of the foreskin.

hemostat. Insert a scissors and advance it with the same attention to position the tip at the coronal sulcus. Incise the crushed tissue to the level of the coronal sulcus (**Figure 149-1C**). If straight scissors are not available, a #15 blade may be used to cut the crushed skin after another instrument is placed underneath the foreskin to protect the glans from injury. **This method of using a scalpel blade is dangerous and not recommended because control is reduced and the potential for error is unnecessarily increased.**

Retract the cut foreskin. This will leave an open wound edge on both sides of the midline (**Figure 149-1D**). Suture the open wound edges using 3-0 or 4-0 chromic gut suture in an interrupted or running pattern. Begin suturing from the midline to the distal end of the incision (**Figure 149-1E**).[5] Return the foreskin to its "resting" position to guard against a newly acquired iatrogenic paraphimosis. Generously apply a topical antibacterial ointment over the suture line and loosely cover it with a bandage of petrolatum gauze and gauze squares. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

Should it be desired, a complete circumcision can be performed after the dorsal slit incision. Using two hemostats, make a series of crushing bites along the foreskin at the level of the coronal sulcus. **Use caution not to crush the skin on the shaft of the penis.** Using scissors, cut the foreskin along the crushed tissue. Approximate the wound edges using 3-0 or 4-0 chromic gut in an interrupted pattern. Carcinoma should always be considered as an etiology of a phimosis and all excised tissue sent to pathology for histologic evaluation.[18]

ALTERNATIVE TECHNIQUE

PREPUTIOPLASTY

The preputioplasty is an alternative surgical treatment to the more radical dorsal slit and circumcision. This tissue-sparing surgical technique can achieve full resolution of a phimosis. Although not typically performed in the Emergency Department, the preputioplasty is a conservative, less traumatic, and less invasive procedure. The procedure consists of one or more short longitudinal incisions which release the stenosis and they are then closed transversely allowing a widening of the phimotic ring and loosening of foreskin (**Figure 149-2**).[13]

Clean, prep, anesthetize, and prepare the penis as described previously. Retract the foreskin until it is completely proximal to the glans (**Figure 149-2B**). The phimotic ring will constrict the penile shaft (**Figure 149-2B**). Carefully make a superficial incision in the phimotic ring with a #15 scalpel blade or fine scissors (**Figure 149-2B**). The phimotic ring will open. Allow the wound to ooze for a few minutes. Close the wound using 3-0 or 4-0 chromic gut suture in an interrupted pattern (**Figure 149-2C**). Return the loosened foreskin over the glans (**Figure 149-2D**). Generously apply a topical antibacterial ointment over the suture line and loosely cover it with a bandage of petrolatum gauze and gauze squares. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

ASSESSMENT

Regardless of the technique, observe the patient in the Emergency Department for 45 to 60 minutes to confirm hemostasis. Observe the patient for full recovery from any sedation or procedural sedation techniques as per hospital policy.

AFTERCARE

The patient may be discharged with Urologic follow-up within 48 hours. Instruct the patient to return to the Emergency Department immediately if the wound is red, has a discharge, is swollen, or if fever develops. The patient should be given oral analgesics for pain control. Patients should be discharged on oral antibiotics whose spectrum covers skin flora. Cephalexin, 500 mg orally four times a day, is usually adequate. Between discharge and examination by a Urologist, the patient should practice gentle daily washing of the penis with soap, avoid placing any powders or creams in the area, and check the wound three to four times daily for signs of infection. Sexual intercourse and masturbation should be avoided until the incisions have completely healed.

The dorsal slit procedure will result in a "beagle-ear" like deformity. While not problematic in most cases, it may increase the chance of getting the foreskin entrapped in a zipper. The Urologist will often perform an elective circumcision for cosmetic purposes.

COMPLICATIONS

Direct mechanical injury to the glans or urethra by inadvertent placement of instruments into the urethra could be devastating but is easily avoidable by following proper technique. Increased bleeding may result if the skin is not crushed by the hemostat before it is cut with the scissors.[5] It is also important to avoid advancing the clamp, and therefore the incision, beyond the comfortable limitation of the coronal sulcus. Otherwise, the skin on the penile shaft will be cut. This can result in a cosmetic defect and possibly skin sloughing requiring a skin graft. Lacerations to the penile shaft skin should be sutured with an absorbable suture.

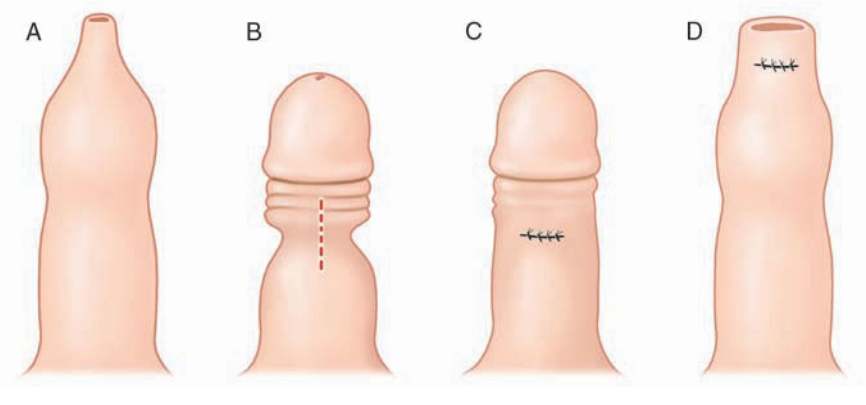

FIGURE 149-2. The preputioplasty. **A.** Penis with tight phimotic ring making it difficult to retract the foreskin. **B.** Foreskin retracted under anaesthetic with the phimotic ring or stenosis constricting the shaft of the penis and creating a "waist." The dotted line represents the vertical incision line. **C.** Incision closed laterally with interrupted sutures. **D.** Penis with the loosened foreskin replaced over the glans.

Wound infection and dehiscence are a possibility with any incision and greatly reduced in conscientious patients.

SUMMARY

From a variety of disease processes, the endpoint of a phimosis causing urinary obstruction lends itself to simple correction by the Emergency Physician. If there is not complete urinary obstruction, a trial of topical corticosteroids is simple, cost effective, and may result in the resolution of the phimosis. Careful performance of the described techniques will result in an excellent functional and aesthetic foreskin repair.

150 Dorsal Slit of the Foreskin

Carlos J. Roldan

INTRODUCTION

Acute conditions affecting the foreskin that must be recognized in the Emergency Department include a phimosis and a paraphimosis. The Emergency Physician must be able to accurately identify and manage these conditions as well as recognize when an urgent Urology consultation is necessary. A dorsal slit of the foreskin can be performed primarily in the Emergency Department. This technique is used to relieve strangulation of the glans by a paraphimosis or to aid in the visualization of the urethral meatus in patients with a phimosis.[1] The techniques are easy to learn and simple to perform.

ANATOMY AND PATHOPHYSIOLOGY

The prepuce, or foreskin, is the skin originating just proximal to the corona that encircles the glans and often extends beyond it.[2] It may be incomplete, primarily at the ventral midline or the frenulum. The frenulum is the fusion site of the preputial and urethral folds. The glans is composed of the corpus spongiosum that enlarges to cover the tips of the corpora cavernosa. It has less erectile tissue than the corpora cavernosa and contains the urethra.[2]

The blood supply to the foreskin and glans is provided by the left and right superficial penile arteries. The arteries are derived from the inferior external pudendal arteries, which are branches of the femoral arteries. The penile arteries travel in the superficial fascia of the penis and above Buck's fascia.[3] The left and right superficial penile arteries freely communicate over the midline. Superficial veins accompany the arteries and ultimately drain to the saphenous veins in the thighs. The lymphatics travel deep to Buck's fascia and ultimately empty into the inguinal chain of lymph nodes. The somatic nerves to the foreskin are derived from the pudendal nerves.[4]

A dorsal slit is performed to reduce a paraphimosis or phimosis when other less invasive techniques are unsuccessful. A paraphimosis is the inability to replace the retracted foreskin over the glans into its naturally occurring position. It is considered an emergency since prolonged retraction of the foreskin creates a constricting ring that quickly compromises vascular and lymphatic circulation with eventual engorgement and necrosis of the glans and foreskin. A phimosis is the inability to retract the distal foreskin over the glans penis.[5,6] Once the foreskin can be retracted so that the glans penis partially appears, a phimosis is no longer present. A more detailed description of the anatomy and pathophysiology of the penis, a paraphimosis, and a phimosis can be found in Chapters 148 and 149.

INDICATIONS

A dorsal slit of the foreskin should be performed to release a paraphimosis or a phimosis if noninvasive and lesser invasive techniques are unsuccessful. A paraphimosis is considered an emergency since prolonged retraction of the foreskin leads to swelling of the prepuce resulting in strangulation injury to the glans.[1] A phimosis should be released if it causes urinary retention. The phimotic foreskin should not be forcibly retracted as this can result in a tearing of the foreskin.

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a paraphimosis. A dorsal slit in children should be performed by a Pediatric Urologist, a Urologist, or after consultation with a Urologist. A dorsal slit for the relief of a paraphimosis should be performed only after noninvasive and lesser invasive techniques have been unsuccessfully attempted (Chapter 148).[7–9]

The ability to pass a urinary catheter (i.e., Foley, coudé, filiforms, and followers) into the bladder eliminates the acute need for reduction of a phimosis. Refer to Chapter 142 for the complete details regarding the techniques of urethral catheterization. Patients with bleeding disorders, gross infections of the foreskin, who are immunocompromised, or who have lesions of the foreskin should have a urinary catheter placed into the bladder rather than an incision of the phimotic foreskin if possible. If a catheter cannot be inserted into the urethra in these patients, a Urologist should be consulted prior to any invasive procedures. Patients with a nonobstructing phimosis should be considered for topical corticosteroids and referred for elective circumcision and not have a dorsal slit procedure.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 5 mL syringe
- 27 gauge needle
- Hemostats, straight or straight Kelly
- #15 scalpel blade on a handle
- Needle driver
- 3-0 or 4-0 chromic catgut, Dexon, or Vicryl
- Petrolatum gauze
- Metzenbaum scissors
- Suture scissors
- 4 × 4 gauze squares
- Sterile gloves
- Sterile drapes
- Topical antibacterial ointment

The use of tissue glue of the type normally found in Emergency Departments has been studied in children undergoing circumcision.[11] It was shown to increase infection, bleeding, and wound dehiscence when compared to suture. The use of suture must be recommended at this time to close the wound edges after the release of a paraphimosis or a phimosis.

PATIENT PREPARATION

Explain the benefits, risks, potential complications, and aftercare of the procedure to the patient and/or their representative. An informed consent should be obtained and placed in the medical record.

Prepare the penis for any intervention. Clean the penis of any dirt, debris, and discharge. Apply drapes to isolate the penis. Apply povidone iodine or chlorhexidine solution onto the penis. If possible, apply the solution under the foreskin using a cotton-tipped applicator if necessary. If the patient has pain in the area of the foreskin, or if a procedure other than catheter insertion is to be performed, the penis should be anesthetized. Refer to Chapter 146 for the complete details regarding penile anesthesia. Alternatively, infiltration of local anesthetic solution can be used to anesthetize the foreskin. Draw up 5 mL of local anesthetic solution without epinephrine into a syringe armed with a 27 gauge needle. Inject a subcutaneous wheal of local anesthetic solution 2 cm proximal to the distal end of the foreskin. Continue subcutaneous infiltration circumferentially around the penis with the local anesthetic solution. The patient may require intravenous sedation or procedural sedation (Chapter 129) prior to the injection of local anesthetic solution into the penis.

The use of topical anesthetics such as lidocaine jelly, prilocaine creams, or combinations (EMLA, LET, and LAT) is not recommended.[10] The application of these mixtures requires an occlusive dressing and 60 to 90 minutes for the anesthetic effect, which may then be inadequate. Their use will also delay the performance of the procedure.

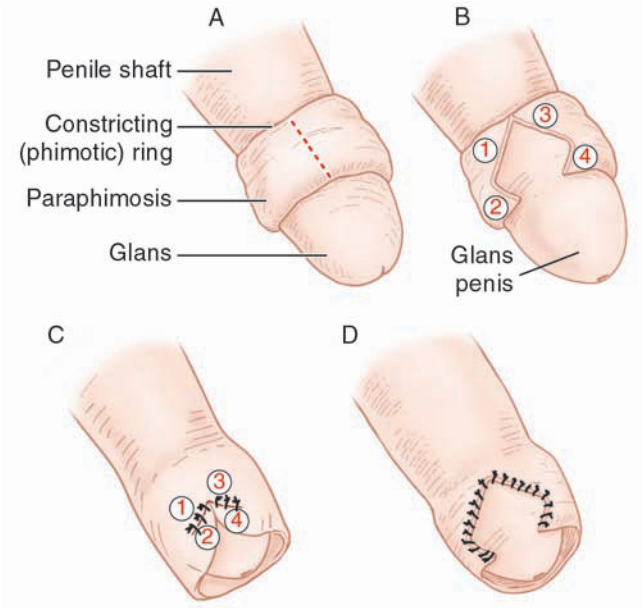

FIGURE 150-1. Dorsal slit of the paraphimotic foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut. A small gap should remain in the midline that is free of sutures. **D.** Alternatively, sew the edges closed with a simple running stitch.

TECHNIQUES

DORSAL SLIT OF THE PARAPHIMOTIC FORESKIN

One must always be prepared to perform surgical techniques if nonsurgical reduction is unsuccessful. This technique involves the incision of the phimotic ring under strict aseptic technique.[12,14,15] Place the patient supine and anesthetize the penis, if it has not been done previously. Apply povidone iodine or chlorhexidine to the penis and let it dry. Apply sterile drapes to isolate a surgical field. Consider the administration of parenteral sedation prior to performing this procedure to alleviate the patient's anxiety.

Clamp a straight-blade hemostat over the foreskin and phimotic ring at the 11 o'clock and 1 o'clock positions. Place one jaw of each hemostat beneath the phimotic ring and the other jaw on top of it. **Be careful not to clamp the skin on the shaft of the penis.** Pull the foreskin taut between the hemostats. Grasp the hemostats with the nondominant hand or have an assistant hold them. Incise the foreskin and phimotic ring at the 12 o'clock position with a scissors or #15 scalpel blade (**Figure 150-1A**). **Be careful not to cut the skin on the shaft of the penis.** Remove the hemostats. The incision will open into a pentagonal shape (**Figure 150-1B**). Reduce the foreskin over the glans. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes.

This technique can be technically difficult for the non-Surgeon. As an alternative to the two-hemostat technique, a one-hemostat technique may be performed. Place one hemostat over the foreskin and phimotic ring at the 12 o'clock position (**Figure 150-1A**). Remove the clamp after 1 to 2 minutes. Cut the crushed tissue with scissors through the phimotic ring. **Be careful not to cut the skin on the shaft of the penis.** The foreskin will then open up as described (**Figure 150-1B**). Once the incision is made bloody edematous fluid will ooze out and this can be sponged. Reduce the foreskin over the glans. A total reduction of paraphimosis has to be accomplished to obtain satisfactory results. Cover the penis with sterile gauze and allow the edges of the incision to ooze for 10 to 15 minutes.

After the foreskin has been incised and reduced over the glans, approximate the cut edges with 3-0 chromic suture using a simple interrupted stitch (**Figure 150-1C**). Sew edge 1 and edge 2, on the illustration, together. Sew edge 3 and edge 4, on the illustration, together. A gap will remain at the 12 o'clock position that corresponds to the area of the initial incision. Alternatively, sew the cut edges with a simple running stitch (**Figure 150-1D**). Loosely apply petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

MODIFIED DORSAL SLIT OF THE PARAPHIMOTIC FORESKIN

A modified dorsal slit technique has been described where only the phimotic ring is cut rather than the entire foreskin.[12,13] Clean, prep, anesthetize, and drape the penis as described previously. A penile block is the preferred method of anesthesia because injection onto the distal penis is extremely painful. As an alternative to a penile block, infiltrate under the phimotic ring at the 12 o'clock position with local anesthetic solution without epinephrine using a 27 gauge needle. Be sure to raise a wheal both proximally and distally to the phimotic ring (along the dotted line in **Figure 150-2A**).

Incise the phimotic ring with a #15 scalpel blade. **Incise only the phimotic ring. Do not extend the cut more than 3 mm proximally or distally to the phimotic ring.** Once incised, the foreskin will spring open into a diamond-shaped defect (**Figure 150-2B**). Reduce the fore-skin. Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes to decompress the foreskin. Approximate the edges of the wound with 3-0 chromic suture in an interrupted

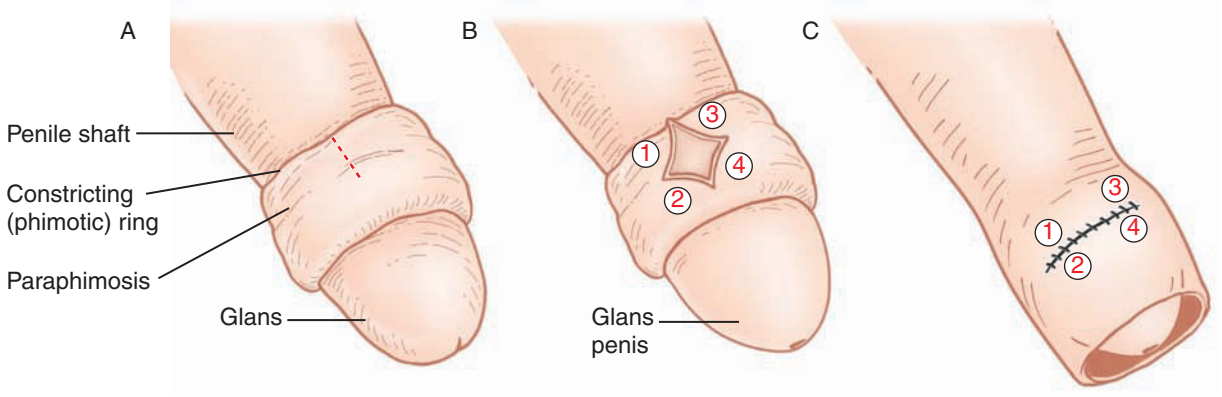

FIGURE 150-2. Modified dorsal slit of the paraphimotic foreskin. **A.** The dotted line represents the incision line. **B.** The foreskin opens after the incision is made. The numbers represent the edges of the incision. **C.** The foreskin has been reduced and the edges of the incision sewn shut.

or running pattern (**Figure 150-2C**). Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

DORSAL SLIT OF THE PHIMOTIC FORESKIN

The preferred method to correct an obstructing phimosis in the Emergency Department setting is the dorsal slit procedure. The patient's penis should be thoroughly anesthetized prior to performing this procedure. Consideration should also be given to administering intravenous analgesics, intravenous sedation, or procedural sedation.

Insert the bottom jaw of a straight hemostat between the foreskin and glans at the 12 o'clock position (**Figure 150-3A**). For those individual patients or cultural situations where dorsal incision of the foreskin, much less excision, is cosmetically unacceptable, a ventral approach may be substituted which will yield an apparently uncircumcised penis without obstructive symptoms.[12] Advance the hemostat until the tip of the jaw is at the coronal sulcus (**Figure 150-3A**). The coronal sulcus is where the foreskin attaches to the penis. Depending on the cause of the phimosis, adhesions may be encountered. These should be gently broken as the hemostat is advanced. The skin of the prepuce is relatively thin and the jaw of the hemostat should be easily palpated. The tip of the jaw should be seen to tent the skin at the coronal sulcus when properly placed (**Figure 150-3B**). **It cannot be overemphasized that the physician must be confident that the instrument has not been inadvertently placed in the urethra. If the jaw of the hemostat cannot be felt and cannot be seen tenting the skin of the foreskin, remove the hemostat and reinsert it.**

Once properly placed, close the hemostat. Allow the hemostat to remain closed for 2 to 3 minutes to crush the skin. Remove the hemostat. Insert a scissors and advance it with the same attention to position the tip at the coronal sulcus. Incise the crushed tissue to the level of the coronal sulcus (**Figure 150-3C**). If straight scissors are not available, a #15 blade may be used to cut the crushed skin after another instrument is placed underneath the foreskin to protect the glans from injury. **This method of using a scalpel blade is dangerous and not recommended because control is reduced and the potential for error is unnecessarily increased.**

Retract the cut foreskin. This will leave an open wound edge on both sides of the midline (**Figure 150-3D**). Cover the penis with gauze and allow the cut edges to ooze for 10 to 15 minutes. Approximate the open wound edges using 3-0 or 4-0 chromic gut suture in an interrupted or running pattern. Begin suturing from the midline to the distal end of the incision (**Figure 150-3E**).[12] Return the foreskin to its "resting" position to guard against a newly acquired iatrogenic paraphimosis. Apply a bandage of petrolatum gauze and gauze squares over the wound. Apply a piece of tape to hold the dressing on the penis. **The tape should not be applied circumferentially as this can cause ischemia to the penis.**

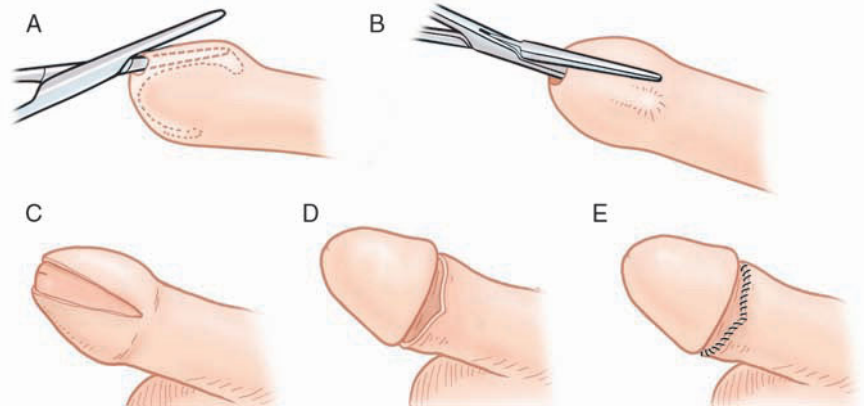

FIGURE 150-3. Dorsal slit of the phimotic foreskin. **A.** A hemostat is inserted under the foreskin and advanced to the coronal sulcus. **B.** The hemostat is elevated to tent the skin and confirm it is properly placed. **C.** The dorsal slit has been made. **D.** The foreskin is retracted. **E.** Interrupted sutures have been placed in the cut edges of the foreskin.

ASSESSMENT

The foreskin should now be retractable to a sufficient degree to allow visualization of the meatus (when performed for a phimosis) or reduced over the glans to relieve pressure (when performed for a paraphimosis). The successfully reduced paraphimosis should have the general appearance of a normal uncircumcised penis. It is normal for residual edema to be present. Reassure the patient that the edema will spontaneously resolve over hours to days. Observe the patient in the Emergency Department for 45 to 60 minutes to confirm hemostasis. Observe the patient for full recovery from any sedation or procedural sedation techniques as per hospital policy.

AFTERCARE

Wound care following a surgical reduction is the same as that for any sutured laceration. Many physicians do not dress the incision site. But if desired, it may be covered with antibiotic ointment or petrolatum gauze and dry sterile gauze.[10] The patient should be counseled on proper wound care. The patient should inspect the glans and foreskin three to four times a day. They should return immediately to the Emergency Department if any signs of infection develop. They should also be advised to avoid intercourse or masturbation for 4 to 6 weeks.[10]

Antibiotics should be prescribed that cover gram-positive organisms. An extended-spectrum penicillin or first-generation cephalosporin is most frequently prescribed. Cephalexin, 500 mg orally four times a day, is usually adequate.

All patients need to follow up with a Urologist in one or two days. The definitive treatment is circumcision, which is typically delayed 7 to 10 days until any edema, inflammation, or ulceration has resolved.[14,15]

COMPLICATIONS

Direct mechanical injury to the glans or urethra by inadvertent placement of instruments into the urethra could be devastating but is easily avoidable by following proper technique. Increased bleeding may result if the skin is not crushed by the hemostat before it is cut with the scissors. It is also important to avoid advancing the clamp, and therefore the incision, beyond the comfortable limitation of the coronal sulcus. Otherwise, the skin on the penile shaft will be cut. This can result in a cosmetic defect and possibly skin sloughing requiring a skin graft. Wound infection and dehiscence are a possibility with any incision and greatly reduced in conscientious patients. Bleeding is a common complication in this very vascular tissue. Venous bleeding can be profuse and it is important to have good control of the tissue edges so that adequate hemostatic stitches can be placed. A compressive dressing may aid in hemostasis. If the penile shaft is lacerated during a surgical reduction, it too should be sutured. And, as with all invasive procedures, infection may be a complication.

SUMMARY

A dorsal slit is an easy and rapid way to relieve strangulation pressure from a paraphimosis or to allow visualization of the urethral meatus from an obstructing phimosis. This procedure is performed primarily in emergency situations as the cosmetic result is usually suboptimal. Patients with a phimosis who are able to void should be referred to a Urologist before performing a dorsal slit. The dorsal slit procedure should only be performed when a phimosis is obstructing and a urethral catheter cannot be placed. A paraphimosis is always an emergency. Often this will reduce with less invasive techniques that should be attempted first. Severe cases will require a dorsal slit.

151 Manual Testicular Detorsion

Steven Go

INTRODUCTION

First described in the English literature by Rigby and Howard in 1907, testicular torsion occurs when the testicle turns around its axis, forcing its blood supply to twist, thereby causing vascular compromise of the testicle (**Figure 151-1**).[1] Testicular torsion is a time-sensitive emergency that demands the Emergency Physician to act swiftly to preserve the testicle. **Testicular torsion is a clinical diagnosis and the primary goal is surgical detorsion in the operating room.** If testicular torsion is strongly suspected clinically, consult a Urologist immediately for a bedside evaluation. Manual detorsion can be attempted while awaiting more definitive surgical intervention.

The incidence of testicular torsion is believed to be approximately 1 in 4000 in males less than 25 years of age.[2] It is primarily a condition that affects the young with a bimodal distribution in the neonatal period and the early teens.[3] Most cases occur in patients less than 21 years of age.[4] Age should not be considered when making the diagnosis, however, as torsion may occur in the antenate, neonate, adult, or geriatric patient.[5–7]

Testicular torsion typically presents with acute or insidious onset of excruciating, usually unilateral testicular and/or scrotal pain. There is a slight predilection for the left testicle.[2] Cases of bilateral torsion can also occur.[8] Torsion may be associated with a history of a recent episode of genital trauma.[9] The patient is often awaken from sleep by the pain. Associated symptoms may include nausea, vomiting, and a low-grade fever.[10] A history of a prior orchiopexy (surgical fastening of the testicle) does not exclude the possibility of torsion.[11]

Physical examination of these patients typically reveals testicular pain to palpation and a painful, edematous scrotum. The testicle may be high-riding with a horizontal lie and anterior rotation of the epididymis.[12] A cremasteric reflex is typically absent but can be present in some cases. Lack of a cremasteric reflex has only a 88.2% sensitivity for torsion.[13–15] Prehn's sign, or the relief of pain with elevation of the scrotum, is classically present in epididymitis and absent in torsion. Unfortunately, Prehn's sign is an imperfect discriminator.[16–18] Bedside Doppler ultrasound stethoscope studies can be misleading, even if flow is heard.[19] Scrotal blood flow can

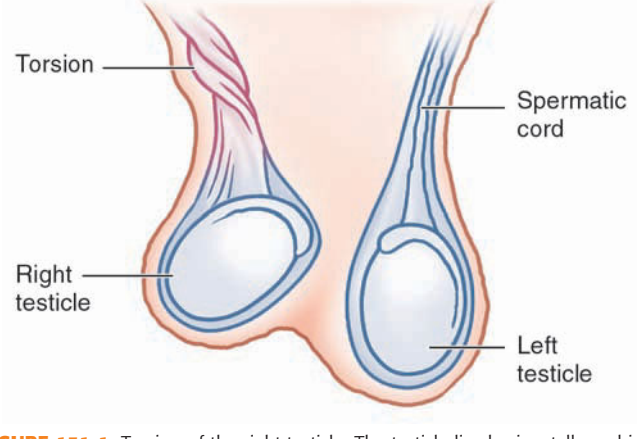

FIGURE 151-1. Torsion of the right testicle. The testicle lies horizontally and in a higher position than the normal testicle.

be erroneously interpreted as testicular blood flow.[19] If flow is not heard, however, one can assume torsion is present.

Color Doppler ultrasonography has largely replaced testicular radionuclide scintigraphy for the confirmation of torsion because of its greater availability, lower cost, and lack of adverse effects. However, two points must be emphasized. **In a patient where torsion is strongly suspected, emergent bedside consultation with a Urologist should not be unduly delayed for the performance of or the results of a radiological study**. This point becomes even more critical the longer the symptoms have been present. Color Doppler ultrasonography has a reported sensitivity for torsion of only 85.7% to 90%.[20–23] **If torsion is suspected and no other competing diagnosis can be definitively confirmed by color Doppler ultrasonography, the patient should still be emergently evaluated by a Urologist.**

The differential diagnosis of the acutely swollen or painful scrotum also includes torsion of the testicular appendage, epididymitis, orchitis, hernia, varicocele, tumor, trauma, idiopathic scrotal edema, fat necrosis, viral inflammation, and Henoch–Schönlein purpura. **As testicular torsion is the diagnosis requiring the most urgent action, it should be first on the differential diagnosis list.** Testicular torsion may result in irreversible damage to the involved testis. It may also affect the contralateral testicle. Recent studies have examined the possible immunologic mechanism for this global effect on fertility but the exact pathophysiology has not been established.[24,25]

ANATOMY AND PATHOPHYSIOLOGY

The testicle is covered by the tunica albuginea, followed by the visceral layer of the tunica vaginalis. The parietal layer of the tunical vaginalis partially encloses both the testicle and the epididymis. The testicular (spermatic) artery acts as the primary blood supply to the testicle and traverses the spermatic cord. Venous drainage is supplied by the pampiniform plexus within the spermatic cord. The above structures, as well as the vas deferens, are enveloped by the cremaster muscle and fascia.

Testicular torsion may be classified as extravaginal or intravaginal.[26] Extravaginal torsion occurs primarily in neonates. The testis, epididymis, and tunica vaginalis twist together on their vertical axis because the gubernaculum has not yet become attached to the scrotal wall. It is thought to be caused by the free rotation of the testicle around the spermatic cord at a level above the tunica vaginalis.[15,27] Intravaginal torsion occurs in peri- or postpubertal males and has been associated with the so-called bell-clapper deformity. In the normal scrotum, the tunica vaginalis only partially covers the epididymis and does not cover the spermatic cord. In the bell-clapper deformity, the tunica vaginalis encases the entire testicle, epididymis, and base of the spermatic cord. This allows the contents to twist and move within the tunica vaginalis as a bell-clapper does within a bell.[26] Both intravaginal and extravaginal torsion usually occur in a medial or inward fashion.

Testicular torsion results in the obstruction of the blood supply to the testis. The venous obstruction leads to edema. This is followed by arterial obstruction that leads to testicular ischemia. Because the degree of torsion or vascular compromise cannot be quantified by current methods, the time for torsion to result in irreversible testicular damage cannot be determined.[26] A complete vascular occlusion will cause a testicle to develop permanent and irreversible damage earlier than a testicle with partial vascular occlusion. The literature is variable and cites a range of 6 to 24 hours of vascular occlusion required to cause irreversible ischemic damage to a testicle. Most authors agree that the best outcomes are obtained with detorsion within 6 hours of symptom onset.[26] Incomplete torsions exist and some blood flow to the testicle may be preserved. **Therefore, a testicle should not be assumed to be nonviable based upon the time of suspected onset alone.**

The definitive therapy for a torsed testicle is surgery. There is agreement that, at the time of surgery, a necrotic testicle should be removed and a pink, healthy appearing testicle should be left in place. The question remains of what to do with those testicles whose viability is not clear at the time of surgery. Current recommendations are to remove an obviously necrotic testicle or a testicle that stays cyanotic after detorsion; but leave in place any testicle which appears viable.[28,29]

Research has addressed the issue of immunology and future fertility post-torsion. The blood-testicle barrier has been well established. The theory exists that ischemic damage to the torsed testicle breaks down the blood-testicle barrier allowing the body to produce autoantibodies that attack the contralateral testicle.[25] Another theory has proposed that abnormal or subfertile testicles are more likely to torse and that these differences in fertility may have predated the torsion.[30,31] These subfertile changes may resolve within several months after orchiectomy of the torsed testicle.[24] Studies in sperm-producing rodents have found evidence of immunologic damage to the contralateral testicle after torsion, especially if the torsed testicle is allowed to remain torsed for more than 24 hours.[24,25] These studies and others seem to support the theory of immunologic damage after ischemia.

INDICATIONS

The Emergency Physician should attempt manual reduction of a torsed testicle while awaiting the arrival of the Urologist.[32] **An attempt should be made to manually reduce all suspected testicular torsions while awaiting the arrival of the Urologist.[32]** If reduced within 6 to 8 hours of the start of symptoms, the survival rate of the testicle after manual detorsion is near 100%.[32] After 8 hours, the risk of testicular atrophy increases but the testis may still be salvageable; especially if the vascular obstruction is incomplete. Successful manual detorsion after longer periods of time becomes difficult due to edema formation. **However, due to the lack of significant complications, manual detorsion should be attempted regardless of the length of symptoms as long as it does not delay definitive surgical management.**

CONTRAINDICATIONS

There are no absolute contraindications to attempt to manually reduce a testicle that is torsed. There are, however, some situations in which it might not be warranted. If the testis has become fixed to the scrotal wall, it may be necrotic and detorsion outside of the Operating Room is not possible.[32] If the Operating Room and Surgeon are available, an attempt at manual detorsion might delay definitive repair. If the degree of swelling and/or pain preclude the examiner from applying firm pressure on the testicle, detorsion might not be possible. If the clinical picture suggests another cause for the patient's symptoms and the suspicion for a testicular torsion is very low, a radiologic study (i.e., testicular scan or Doppler ultrasound) might be warranted prior to an attempt at detorsion. If the testicle has been torsed for more than 24 hours, orchiectomy without detorsion might help to preserve fertility in the contralateral testicle.[25] However, this has not been sufficiently confirmed and is not currently recommended.

EQUIPMENT

No equipment is required to manually detorse a testicle. However, as the testicle is tender and the procedure is bound to be painful, consider the judicious administration of parenteral analgesia, sedation,

or procedural sedation (Chapter 129). The use of a Doppler stethoscope or color Doppler ultrasound to assist with the diagnosis and determination of a successful detorsion is helpful but not required.

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative. Explain that the procedure will be quick but painful. Explain that giving medicine to relieve the pain may interfere with the determination of success. Inform the patient that there are no risks to attempting to manually reduce the torsed testicle. Potential complications include continued pain, increased pain, and the inability to detorse the testicle. No matter what result is obtained with manual detorsion, an operation will be necessary prior to discharge to prevent future episodes of torsion.[10] If manual detorsion is unsuccessful, emergent operative intervention may be required. Therefore, the patient should be kept *non per os* (NPO).

The use of anesthesia is not absolutely contraindicated. It may be required depending on the patient's age, ability to cooperate, and the examiner's preference. The use of a spermatic cord block should be avoided as it interferes with the patient's ability to assess pain and the determination of a successful detorsion.[30] The injection of local anesthetic solution into the spermatic cord may further compromise testicular blood flow.[31] Options for pain relief, when required, include procedural sedation (Chapter 129), intravenous analgesics, and/or intravenous sedatives.

TECHNIQUE

The direction of most torsions has been described as inward or medial, but they can also be outward or lateral.[10] This rotational predilection explains why the initial detorsion attempt should be in an outward or lateral direction (**Figure 151-2**). This has also been described as "detorse as you would open a book" or "supinate the hand as the testicle is rotated."[30] Another way to think of it is if you are looking at the patient from the foot of the bed. Rotate the patient's right testicle counter clockwise and the patient's left testicle clockwise (**Figure 151-2**).

Place the patient semirecumbent or supine. Stand next to the patient. Place the dominant hand on the patient's torsed testicle. Grasp the spermatic cord with the other hand to stabilize it from moving. Grasp the testicle gently but firmly. Rotate the testicle within the scrotum 180° outward (**Figure 151-2**). **There should be no resistance to the rotation.** While some authors have maintained the need to rotate the torsed testicle in two planes[33] (caudal to cranial and medial to lateral), others have reported success with single plane rotation.[26]

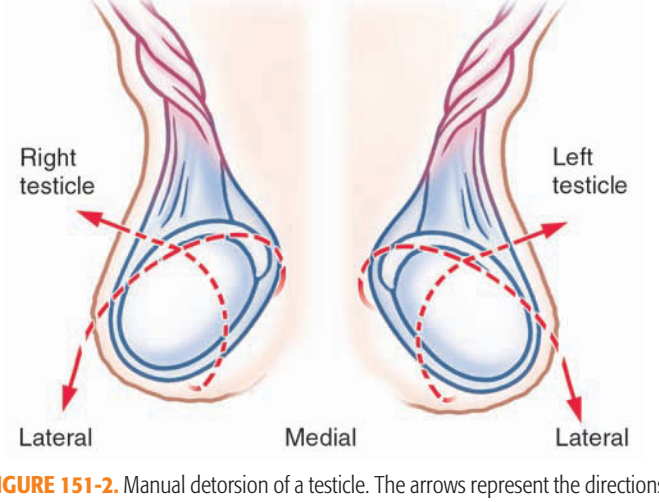

FIGURE 151-2. Manual detorsion of a testicle. The arrows represent the directions to initially attempt to rotate the testicle.

The average degree of torsion has been cited as 720°. It can range from 180° to 1080°.[10] **Continue to detorse the testicle until the patient experiences pain relief and the normal scrotal anatomy is restored.**[26] If at any point in the procedure the patient experiences an increase in pain or there is resistance to rotating the testicle, stop and attempt to detorse the testicle in the opposite direction.[32] Occasionally, a testicle may be torsed outward or laterally.

ASSESSMENT

Successful detorsion is marked by both the sudden relief of pain and the restoration of the normal scrotal anatomy. The normal anatomy is indicated by a lengthening of the spermatic cord and a vertical lie of the testicle.[33] If available, a Doppler stethoscope or color Doppler ultrasound may be used to monitor the effects of the detorsion. The resolution of edema will depend on the degree and duration of ischemia, but will not be as immediate as the pain relief. If the patient has relief of pain but the testicle is still high riding or horizontal, continue to detorse the testicle in the same direction until there is complete pain relief and a return of the normal scrotal anatomy.

AFTERCARE

All patients with a diagnosis of testicular torsion should be admitted to the hospital with an emergent Urological consultation. This is true despite a successful manual detorsion. The timing of the operative intervention will be changed from emergent to urgent if the testicle is detorsed in the Emergency Department.[32,34,35] Urgent surgery is still required because, even with pain relief, the torsion may not have been completely reduced. One study found evidence of continued torsion with venous congestion even after successful manual detorsion. Following testicular torsion, the patient must undergo bilateral orchiopexy. **The bell-clapper deformity that is implicated in many testicular torsions is almost always bilateral.[15] Therefore, the contralateral testicle is at increased risk for torsion.**

COMPLICATIONS

There are few complications to manual detorsion and none that should deter the Emergency Physician from an attempt at detorsion should it be indicated. The procedure is painful and detorsion in the wrong direction will initially increase the patient's discomfort. There is also the possibility that, despite proper technique, the Emergency Physician will be unable to detorse the testicle and emergent surgery will be required. If it turns out that testicular torsion is not the correct diagnosis, the patient will have endured an uncomfortable procedure without gain. While detorsion in the wrong direction may temporarily increase the degree of vascular compromise, it should cause no increase in ischemia if detorsed in the opposite direction. Complications may also arise from a delay in notification of the Urologist.[30]

A more serious potential complication stems from the false sense of security obtained when the patient has pain relief. Manual detorsion may only partially restore blood flow and rapid surgical intervention may still be required. Delaying the trip to the Operating Room due to lack of pain may cause "castration by procrastination."[30]

Due to the risk of impaired fertility after torsion, all efforts must be undertaken to preserve the contralateral testicle and future fertility. Animal studies suggest that detorsion of an ischemic testicle

can cause neurohormonal-mediated damage to the contralateral testicle.[36,37] However, these theories remain controversial and should not be used to justify not attempting a manual detorsion.[15,38]

SUMMARY

Emergency Physicians must be aware of the possibility and urgency of a testicular torsion. They should be prepared to rapidly attempt manual detorsion since "time is testicle." Early notification of the Urologist is essential as the ischemia time and testicular salvage are inversely proportional. Manual detorsion should be attempted on all patients as it may successfully relieve or reduce the ischemia, increasing testicular survival and future fertility. All patients with testicular torsion should receive definitive therapy and repair in the operating room to prevent future episodes of torsion.

152 Zipper Injury Management

Zach Kassutto

INTRODUCTION

Zipper injuries frequently occur to the foreskin, the skin of the penis, and the scrotum. Zipper injuries result in skin and soft tissue entrapment when the zipper is opened or closed. It primarily occurs in uncircumcised young boys, intoxicated adults, the mentally handicapped, males not wearing underwear, and elderly men suffering from movement or cognitive disorders. The most common type of zipper entrapment compresses the skin between the sliding piece (fastener mechanism) and the teeth of the zipper. Another type of entrapment involves the skin between the teeth of the zipper after the sliding piece has moved beyond the area.[1,2] Multiple methods to extract the entrapped skin have been reported.[1–15] These methods range from manipulation to tooth-by-tooth extraction to circumcision. Treatment should be guided by the type of entrapment.[1] Removal of the zipper can be performed quickly using basic tools to extract the entrapped tissue and thus prevent or limit secondary injury.

ANATOMY AND PATHOPHYSIOLOGY

The zipper is a simple device that is used daily by millions of people (**Figure 152-1**). It consists of a sliding piece that moves in two directions. The sliding piece is composed of a front and back plate connected by the median bar.[5] The median bar is usually located at the top of the sliding piece. A finger grip is attached to the front plate of the sliding piece and functions as a handle to move the sliding piece. The teeth are two opposing sets of rectangular metal or plastic pieces attached to fabric to keep them aligned. Moving the sliding piece across an open zipper will interlock the teeth and close the zipper. Reversing the sliding piece direction will unlock the teeth and open the zipper.

Although any area of skin can become entrapped in a zipper, it primarily occurs to the foreskin, penis, and scrotum. Entrapment often occurs in those who are in a rush to get dressed, not wearing underwear, or intoxicated, or in a rush to zip up their pants. Zipper injuries can be extremely painful. Patients are often unable to undo the entrapment themselves and present to the Emergency Department for help. Because this is an embarrassing injury, patients often present after attempts at self-extraction and a few hours after the injury. Delays in seeking medical care may result in significant edema that can complicate the removal of the entrapped tissue.

INDICATIONS

Skin entrapped between the sliding piece and teeth or between the teeth of the zipper must be extricated. The skin should be released as soon as possible to minimize edema and prevent necrosis.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of a zipper, the slider, or the teeth from an entrapped piece of skin. Consult a Urologist after releasing the entrapment in cases of significant edema, skin necrosis, urethral involvement, or infection.

EQUIPMENT

- Heavy-duty wire cutter or bone cutter
- Scissors, bandage or Mayo
- Scissors, small or iris
- Topical anesthetic, e.g., EMLA cream
- Local anesthetic solution without epinephrine
- Mineral oil
- Miniature hacksaw
- 27 gauge needle
- 5 mL syringe

PATIENT PREPARATION

Explain the procedure and aftercare required to the patient and/or their representative. Obtain appropriate consent to perform the procedure. Assess the patient's level of anxiety and pain as

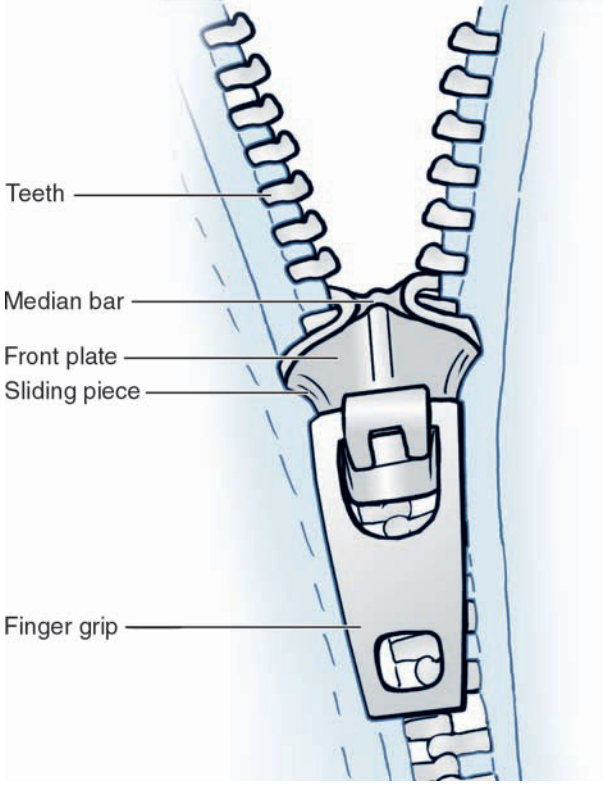

FIGURE 152-1. Anatomy of a zipper.

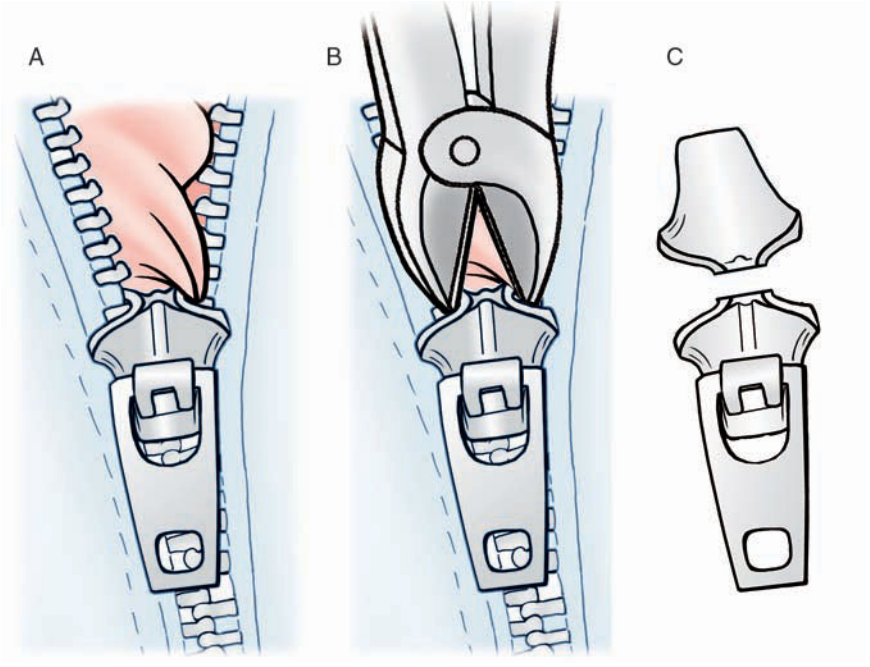

FIGURE 152-2. Cutting the median bar of the zipper. **A.** Skin entrapped between the sliding piece and the teeth. **B.** The median bar is cut. **C.** The front and back plates separate after the median bar is cut and the skin is released.

they must remain calm during the procedure to avoid secondary injury. The application of a topical anesthetic such as EMLA cream may be helpful but delays extraction of the entrapped skin. If the patient has significant pain, local anesthetic solution can be subcutaneously infiltrated around the entrapped skin or a penile block (Chapter 146) can be performed. The application of parenteral analgesia, sedation, or procedural sedation may be required in rare instances.

TECHNIQUES

MANUAL REMOVAL

Apply mineral oil liberally to the zipper and entrapped skin. Allow the mineral oil to soak the skin and zipper for approximately 10 minutes. Apply gentle but steady traction on the zipper, away from the entrapped tissue with special care to avoid further injury.[9,14,15] Attempt to dislodge the zipper manually. **Do not forcefully try to unzip it. Excessive force is unnecessary and can result in avulsions and lacerations to the skin.** If this fails to release the tissue, perform one of the zipper disassembly techniques listed below.

CUTTING OF THE MEDIAN BAR

The median bar can be cut with a heavy-duty wire cutter or bone cutter.[6,7] If the skin is entrapped between the sliding piece and the teeth (**Figure 152-2A**), carefully cut the median bar (**Figure 152-2B**). The front and back plates of the zipper will separate and release the entrapped skin (**Figure 152-2C**). Occasionally, the skin is entrapped between the teeth of the zipper (**Figure 152-3**). Cut the median bar of the sliding piece to remove the zipper. Manually pull the two rows of teeth apart to release the entrapped skin.

CUTTING OF THE CLOTH SURROUNDING ZIPPER TEETH

Occasionally, the skin is trapped between the teeth of the zipper and a wire cutter or bone cutter is not available.[8] Cut the cloth holding the zipper to the clothes with a bandage or Mayo scissors (**Figure 152-4**, long dashed lines). Using a small or iris scissors, cut the cloth between the individual teeth that are entrapping the skin (**Figure 152-4**, small dashed lines). Separate the teeth and free the entrapped skin.

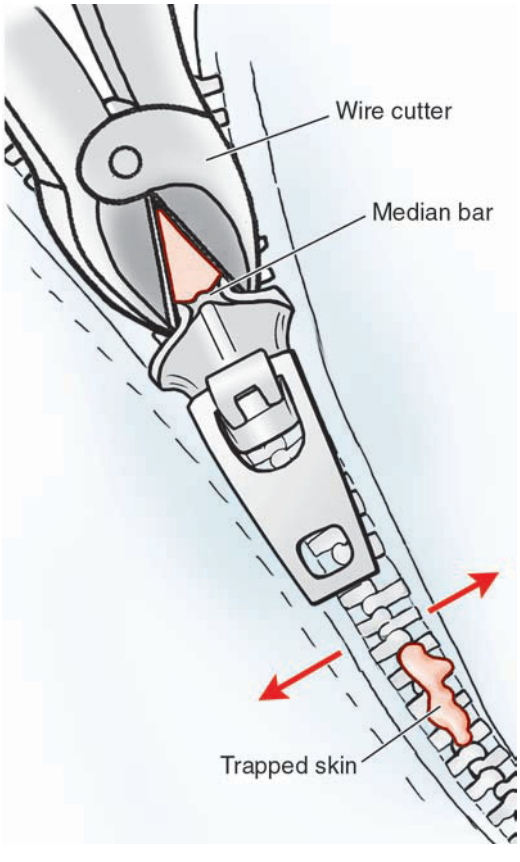

FIGURE 152-3. Skin entrapped in the zipper teeth. Cut the median bar to remove the zipper and manually separate (*arrows*) the two rows of teeth to release the entrapped skin.

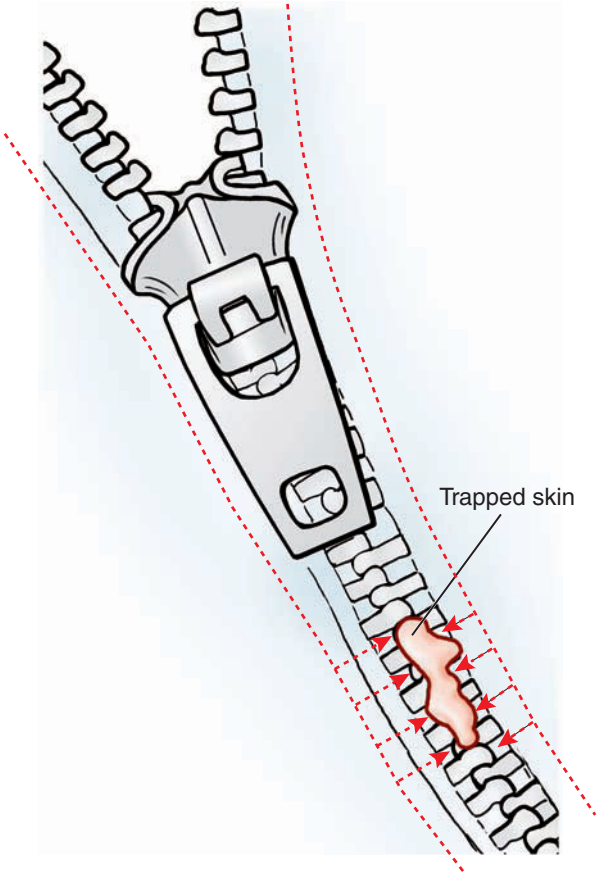

FIGURE 152-4. Skin entrapped in the zipper teeth. Cut the cloth holding the zipper to the clothes (*long dashed lines*) then cut the cloth between the teeth (*short dashed lines*).

This technique is less than ideal. Cutting the cloth between the teeth of the zipper may cause lacerations to the entrapped skin. It is very painful for the patient when the skin is cut. Exercise great caution when cutting the zipper. Given this risk, some prefer cutting the median bar of the fastener mechanism as described above. It is worth the additional time to locate and borrow a heavy-duty wire cutter from the Maintenance Department to cut the median bar.

CUTTING THE ZIPPER TEETH

Cutting the median bar requires the proper equipment and significant strength. Skin trapped between the teeth of the zipper can be released by cutting across the zipper teeth. Cut across the closed zipper teeth using a heavy duty scissors or wire cutter. Pull both halves of the zipper apart to release the entrapped skin. This method is faster and easier than cutting the median bar if the skin is trapped only in the zipper teeth.[12]

ALTERNATIVE TECHNIQUES

If an appropriate wire cutter or bone cutter is not available, or the median bar cannot be accessed with a cutter, the previously mentioned techniques for zipper removal cannot be performed. Alternative techniques do exist but are less than ideal. Each has its own risks and contraindications. The first option is to excise the entrapped skin. This should be considered only if the excised tissue is superficial or redundant and allows for easy removal. A second alternative is to cut the median bar with a miniature hacksaw blade to divide it.[10] This technique carries the risk for significant injury to the skin and soft tissues. A method using a screwdriver has been described to release skin trapped within the sliding piece.[13] Insert the flat blade between the inner and outer faceplates of the slider. Twist the screwdriver clockwise and counterclockwise to widen the gap between the faceplates and release the entrapped skin. If the aforementioned alternatives are not effective to remove a zipper, consult a Urologist for consideration of more aggressive surgical interventions such as an elliptical skin excision or a circumcision.[6,15]

ASSESSMENT

Assess the tissue for any signs of injury after the zipper has been removed from the skin. Any open wounds should be cleaned. Apply an antibiotic ointment and gauze bandage over the wound. A Urologist should be consulted for injuries to deeper penile or scrotal structures, if the entrapped tissue is not viable, if the tissue appears infected, or if the laceration is extensive.[11]

AFTERCARE

Patients with zipper injuries are usually discharged home from the Emergency Department. Their tetanus immune status should be checked and updated if necessary. The patient should be instructed on local wound care and signs of infection. They should return immediately to the Emergency Department if they develop redness, swelling, pus in the wound, or a fever. Otherwise, routine follow-up within 48 hours to evaluate any wounds or injured tissue is satisfactory for most patients. Although no guidelines or evidence exists, some physicians often prescribe oral antibiotics if there are any abrasions or lacerations to the skin. Nonsteroidal anti-inflammatory drugs can be used to provide analgesia.

COMPLICATIONS

Very few complications are associated with the removal of a zipper. Lacerations to the skin and deeper structures may occur. Superficial lacerations are commonly associated with cutting of the median bar. Deep lacerations are due to improper positioning of the wire cutter and can be prevented. Superficial lacerations will heal and require no special care. Large superficial lacerations and deep lacerations will require suturing. Hemorrhage from any laceration can be controlled with the application of manual pressure. Local infections may occur from zipper abrasions, abrasions and lacerations from removal of the zipper, or due to nonviable and crushed skin.

SUMMARY

Zipper injuries may occur when opening or closing a zipper. The foreskin, skin of the penis, and the scrotum are the structures most commonly entrapped and injured by zippers. Injuries are most common in uncircumcised young boys, but can occur in adults with some cognitive or physical impairment. After assessing the degree of injury and the type of entrapment, the zipper should be disengaged from the entrapped tissue. Zipper removal is quick, simple, and very satisfying to the patient.

SECTION 12

Ophthalmologic Procedures

153 Eye Examination

Shari Schabowski

INTRODUCTION

Emergency Physicians often approach the eye examination with some degree of apprehension. Eye complaints comprise up to 10% of Emergency Department visits. A systematic approach to the eye examination can alleviate any discomfort and provide the basis for an accurate diagnosis and treatment.[1–14] The most common ophthalmologic problems that present to an Emergency Department are injuries, inflammation, infections, and visual disturbances.

A careful history will help to guide the differential diagnosis and the physical examination. It must include a history of the presenting complaint, the mechanism of any injury, exposures to chemicals or infectious agents, baseline visual acuity, known ophthalmologic problems, baseline medical problems, current medications, and any known allergies. The eye examination progresses from the outside and works inward, beginning with the visual acuity to assess the function of the eye. **It is important to routinely inspect all anatomic structures of the eye regardless of the presenting eye complaint.** Secondary problems, such as corneal lesions associated with conjunctivitis, may be missed if a complete examination is not performed on all patients.

EYE ANATOMY

The bony orbit is pyramidal in shape and surrounds the eyeball and its associated neurovascular structures. The blood supply to the structures of the orbit originates from the ophthalmic artery. The anatomy of the eyeball and its surrounding soft tissue structures is demonstrated in **Figure 153-1**. A detailed discussion of the complex anatomy of the eye is beyond the scope of this chapter. The anatomy relevant to the eye examination will be discussed throughout this chapter.

VISUAL ACUITY

Visual acuity is referred to as the vital sign of the eyes. It provides a means for the functional assessment of this delicate sensory apparatus. **Documentation of the visual acuity is essential when approaching a patient with eye complaints.** Assess the patient's visual acuity as soon as possible, preferably as part of the triage assessment. Test and document the patient's visual acuity before the physical examination begins. There are few exceptions to this rule. Chemical exposures to the eye require immediate irrigation to avoid potentially irreversible visual loss. **In these cases, irrigation should not be delayed for visual acuity testing.** In all other cases, visual acuity testing should be the primary component of the ophthalmologic exam. **Failure to document visual acuity is a common omission and may have medicolegal ramifications.**

Always test each eye individually and then both simultaneously. Test and document the visual acuity with the respective annotation to the right eye (OD), the left eye (OS), and both eyes (OU). Test the problematic eye first. Completely cover the eye not being tested. Light shining into the opposite eye may adversely affect the results of visual acuity testing. A list of commonly used abbreviations in the measurement of visual acuity is presented in **Table 153-1**. Inquire as to the patient's baseline visual acuity and whether they wear corrective lenses for reference. Test the visual acuity using corrective lenses whenever possible. When corrective lens are unavailable, use of the pinhole device will help to correct any refractory errors. The abbreviations for the documentation of with and without correction are cc and sc, respectively.

Use caution when allowing contact lenses to be used as a visual aid in patients with eye pain, an eye injury, or an eye discharge. Their application may worsen the ocular condition. **Remove all contact lenses before the slit lamp examination and fluorescein staining. Fluorescein will permanently stain soft contact lenses and may stain hard contact lenses.**

An accurate assessment of visual acuity is essential and this cannot be overemphasized. It is not uncommon for a Physician to miss a secondary ophthalmologic diagnosis when they do not recognize a change in visual acuity. **As a rule of thumb, a patient with previously normal (20/20) vision with or without correction that has an acute deterioration to 20/50 or less suggests a serious ophthalmologic condition.** These cases require emergent consultation and prompt referral to an Ophthalmologist.

VISUAL ACUITY CHARTS

The Snellen eye chart is the most commonly used tool for assessing visual acuity (**Figure 153-2**). Place the Snellen chart on a flat wall in a well-lit room without obstructions. Place the patient standing 20 feet from the chart. With one eye completely covered, instruct the patient to read each line of the chart beginning at the top and proceeding to the bottom or until they are unable to correctly and consistently read the letters. The visual acuity is the fraction corresponding to the last line that the patient identifies at least half of the letters correctly (i.e., 20/40). The numerator corresponds to what the patient is able to see at 20 feet. The denominator corresponds to the distance where a patient with normal vision would be able to read the same line accurately. For example, a patient with a visual acuity of 20/40 sees at 20 feet what a patient with normal vision would see at 40 feet. Document the fraction corresponding to the line minus the number of letters missed if the patient is able to accurately identify more than half of the letters on that line (i.e., 20/40 −3).

When a patient is unable to read the Snellen chart at 20 feet, move the patient closer and reevaluate the visual acuity. Test the patient 10 feet from the chart. The test is the same at 10 feet as it is at 20 feet only the documentation changes. Recall that the numerator corresponds to the patient's distance from the chart. If starting at the 10 foot mark and the patient is able to read the letter at the line designated 20/200 then document 10/200. The test can also be performed at 5 feet or closer if necessary, with the appropriate change in the numerator.

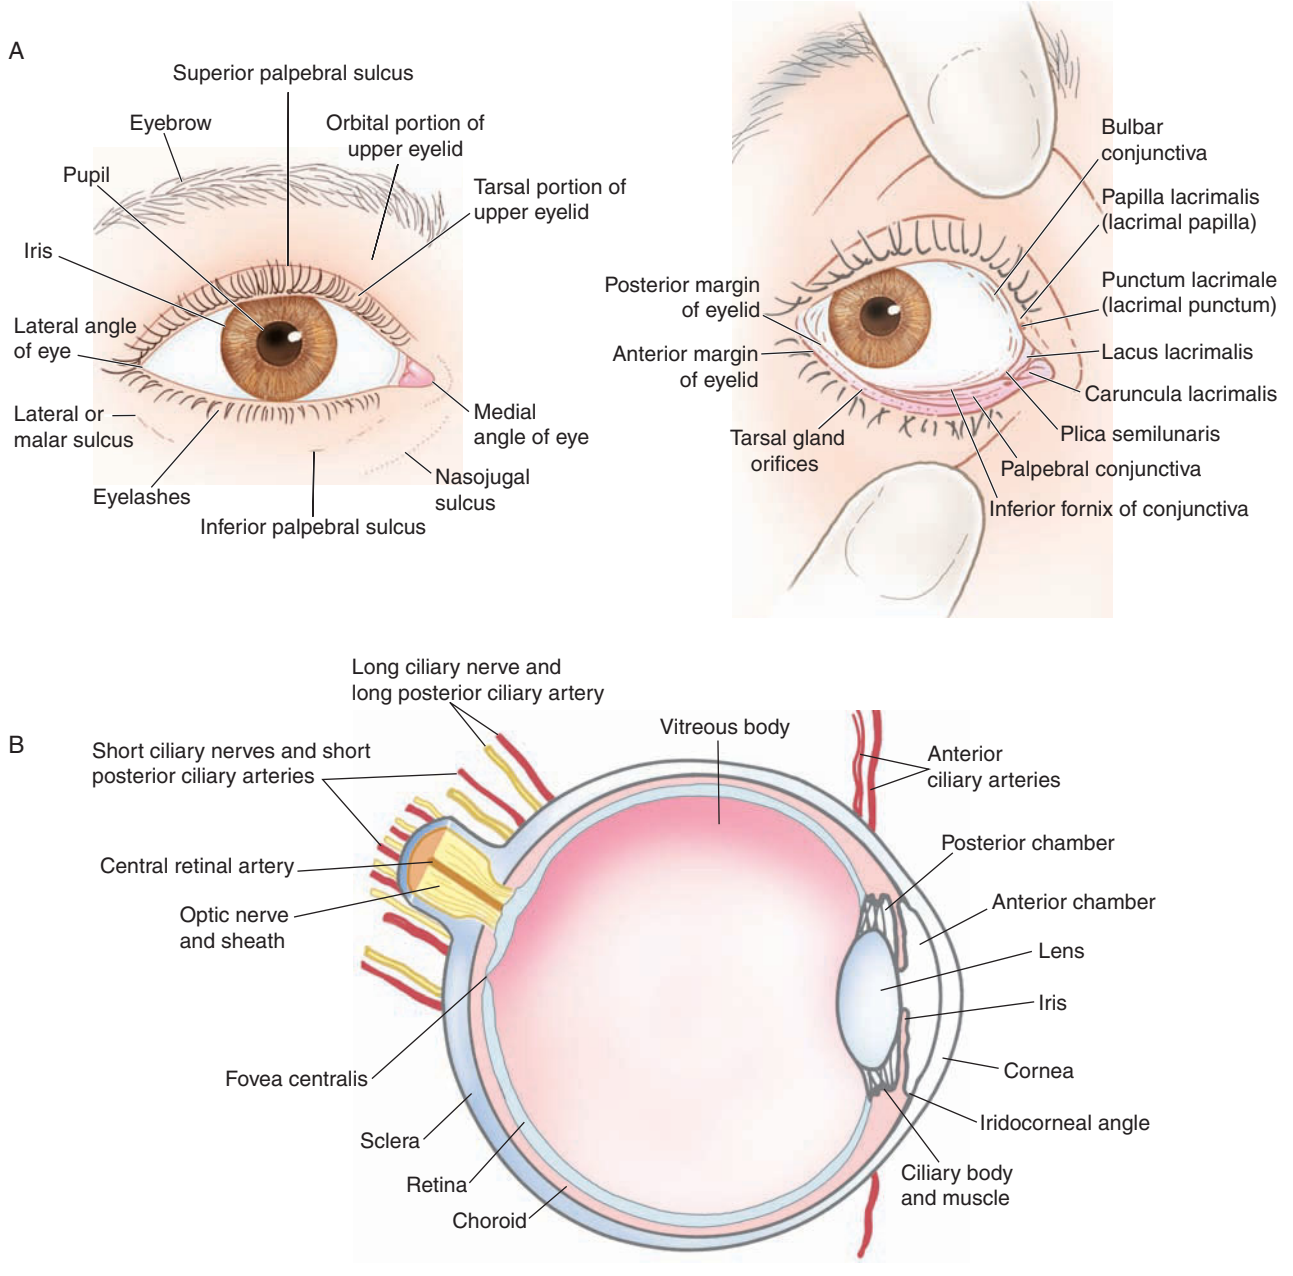

FIGURE 153-1. Anatomy of the eye and its surrounding soft tissues. **A.** Surface anatomy. **B.** Midsagittal section through the eyeball.

TABLE 153-1 Commonly Used Abbreviations for the Documentation of Visual Acuity

OD = right eye
OS = left eye
OU = both eyes
cc = with correction
sc = without correction
CF = counts fingers
HM = hand movement
LP = light perception
NLP = no light perception
+ = positive
– = negative

The Snellen chart is the most effective tool for documenting an accurate and reproducible visual acuity. There are circumstances that render this tool less effective and inaccurate. The chart utilizes the English alphabet and effective use requires that the patient can identify all letters. This is difficult, if not impossible, in patients who are illiterate or do not speak and/or read English. The illiterate E chart is an alternative (**Figure 153-3**). Instruct the patient to identify the direction that each "E" is facing. An alternative is to use a pediatric visual acuity chart (**Figure 153-4**). Instruct the patient to identify the objects on each line. Both of these visual acuity charts are assessed and documented like that of the Snellen chart.

There are a few circumstances where the standard eye chart may give falsely low and inaccurate readings. Patients with eye pain or photophobia may have difficulty reading the chart in bright light secondary to excessive lacrimation, blepharospasm, or pain. There

are several options to provide a more optimal assessment of visual acuity. A Rosenbaum card is the handheld equivalent of the Snellen chart (**Figure 153-5**). It is viewed at a distance of 14 inches. Its advantages are that it can be used in the patient's room with less-offensive lighting and it can adjust for refractory errors in near-sighted patients who present without correction. A clever idea that some use is to attach a 14 inch string to the Rosenbaum card so that it can be accurately tested at the exact distance each time. A near vision test for children may also be used to assess visual acuity (**Figure 153-6**).

Photophobia or eye pain, particularly that which results from corneal injuries or lesions, may prevent the patient from complying with the visual examination. They may often have difficulty opening the eye at all. The instillation of a topical ophthalmic anesthetic agent may be remarkably helpful as an adjunct to the visual acuity evaluation as well as for the remainder of the eye examination.

PINHOLE DEVICE

The pinhole device can filter out excessive light (**Figure 153-7**). It allows direct light rays to pass through the holes while blocking divergent light rays. This results in a sharper, but dimmer, image on the retina. The pinhole device may correct refractory errors to 20/30. An index card punctured multiple times with an 18 gauge needle can substitute if the pinhole device is not available. The pinhole device should be used in a well-lit room because it results in a dimmer image on the retina. Instruct the patient to place the pinhole device over the eye being tested and close the other eye. Instruct the patient to read the visual acuity chart. Record the patient's visual acuity in each eye. Make a notation in the record that the pinhole device (PH) was used in the measurement of the visual acuity.

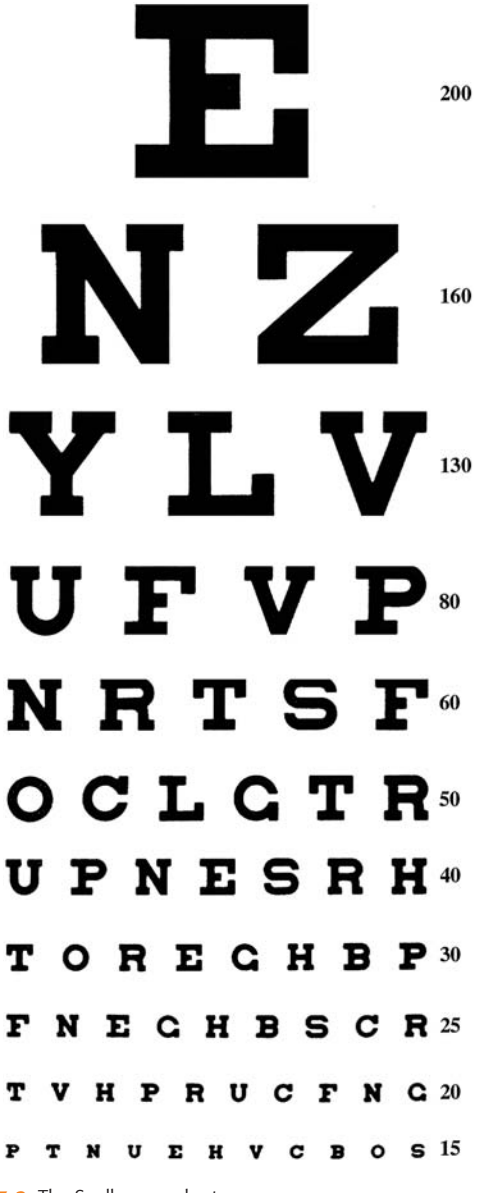

FIGURE 153-2. The Snellen eye chart.

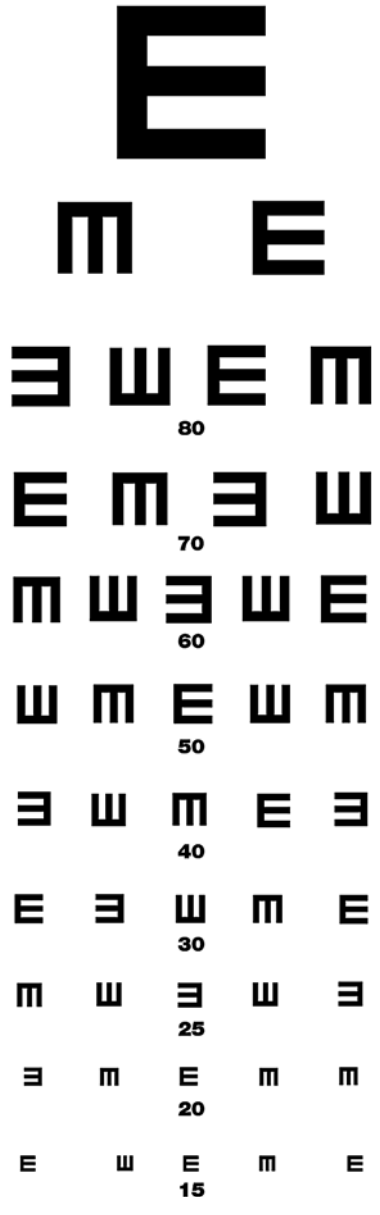

FIGURE 153-3. The illiterate E chart.

FINGER COUNTING

Another means of visual acuity assessment must be utilized if the patient is unable to identify the letter or object in the 20/200 position, the first and largest letter in the visual acuity chart. The next level of visual acuity that is traditionally accepted is the ability to count fingers (CF). It is important for documentation that the

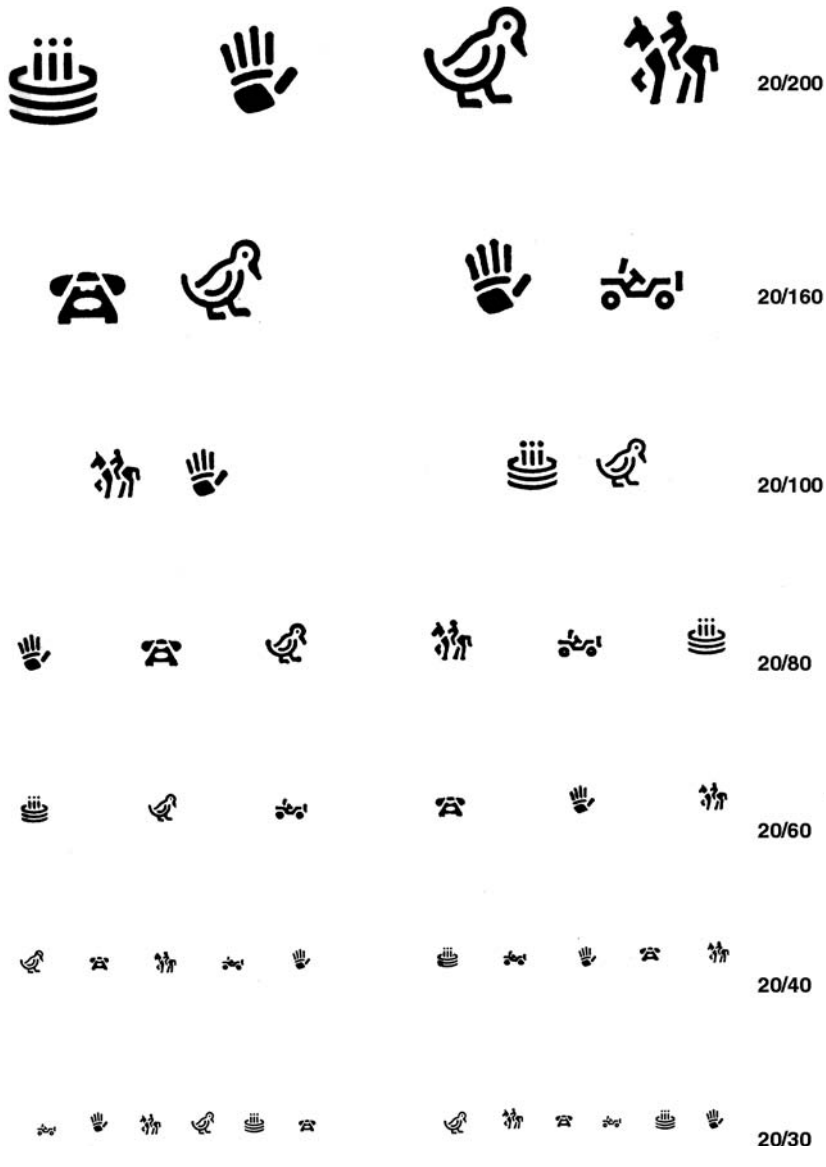

FIGURE 153-4. The pediatric visual acuity chart.

examiner note at what distance from the eye the patient is able to consistently count the examiner's fingers (e.g., OD CF at 12 inches). **The distance used for counting fingers is the distance where the patient is first able to accurately complete the test.** Test one eye at a time and then both eyes simultaneously.

Documentation of "CF at 2 feet" means that the patient can accurately count fingers starting at 2 feet. This implies that the patient cannot accurately count fingers if they were held at a distance greater than 2 feet. **It is thus very important to determine the distance where the patient can accurately count fingers and measure this distance with a tape measure and not estimate.**

HAND MOVEMENTS

The next test of visual acuity to perform is hand movements if the patient cannot count fingers. Move or wave a hand back and forth in front of the eye being examined. Document hand movement positive (HM+) or hand movement negative (HM–). Note the distance from the eye that hand movement is first visible (i.e., how close to the eye must the hand be positioned) in the medical record (e.g., HM+ at 12 inches). Test one eye at a time and then both eyes simultaneously.

LIGHT PERCEPTION

If the patient is unable to perceive hand movement, the next determination of visual acuity is light perception. Use a penlight or ophthalmoscope to determine the presence or absence of light perception. Shine the light directly into one eye while the opposite eye is covered. Document the patient's ability to correctly identify when the light is on and off. This is noted as light perception positive (LP+) or light perception negative (LP–). Test one eye at a time and then both eyes simultaneously. **True blindness is present when the patient has no light perception.**

UNCOOPERATIVE OR UNRESPONSIVE PATIENTS

Unresponsive patients are a challenge for the evaluation of visual acuity. First shine a light into each of the patient's eyes to test for pupillary reactivity. Move the light slowly through all of the cardinal positions to identify if the patient is able to track the light movement. Refer to the evaluation of extraocular movements section below. Perform the doll's eyes maneuver if the patient is unable to track the light.

A difficult situation occurs in the patient whose visual acuity is "no light perception or LP–" but has normal pupillary

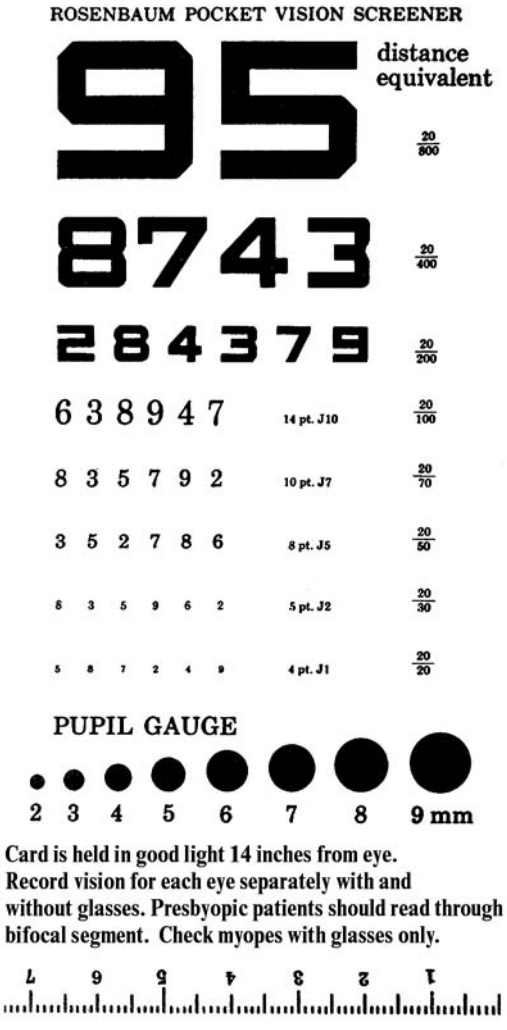

FIGURE 153-5. The Rosenbaum pocket vision screener.

responses and normal responses to the doll's eyes maneuver. This suggests that the visual loss is not anatomic or physiologic, but rather has a psychologic component. Test the optokinetic reflex using either a spinning device or a scintoscope in order to narrow the differential diagnosis. A patient who can see movement will not be able to resist the normal tracking response to the rotating cylinder. A positive response will appear as nystagmus upon examination.

PEDIATRIC VISUAL ACUITY TESTING

It is important to evaluate the vision of infants. There is a critical time during which visual problems must be corrected to avoid permanent visual disturbances. This is optimally before 4 months of age. The eyes continue to develop quickly up to 2 years of age. Refer any questionable visual disturbances to a Pediatric Ophthalmologist.

Infants from term delivery to 3 to 4 months of age are not able to consistently follow and track objects. An infant's eyes may not move in perfect alignment until the age of approximately 3 to 4 months. Infants begin to focus on faces and follow them at approximately 6 weeks of age. They should consistently focus on and follow objects at 4 months of age.

Testing an infant's vision can be quite difficult. Place the infant with their parent holding them in the feeding position. Cover one of the infant's eyes. Ask the parent to move their head from side to side. Note whether the infant's uncovered eye tracks the parent's face. Repeat this with the opposite eye covered. The inability to track objects suggests that the visual acuity is 20/200 or less.

Children who cannot yet read or identify the letters of the alphabet are at a disadvantage when using the Snellen chart (**Figure 153-2**). Use the illiterate E chart (**Figure 153-3**), the pediatric visual acuity chart (**Figure 153-4**), the pediatric near vision test (**Figure 153-6**), or the Allen chart (**Figure 153-8**) to test their visual acuity. The illiterate E chart requires the patient to identify the direction that each variably rotated letter E faces (i.e., up, down, right, and left). Some clinicians find it helpful to describe the E as a table and ask which way the legs are facing. The procedure and documentation is otherwise the same as with the Snellen chart. The pediatric charts use shapes of common objects in the place of letters and apply the same corresponding fractions for determining visual acuity. Have the child identify each of the pictures before beginning the examination to ensure that the child knows what the picture represents. Children may use unexpected words to identify the objects, which may complicate the interpretation of the exam.

GENERAL INSPECTION OF THE EYE

The examination of the eye proceeds from the outside and works inward. Begin with inspecting the external structures. Note the presence of any enophthalmos or exophthalmos. This is best accomplished by viewing the eyes from above and behind the patient. The normal globe position is just within the orbital rim. Enophthalmos is a recession of the globe within the bony orbit. It is an important clue for the presence of a blow-out or orbital floor fracture. Exophthalmos is a protrusion of the globe from the bony orbit. It may be an important clue to the presence of a retrobulbar hemorrhage or an orbital cellulitis. Esotropia refers to an inward or nasal deviation of the globe. Exotropia refers to an outward or temporal deviation of the globe.

Evaluate the eyes and eyelids for symmetry, lid position, obvious injuries, lesions, discoloration, and/or swelling. Ptosis suggests a Horner's syndrome or a third cranial nerve abnormality. **Any evidence of facial trauma or eye trauma raises the possibility of a ruptured globe. Avoid placing pressure directly on the globe if there is any possibility of a ruptured globe. Inadvertent tactile pressure placed on a ruptured globe may result in extrusion of intraocular structures.** This can result in an otherwise avoidable visual loss that is typically not reparable. Manipulate the eyelids by applying pressure over the bony orbit instead of directly on the globe (**Figure 153-9**).

EVALUATION OF EXTRAOCULAR MOVEMENTS

Extraocular movements are easily assessed in the cooperative patient. Instruct the patient to keep their head still and directed toward the examiner. Instruct the patient to follow the motions of a finger with only their eyes as it follows the pattern of an H (**Figure 153-10**). This is referred to as the six cardinal positions for testing extraocular muscle movements. It may be helpful to retract the patient's eyelids to better visualize the eye movements. Observe the eyes for symmetric or conjugate gaze as each position is reached. Note whether the patient sees one finger clearly at each position. Ask the patient to describe the orientation of the images (i.e., side to side) if more than one image is noted. Assess the far lateral positions by paying careful attention for evidence of nystagmus. A few beats of nystagmus that quickly extinguishes is within normal limits.

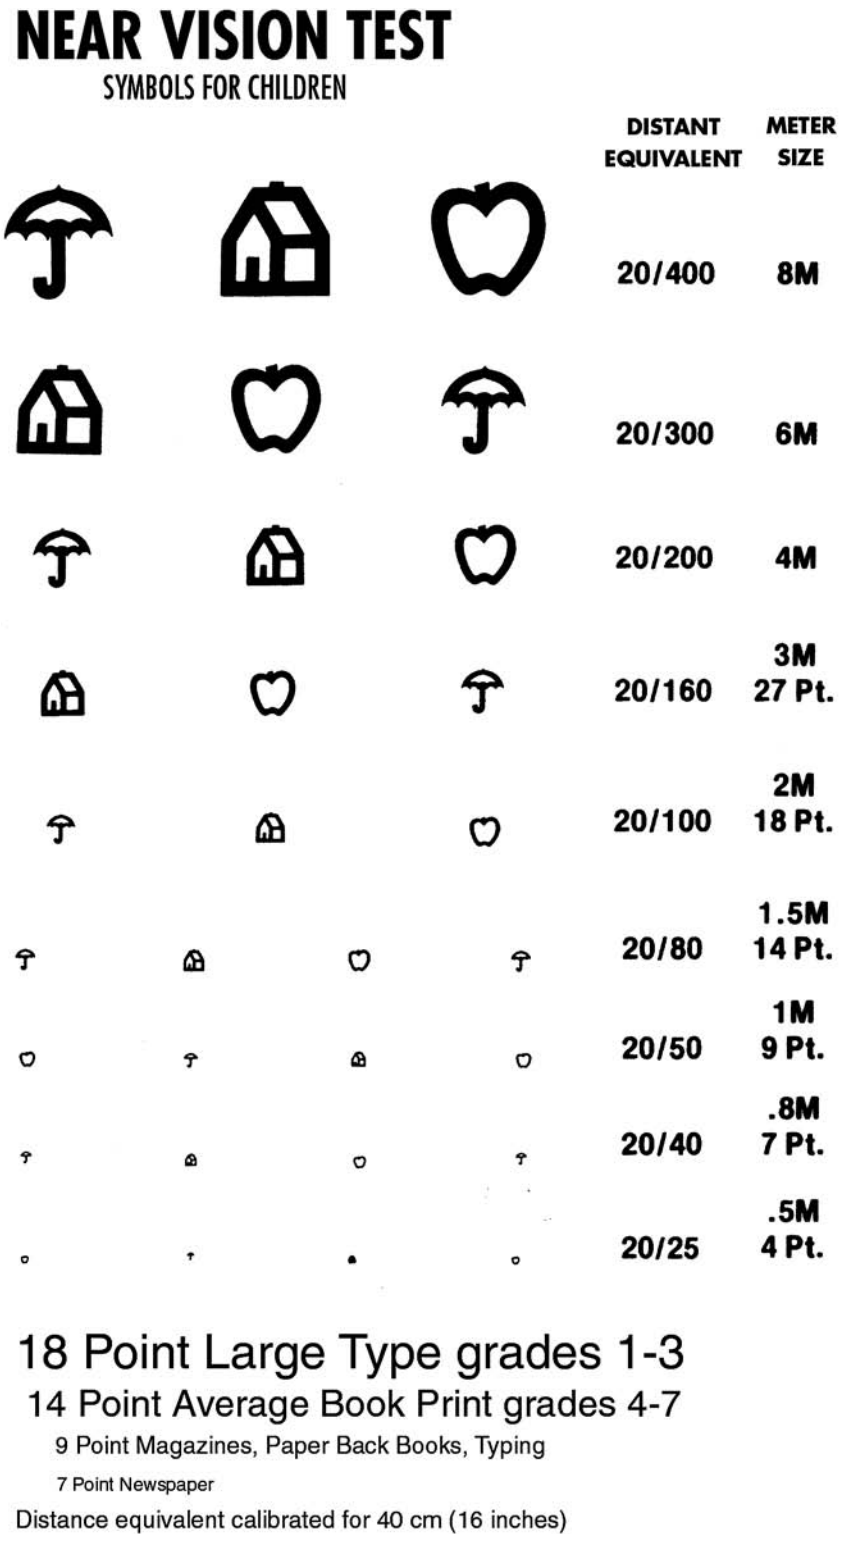

FIGURE 153-6. The near vision visual acuity test uses symbols for children.

Keep in mind that the nose may obstruct the view at extreme points. Move the examining hand into a plane that is a few inches closer to the examiner if this occurs (i.e., a few inches away from the patient), and repeat the testing.

It is helpful to use a penlight directed toward the patient's eyes during the examination when a question of subtle disconjugate gaze is entertained, particularly in the position where the patient complains of diplopia. Look into the patient's pupils to see the reflection of the light (**Figure 153-11**). The reflection of the light is symmetrical, located in the same position in each pupil, if the gaze is conjugate (**Figure 153-11A**). Asymmetrical light reflection is noted in cases of disconjugate gaze (**Figure 153-11B**).

Consider the innervation of the extraocular muscles in order to narrow the differential diagnosis when abnormal extraocular movements are identified. The lateral rectus muscle is innervated by the sixth cranial nerve (CN VI). The superior oblique muscle is innervated by the fourth cranial nerve (CN IV). The remaining extraocular muscles are innervated by the third cranial nerve (CN III). An

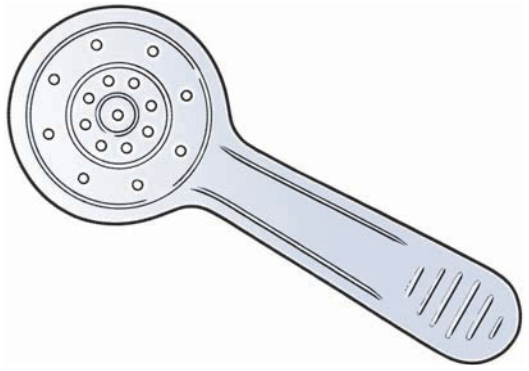

FIGURE 153-7. The pinhole device.

isolated sixth cranial nerve palsy, particularly in a child, strongly suggests an intracranial neoplasm. A complete third cranial nerve palsy suggests an intracranial aneurysm pressing on the oculomotor nerve, particularly when the pupil is involved. A physical obstruction originating in the retrobulbar region manifests as restricted extraocular movements in one eye. Consider the presence of an orbital cellulitis or a retrobulbar hemorrhage in the appropriate clinical setting.

Consider the presence of an orbital floor or blow-out fracture if the patient is unable to elevate one of the eyes. The etiology of the restricted movement may be physical entrapment of the inferior rectus and/or inferior oblique muscles within the orbital floor fracture or a contusion of the nerve innervating the inferior oblique muscle. The two must be distinguished by an Ophthalmologist as the management, treatment, and follow-up are different. Place two drops of a topical ophthalmic anesthetic agent into the affected eye. Grasp the bulbar conjunctiva with forceps and attempt to gently elevate the eye. A physical cause is ruled out if the eye is able to be elevated and a nerve contusion is likely.

EXAMINATION OF THE PUPILS

Place the patient with their head looking directly forward while retracting the upper eyelid. Complete the pupillary examination and a cursory evaluation of the cornea and anterior chamber simultaneously. Clinicians commonly use the abbreviation "PERRLA" as documentation for the pupillary examination. "PERRLA" means the pupils are equal, round, and reactive to light with normal accommodation. **Be sure that you assess accommodation if you use this acronym. In any case, this abbreviation is typically inadequate when a patient has emergent eye complaints.**

When dealing with emergent eye complaints it is important to document a detailed pupillary exam. Darken the room as much

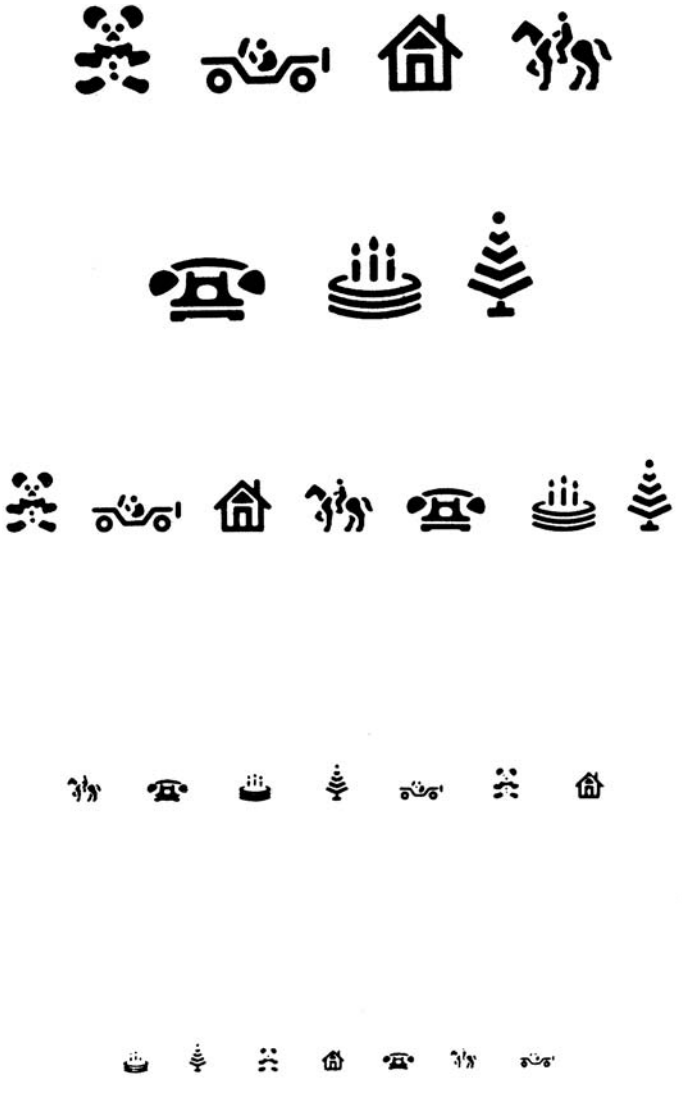

FIGURE 153-8. The Allen chart to measure pediatric visual acuity.

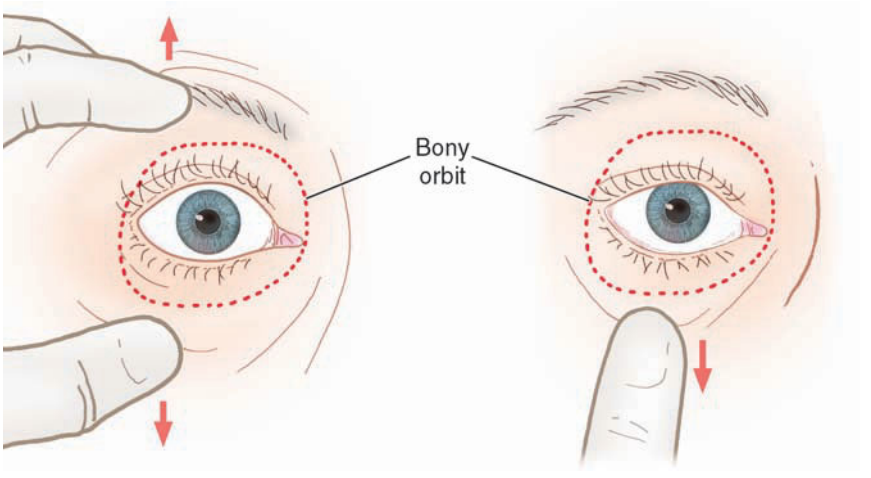

FIGURE 153-9. Open and close the eyelids by applying pressure over the bony orbit in suspected cases of a ruptured globe.

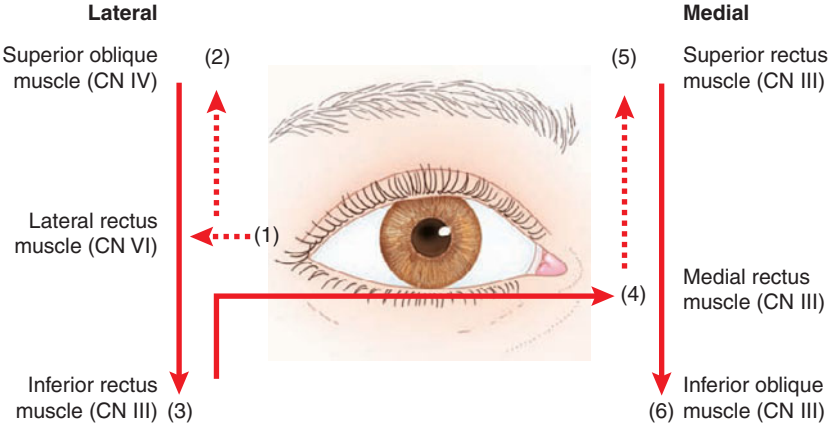

FIGURE 153-10. The six cardinal positions for testing extraocular muscle movements. Start with the eye facing forward and follow the order of the numbers, also known as the six cardinal positions. Note that the testing follows an H-shape.

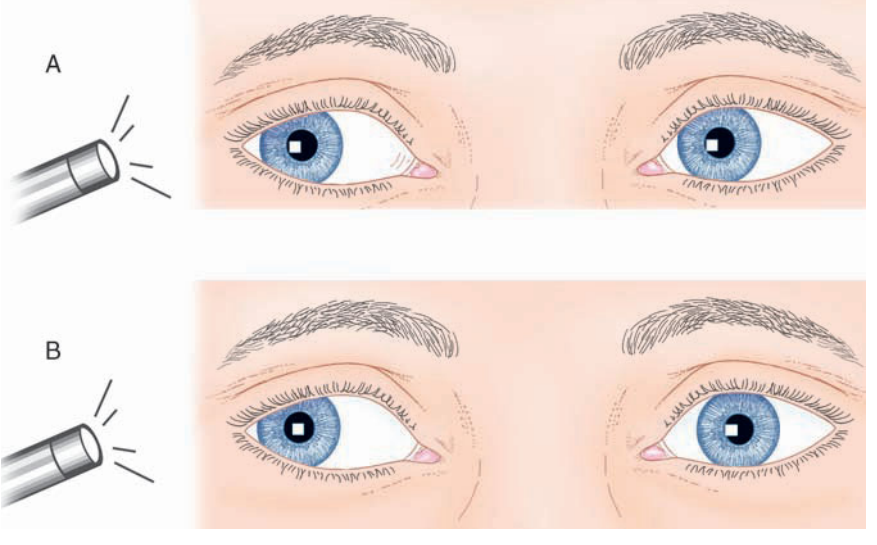

FIGURE 153-11. Shine a penlight into the eyes in the position that the patient complains of diplopia. Observe the light reflection in the pupils. **A.** Conjugate gaze. **B.** Disconjugate gaze.

as possible. Instruct the patient to focus on a distant object. The normal response is symmetric dilation of the pupils. Note the size, in millimeters, of each pupil. Shine a focused beam of light into one eye to test reactivity, or the direct pupillary response to light. The normal pupil will constrict immediately and briskly. Document the direct response to light in millimeters at maximal constriction (e.g., OD = 4 mm → 2 mm). Note if the pupil is not briskly reactive (e.g., OS = 5 mm → 3 mm, sluggish) or if it dilates (e.g., OS = 3 mm → 6 mm). Repeat this test with the contralateral eye.

The consensual pupillary response is the reaction of the contralateral eye to light shined into the opposite eye. The normal consensual pupillary response is constriction of the contralateral pupil when light is shined into the opposite eye. This occurs because some of the efferent optic nerve fibers cross the midbrain to the contralateral optic tract and result in constriction of the contralateral pupil. Be careful to document a normal consensual response if it is present.

When assessing an inflamed eye, the consensual pupillary response can be used as a diagnostic tool. Close and cover the affected eye and shine the light in the opposite eye. With the cornea protected by the lid on the affected side, if the consensual pupillary response causes pain in the affected eye it suggests deep inflammation or a uveitis.

A common example of an abnormal pupillary examination illustrates the importance of paying specific attention to the consensual pupillary response. The relative afferent pupillary defect (RAPD) results from the tested eye not perceiving the light. There is no perception of light (LP–) transmitted to the optic tracts. The tested pupil will not constrict to direct light. The pupil may, in fact, inappropriately dilate in response to direct light. There will be no consensual response in the contralateral pupil. The contralateral pupil will constrict appropriately to direct light and the previously unresponsive pupil will demonstrate a normal consensual response. The "swinging flashlight test" is used to test for a RAPD. Shine the light into one eye. Note the direct and consensual responses. Swing the light over to test the opposite eye. Note the direct and consensual responses.

A common problem for the Emergency Physician is the patient with unequal pupils. In the appropriate context, the primary consideration is typically a "blown pupil" suggesting an uncal brain herniation from a mass lesion. This would be very unusual in a patient who is awake, alert, and cooperating with the eye examination. In this case, physiologic anisocoria is the most common cause. Patients with physiologic anisocoria will have a normal response to light and typically the difference in pupillary size will be no more than 2 to 3 mm. **If the response is abnormal, the Emergency Physician must determine which of the two pupils is problematic.** The normal response to a darkened room is dilation. The pupil that does not dilate is abnormally miotic. The appropriate response to bright light is constriction. The pupil that does not constrict is abnormally mydriatic.

It is important to note and document the shape of each pupil. They should be round and regular. Irregularly shaped pupils may give important clues to otherwise undiagnosed injuries. A "D-shaped" pupil suggests a disruption of the ciliary muscles in the region adjacent to the flat part of the "D". A teardrop-shaped pupil suggests a ruptured globe, with the point of the teardrop directed toward the point of penetration. A quivering and dilated pupil that does not react appropriately to light suggests a lens dislocation partially obstructing the visual axis. An irregularly shaped pupil may be an important diagnostic clue, but do not be misled. The most common cause of an irregularly shaped pupil is a postoperative change. **Always inquire about previous eye surgery or old injuries, especially if an abnormality is noted.**

A new device, the NeurOptics® NPi™-100 pupillometer, has been developed to accurately measure pupil size and reactivity (NeurOptics, Irvine, CA). This handheld device is easy to use, takes over 30 pictures a second, analyzes the pictures, and prints via infrared to a portable printer. It can display values over time numerically or graphically. While not for routine daily use, it has a role in the evaluation of critically ill or injured patients.

EXAMINATION OF THE EXTERNAL STRUCTURES

The examination should proceed from the outside and work inward following an anatomic checklist. Examine the eyelids, lash line, and tarsal plates. Examine them for symmetry, normal position of the eyelashes, injury, infection, or inflammation. Examine the puncta of the lacrimal apparatus for signs of inflammation and obstruction. Examine the bulbar conjunctiva and vasculature for injection, ciliary flush, chemosis, discharge, and foreign bodies. Examine the cornea for clarity, evidence of injury, lesions, or foreign bodies. Examine the palpebral conjunctiva and cul-de-sac for injection, foreign bodies, discharge, and lymphatic (follicular) enlargement. Examine the anterior chamber for clarity, depth, and particulate matter.

Expose the structures of the inner aspect of the upper eyelid. Evert the eyelids (**Figures 153-12 & 153-13**) or retract the eyelids (**Figures 153-14 & 153-15**). Place the patient facing forward

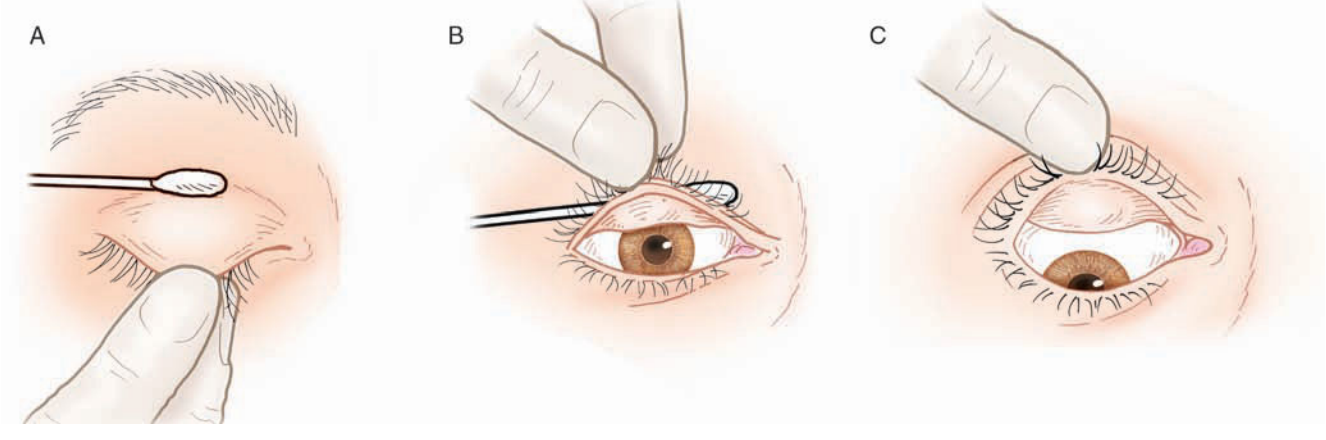

FIGURE 153-12. Eversion of the upper eyelid. **A.** Grasp and pull down the upper eyelashes while simultaneously placing a cotton-tipped applicator at the base of the upper eyelid. **B.** Flip the upper eyelid over the cotton-tipped applicator. **C.** Hold the everted eyelid in place and gently remove the cotton-tipped applicator.

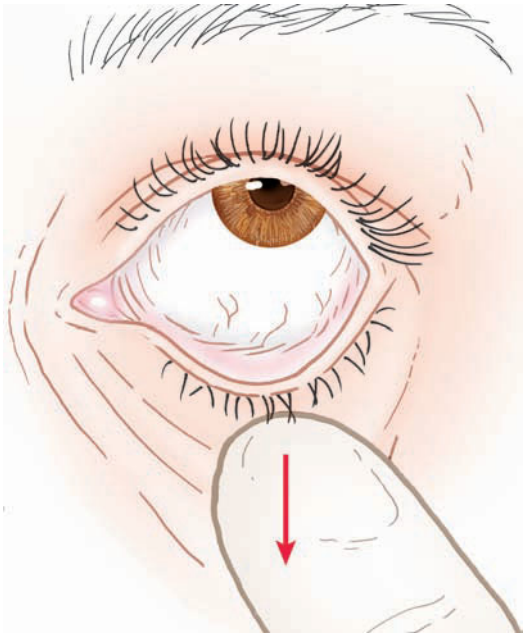

FIGURE 153-13. Eversion of the lower eyelid.

with their eyes focused downward to evert the upper eyelid (**Figure 153-12**). **The patient's eyes must remain directed downward during the entirety of the exam as looking up or forward will cause the eyelids to return to their natural position.** This process requires the use of a cotton-tipped applicator. An assistant may be required to aim and focus a light source during the examination as it may require two hands to evert and hold the eyelids in position.

Grasp the midpoint of the upper eyelash line or the tarsal plate between the index finger and thumb (**Figure 153-12A**). Place a cotton-tipped applicator 0.5 to 1.0 cm superior to the tarsal plate, with the cotton tip in the midplane of the upper eyelid (**Figure 153-12A**). Apply gentle pressure directed slightly downward against the upper eyelid with the cotton-tipped applicator. Use the other hand to pull the eyelid upward and evert it (**Figure 153-12B**). The upper eyelid may not completely evert. Sweep the cotton-tipped applicator from left to right while still holding the lash line in one hand and simultaneously applying gentle downward pressure with the applicator within the false pocket to completely evert the upper eyelid (**Figure 153-12C**). Gently and slowly remove the cotton-tipped applicator.

Eversion of the lower eyelid is much simpler (**Figure 153-13**). Instruct the patient to look upward. Place the index finger on the patient's lower eyelid. Apply downward traction to evert the lower eyelid.

The use of a Desmarres eyelid retractor is an alternative option, if available, to retract the eyelids. It is very difficult to manually evert the eyelids when they are swollen. Manual eyelid eversion can result in excessive pressure being placed on the potentially injured globe. An eyelid retractor can be used to avoid placing pressure on the globe (**Figure 153-14**). Place the patient facing forward with their eyes directed downward. Place the eyelid retractor approximately 5 mm above the tarsal plate on the outer surface of the eyelid (**Figure 153-14A**). Grasp the midpoint of the upper eyelash line or the tarsal plate between the index finger and thumb. Slightly retract the upper eyelid away from the globe. Elevate and retract the tarsal plate upward to evert the eyelid onto the retractor (**Figure 153-14B**). Lift the retractor upward to fully expose the undersurface of the eyelid (**Figure 153-14C**).

This technique allows the eyelid to be retracted with one hand while directing the light with the other hand. It also prevents any pressure from being placed on the globe if a rupture is suspected. It may be necessary to slide the retractor 0.5 cm to the left and to the right of midline to fully visualize the ocular structures. Use the same technique to retract the lower eyelids. Instruct the patient to direct their gaze and focus upward when retracting the lower eyelid.

A simple method to retract, but not evert, the eyelid with the Desmarres retractor is shown in **Figure 153-15**. Place the eyelid retractor in front of the upper eyelid (**Figure 153-15A**). Gently insert the retractor under the upper eyelid (**Figure 153-15B**). Apply slight outward traction on the retractor to securely grasp the tarsal plate. Rotate the retractor upward to retract the upper eyelid (**Figure 153-15B**). Elevate the retractor upward to open the eyelid (**Figure 153-15C**). Use the same technique to retract the lower eyelid. **Never use this technique if a foreign body or ruptured globe is suspected.** It may cause secondary injury by embedding a foreign body, perforating the globe with the foreign body, or expressing the ocular contents if the globe is ruptured.

Eyelid retractors are not uniformly available in all Emergency Departments. They should be part of an "eye kit" (**Table 153-2**). An alternative used by some is to unfold a paper clip and bend it into shape with a hemostat (**Figure 153-16**). **This is not recommended by the editor as the metal coating on the paper clip flakes off and can result in corneal abrasions and foreign bodies.** Plastic-coated paper clips, if available, might be a safer alternative to metal paper clips.

SLIT LAMP EXAMINATION

The slit lamp is an essential piece of machinery for a thorough eye examination (**Figure 153-17**). It is an invaluable resource that can be used to identify and aid in the treatment of ophthalmologic problems that might otherwise go unrecognized. It provides an adjustable light source with variable magnification. The eyes remain in a fixed position while the light and microscope are

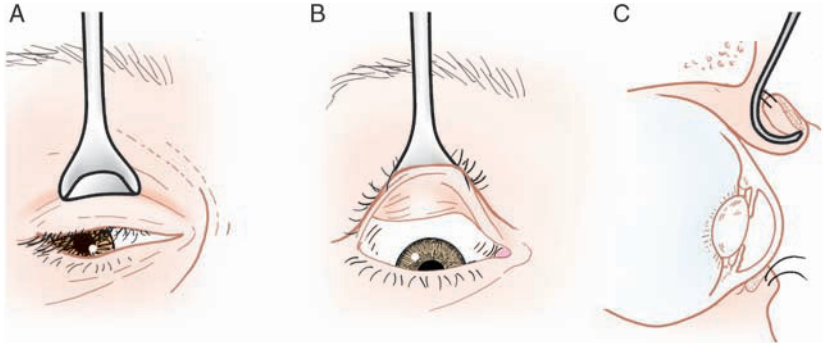

FIGURE 153-14. Eversion of the upper eyelid with a Desmarres retractor. **A.** Place the retractor 5 mm above the tarsal plate. **B.** Grasp the eyelashes and evert the upper eyelid over the retractor. **C.** Elevate the retractor to fully expose the under surface of the eyelid.

independently adjusted. The result of these attributes is that it can focus precisely on the structures of the eye and provide a three-dimensional image. The slit lamp provides valuable information, particularly when examining the cornea and the anterior chamber. The three-dimensional microscopic capability is best demonstrated when examining the intricate topography of the iris.

It may be helpful to set up the slit lamp before the patient is in the room until one feels comfortable using the slit lamp. Place one hand against the middle of the forehead bar in the examination plane to help become familiar with the capabilities of the machine and the joystick. Practice focusing the slit lamp on the details of the skin on your hand. Adjust the focus and depth of vision by sliding the joystick to move the entire slit lamp apparatus forward and backward. Slide the joystick side to side to scan across and examine the entire width of the hand. Rotate the joystick clockwise and counterclockwise to move the line of vision up and down.

Place the slit lamp in the standard position. **It takes very few adjustments of the slit lamp to complete the entire examination.** The slit lamp can be focused and locked in position with the knob located on the table base for procedures that require the Emergency Physician's hands to be free (e.g., foreign bodies embedded within the cornea). This allows one hand to hold the eyelids open while using the appropriate tool in the other hand.

SETTING UP THE SLIT LAMP

The slit lamp has many parts, most of which are capable of movement. The slit lamp components are often moved into a complete disarray by previous users. The position should be checked when the Emergency Physician sits down to use the slit lamp. **It is important to start by readjusting the slit lamp to a "standard operating position."**

TABLE 153-2 Recommendations for a Complete Emergency Department Eye Examination Kit

Rosenbaum card
"E" chart
Pinhole device
Lid retractor
Fluorescein strips (individually packaged)
Slit lamp
Alcohol swabs
Ophthalmoscope
Topical anesthetic agent, e.g., proparacaine or tetracaine
Topical mydriatic agent, e.g., phenylephrine
Topical cycloplegic agents, e.g., homatropine or cyclopentolate
Topical pupillary constrictors, e.g., pilocarpine and timolol

The body of the slit lamp has three rotating arms. The examiner's neutral position is designated as 0° and the center of the chin rest is designated 180°. The lower arm rotates the binocular microscope. It is rarely, if ever, necessary to move the rotating binocular microscope from the 0° position for the purposes of an Emergency Department examination. The next two arms are moved as a unit. The lower arm rotates the light 90° in either direction. The light source remains directed toward the structure that is being focused upon. The angle of the light is changed when the arm is rotated up to 90° in either direction. The standard position for the light is to rotate it 45° to the examiner's left to examine the patient's right eye and 45° to the examiner's right to examine the patient's left eye. Rotation of the upper arm independently rotates the slit of light in the coronal plane. It is unnecessary to rotate the two upper arms independently during the Emergency Department examination.

The eyepieces of the binocular microscope can be adjusted and focused independently in accordance to the Emergency Physician's needs. The standard starting position is in the 0 and 0 position. The eyepieces can be adjusted to compensate for refractory errors and to correct for the interpupillary distance of the Emergency Physician.

Two levels of magnification are typically available (10× and 16×). The switch to change magnification is located just below the eyepieces. The standard beginning position is low magnification. The

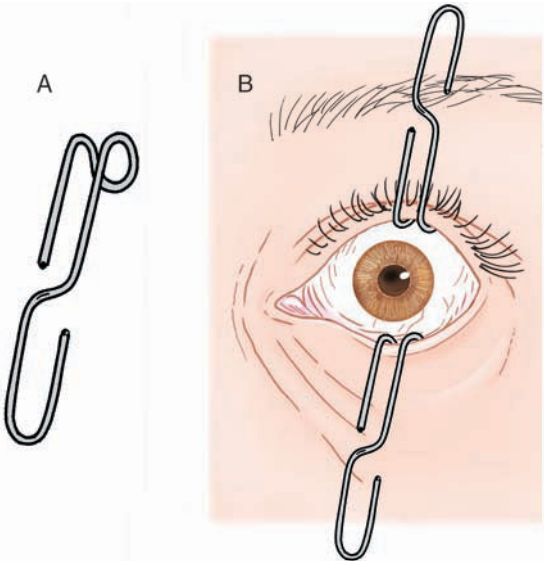

FIGURE 153-16. An alternative to an eyelid retractor. **A.** Unfold a paper clip and bend it into shape with a hemostat. **B.** Paper clips used to retract the eyelids.

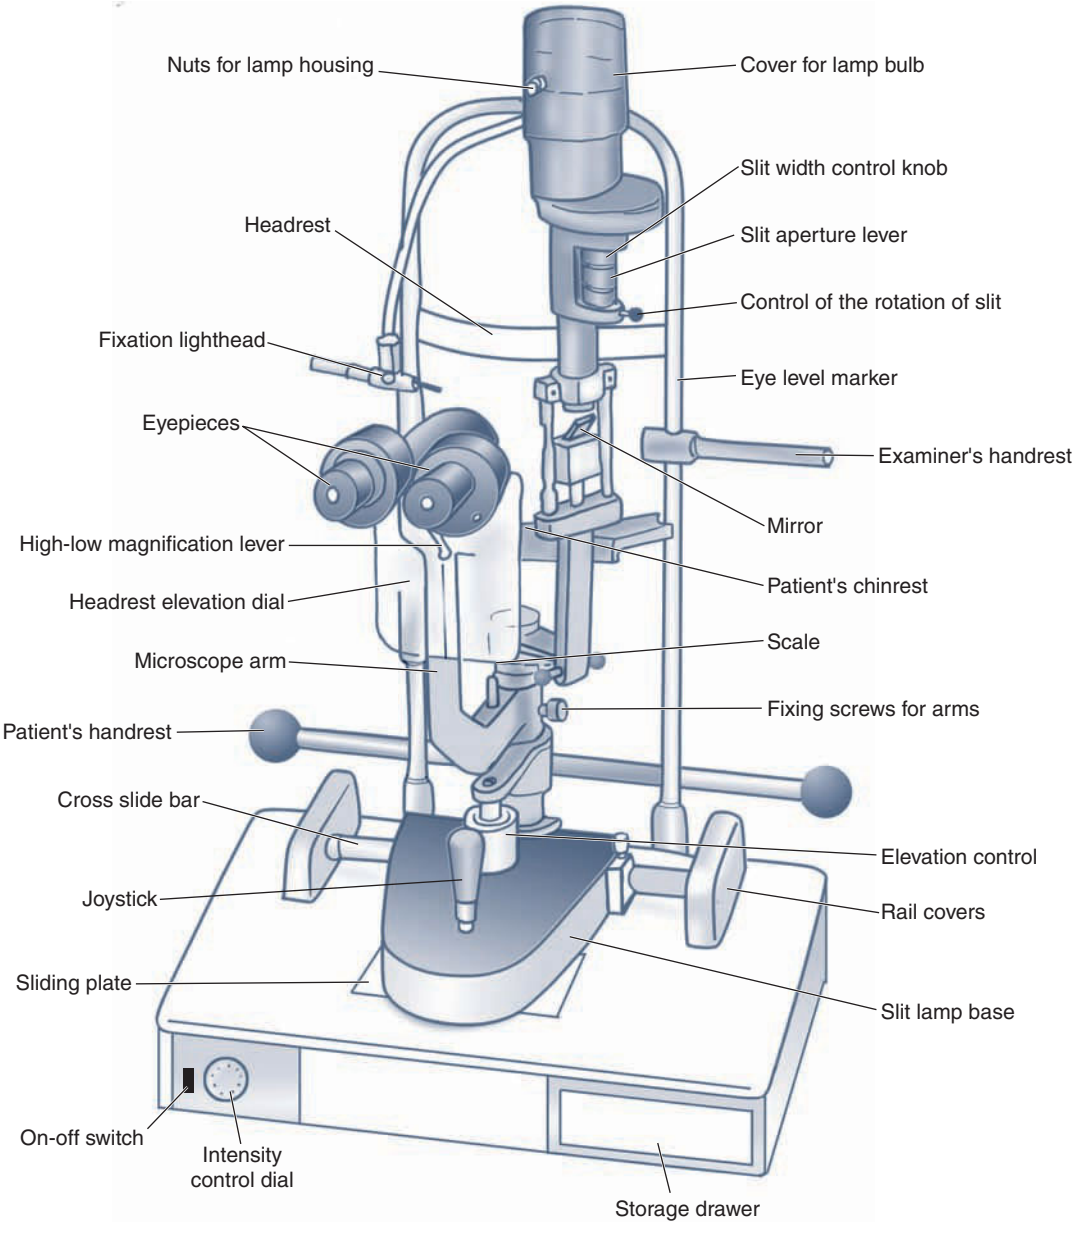

FIGURE 153-17. The slit lamp.

higher power may be helpful when examining the details of the cornea or looking for cellular or inflammatory material within the anterior chamber.

The next step is to find the on–off switch. It is typically located just under the table base and on the left. Place one hand in the examination plane against the headband where it should pick up a focused beam of light to ensure that the light source is functional. Observe the top of the slit lamp to determine whether light shines through the casing that houses the light source. The bulb will periodically need to be replaced. Remove the casing and replace the bulb as needed. The correct position for the bulb is obvious as it has a notch that fits into a corresponding notch in the housing.

The focused light can be adjusted in intensity, color, vertical width, and horizontal width. The standard position is for the light to be at its maximum size with a circular beam of white light at a moderate intensity. This position is used for scanning the eye and examining the external structures. Three independent adjustment mechanisms interact to create the most appropriate illumination to meet examination needs.

The color of the light and the intensity of the light originate from the same mechanism. Most of the positions represent variations in intensity of a white light. There are two other options for color. The cobalt blue light is used for emphasizing corneal lesions that pick up fluorescein stain. The green light or red filter is helpful for patients who cannot tolerate the white light secondary to photophobia. This green light will cause red structures to appear darker or black.

The horizontal width of the light can be adjusted with the knob located at the base of the middle arm. The light can be narrowed to 1 to 2 mm or a "slit" for evaluating the depth of corneal lesions (**Figure 153-18A**). The vertical control is used in conjunction with the horizontal control. Narrow the horizontal width to 2 to 3 mm and the vertical width to 2 mm when examining the anterior chamber. This creates a small focused beam. Rotate the light 30° to 60° in order to illuminate the depth of the anterior chamber (**Figure 153-18B**). This orientation is most beneficial when attempting to identify cellular or inflammatory material within the anterior chamber.

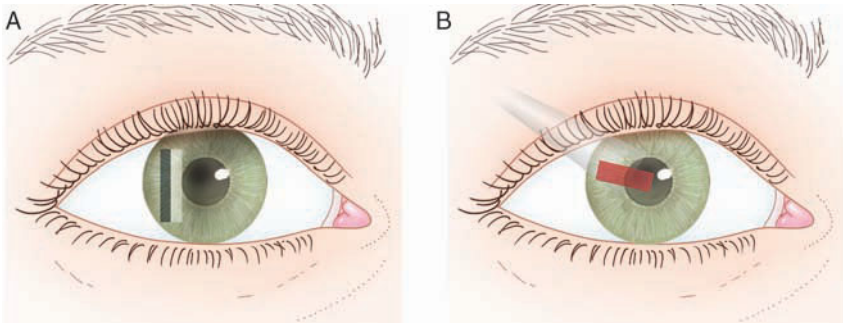

FIGURE 153-18. The light of the slit lamp. **A.** A narrow slit to focus on the cornea. **B.** A focused beam of light directed from a 45° angle illuminates the anterior chamber.

PATIENT POSITIONING

Cleanse the chin rest and the forehead bar before the slit lamp is used to examine a patient. The patient must be able to tolerate a seated position, leaning slightly forward with their head placed in the chin rest and their forehead pressed against the bar to use the slit lamp (**Figure 153-19**). The slit lamp examination cannot be completed in a patient who cannot remain in a seated position. **Patients will often need to be reminded to keep their head in the chin rest and their forehead against the bar.** Subtle movements from this position will change the viewing plane and disrupt the focus on the structures of the eye. **Always check the patient's position if you are having difficulty focusing the slit lamp.**

A motorized chair with the ability to move up and down is optimal for this examination. The slit lamp can be adjusted to match the height of a chair or stretcher if necessary by pressing the release bar located below the slit lamp table to move the entire table up and down. When the table height is properly positioned, release the bar to lock the table at this new height. The level of the chin bar can be adjusted to account for the subtle differences in the length of individual patient faces. Rotate the knob located at the base of the chin rest apparatus to move it up and down. Raise or lower the chin bar so that the reference mark located below the forehead bar is at the patient's eye level.

Use the joystick to move the slit lamp and scan the patient's eye. The patient must keep their eye in a fixed position while the Emergency Physician uses the joystick to move the slit lamp and scan the eye. Instruct the patient to focus their eye on your shoulder or earlobe. It is very difficult for the Emergency Physician to focus and complete a thorough examination if the patient's eyes wander.

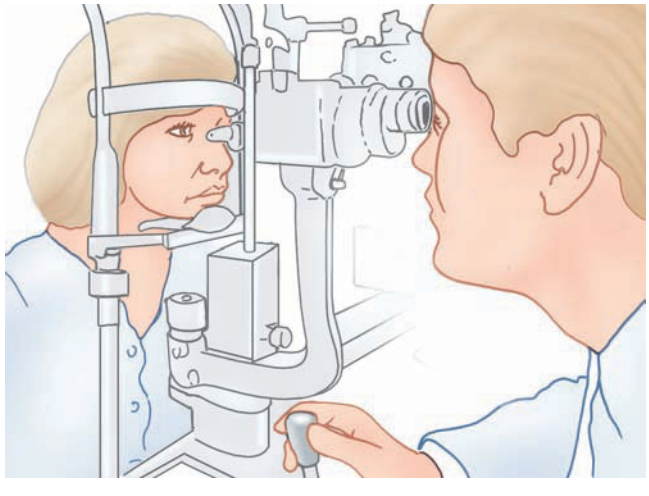

FIGURE 153-19. Patient positioning in the slit lamp.

THE SLIT LAMP EXAMINATION

The slit lamp examination begins with an overall microscope-enhanced evaluation of the external structures of the eye including the lash line, the bulbar conjunctiva, the palpebral conjunctiva, and the lacrimal puncta. The cornea is best evaluated primarily with a wide beam and the fine details are evaluated with the slit. **Do not focus the light into the pupil for an extended period of time.** It is very uncomfortable for the patient and may result in injury. The normal cornea is perfectly clear and homogeneous. Note any deviation from this if applicable. Specific abnormalities are best documented in writing in addition to a basic schematic diagram.

The anterior chamber should be clear and without particulate matter. It may be difficult initially to identify cells floating in the anterior chamber. They appear like "dust in a sunbeam." The cells, if not clumped, are barely visible with the microscope at the lowest magnification. They do, however, often reflect the light slightly, and this may catch the Emergency Physician's eye. Take care to pay special attention to the lower one-fourth of the anterior chamber because, in an upright position, cells and inflammatory products tend to settle and may form a meniscus. Flare is the noncellular inflammatory material in the anterior chamber that makes the aqueous humor appear hazy, or gelatinous, and obscure the details of the iris. Use the high-power magnification to identify particulate matter after scanning the anterior chamber with the low-power magnification.

ADMINISTRATION OF FLUORESCEIN

Repeat the corneal examination with the aid of fluorescein stain after the slit lamp examination is completed without stain. Fluorescein is a hydrophilic substance that stains and illuminates any portion of the cornea where there is a breech in the epithelium. The addition of fluorescein helps to illuminate corneal lesions that might otherwise go unrecognized. This includes corneal abrasions or keratopathy associated with viral infections. Fluorescein is most commonly packaged as individual single-use strips. There is the potential for infectious agents to be transmitted when one fluorescein strip is used for both eyes or when a multidose vial of fluorescein solution is used. Take care to avoid iatrogenically transmitted infections.

Remove all contact lenses before the slit lamp examination and fluorescein staining. Accidental application of fluorescein without their removal will permanently stain contact lenses. Place a small drop of saline or topical ophthalmic anesthetic solution onto the tip of the fluorescein strip. Retract the lower eyelid by placing pressure on the skin overlying the inferior orbital rim and distracting it downward. Ask the patient to look upward to facilitate the administration of the stain and to avoid inadvertent corneal injuries caused by the strip itself. Touch the fluorescein strip lightly against the palpebral conjunctiva of the inferior eyelid (**Figure 153-20A**).

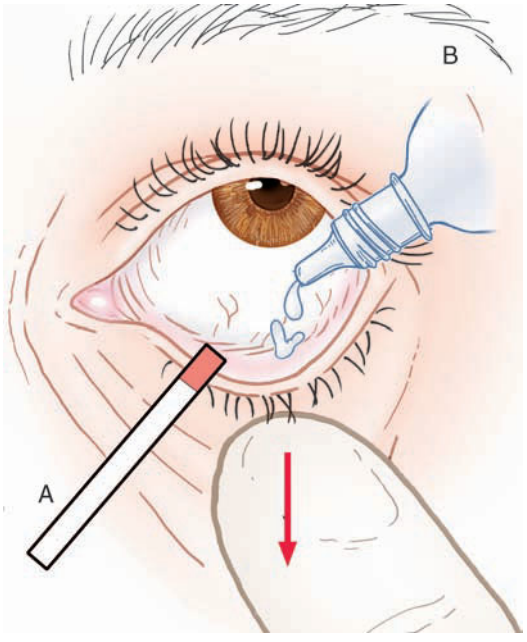

FIGURE 153-20. Instillation of fluorescein stain. **A.** Fluorescein-tipped strips. **B.** Aqueous fluorescein solution.

Remove the fluorescein strip. Ask the patient to gently open and close their eyelids to distribute the fluorescein across the entire eye.

Aqueous fluorescein solution can be used as an alternative to the paper strips. Retract the lower eyelid and instill two drops of fluorescein into the cul-de-sac of the lower eyelid (**Figure 153-20B**). **Take special care when using fluorescein to avoid accidentally staining the patient's skin, clothing, or contact lenses.** Most Emergency Departments use fluorescein strips rather than liquid solution. The liquid solution, or the tip of the applicator, can become contaminated and transmit infection.

A small amount of fluorescein is required to adequately stain the cornea. A common mistake is to apply an excessive amount of fluorescein stain. This illuminates the entire tear film and makes it difficult to evaluate subtle lesions on the cornea. Ask the patient to blink several times to remove the excess fluorescein from the cornea. This maneuver will not remove the fluorescein adhering to any corneal defects. If blinking does not remove the excess fluorescein, place one or two drops of sterile saline or eyewash onto the eye. Avoid the use of excessive fluorescein as it is likely to obscure exam and potentially stain the patient's skin.

The underlying cell layers of the cornea will hold the fluorescein stain if the corneal epithelium is injured. This allows corneal lesions to be visualized. Use the cobalt blue light, preferably in conjunction with the slit lamp, to identify and evaluate any corneal lesions that become apparent. The regions that stain with fluorescein and are visible with the cobalt blue light will appear bright yellow to yellow-green. **The green light on the ophthalmoscope and the slit lamp are not intended to be used to illuminate the fluorescein stain.** The green light will enhance the stain in some circumstances but is not as reliable as the cobalt blue light source.

EYEDROP ADMINISTRATION

TRADITIONAL METHODS

Topical ophthalmologic medications are used for examining and treating the eyes. Eyedrops and ophthalmologic ointments are most effectively and accurately instilled within the lower eyelid (**Figure 153-21**). Instruct the patient to direct their head toward the examiner with their eyes looking upward (**Figure 153-21A**). Patients often close their eyes at this point. Retract the lower eyelid, without placing pressure on the globe, and expose the inferior cul-de-sac (**Figure 153-21B**). Apply the drops, or ointment, in the cul-de-sac (**Figure 153-21C**). Close the eyelid and apply thumb pressure over the lacrimal duct (**Figure 153-21D**). This prevents the liquid medicine from immediately draining through the nasolacrimal duct and

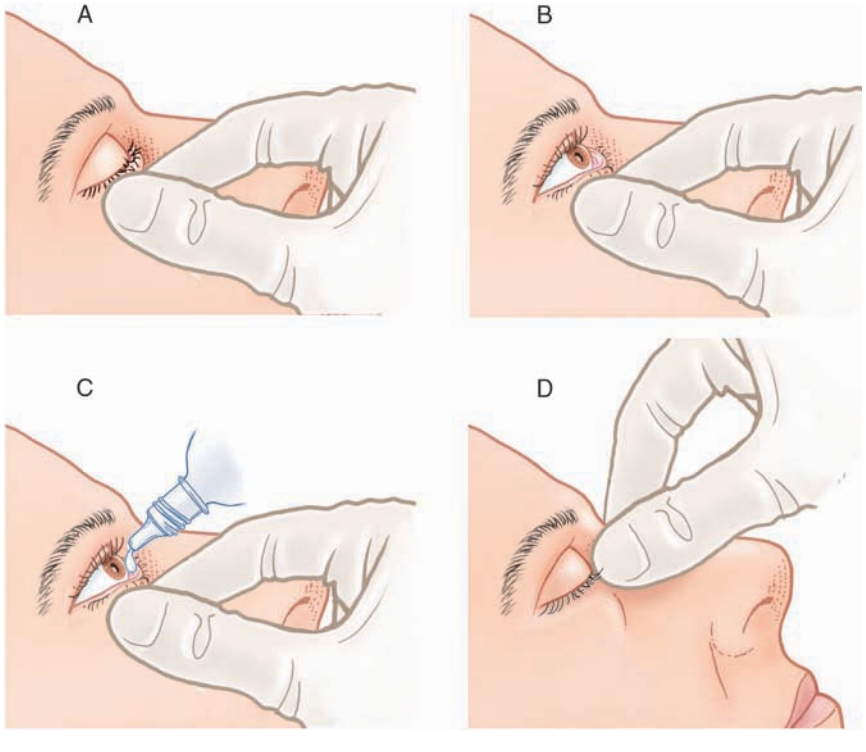

FIGURE 153-21. The instillation of eyedrops. **A.** Grasp the lower eyelid. **B.** Pull the lower eyelid downward and outward to expose the cul-de-sac. **C.** Place the drops into the cul-de-sac. **D.** Apply thumb pressure over the lacrimal duct to prevent drainage of the drops into the nose.

FIGURE 153-22. The instillation of eyedrops in an uncooperative patient.

into the nose. Instruct the patient to blink once or twice to quickly distribute the medication across the globe. This last step, applying pressure on the lacrimal duct, is unnecessary if instilling an ophthalmic ointment.

UNCOOPERATIVE PATIENTS

Some patients require but do not want medication in their eyes. The best examples of these challenging patients are infants, small children, and patients with altered mental status. Prying the eyes of these patients open and applying the drops is difficult for both the physician and the patient. **Forcefully opening the eyelids is potentially dangerous because secondary injuries may occur.** The majority of medication is typically applied to the physician's hand or the stretcher, as anyone who has tried this approach knows. An alternative approach in this situation is advisable.

The problem is that the uncooperative patient squeezes their eyes closed tightly. Place the patient supine with an assistant holding the head in a fixed upright position with the eyes facing the ceiling in order to overcome this challenge (**Figure 153-22**). Note the small anatomic depression created over the medial canthus of each eye when they are closed tightly. Place the eyedrops in this anatomic depression to create a shallow pool (**Figure 153-22**). Firmly maintain the patient's head in this position until they spontaneously open their eyes and allow the medication to spread across the globe.

OPHTHALMIC ANESTHETIC AGENTS

Two types of eye medications are required in drop form for most routine ophthalmologic examinations, a topical ophthalmic anesthetic agent, and a dilating agent. Topical ophthalmic anesthetic agents provide relief from eye pain and photophobia. This may help the patient to cooperate with the necessary examination. Topical ophthalmic anesthetic agents may be used as adjuncts to fluorescein application and to facilitate the placement of eyelid retractors. They may at times be used as an adjunctive diagnostic tool. There are several possible causes of eye pain and photophobia that must be differentiated, some of which may coexist. Complete symptom relief with a topical ophthalmic anesthetic agent suggests that the etiology of the pain is the conjunctiva or cornea.

Tetracaine hydrochloride and proparacaine hydrochloride are the most commonly available agents. Their onset of action and duration of action are similar. The onset is within 1 minute and lasts approximately 10 to 20 minutes. Tetracaine hydrochloride (Pontocaine) instillation often results in a transient stinging sensation that lasts 3 to 10 seconds before dissipating. Proparacaine hydrochloride (Ophthetic or Ophthaine) does not result in the stinging sensation.

Topical ophthalmic anesthetic agents are toxic to corneal epithelial cells and can delay corneal healing.[15] **They are currently used in the Emergency Department only to aid in the diagnosis and evaluation of an eye problem. They should not be prescribed for treatment outside the Emergency Department except by an Ophthalmologist.** These agents are currently being used for up to 4 days on an outpatient basis after photorefractive keratectomy surgery.[16] Several small studies suggest these agents are safe to use for a few days without adverse effects.[17,18] With additional studies, the Emergency Department practice of not prescribing topical ophthalmic anesthetic agents for outpatient use may change.

PUPILLARY DILATING AGENTS

Dilating agents are used as an adjunct to the fundoscopic examination. **Always perform and document a complete pupillary examination before instilling dilating agents.** It is important to document the use of dilating agents and the time of administration. **Avoid using dilating agents in patients who require serial pupillary examinations to follow their neurologic status. Dilating agents are contraindicated in patients with a known or suspected narrow iridocorneal angle.** Dilating the pupil may result in acute angle-closure glaucoma. Some intraocular lens implants may become dislodged if the pupils are pharmacologically dilated. **Inquire about ocular surgery, known narrow angles, and glaucoma prior to dilating any pupils.**

Dilating agents are categorized as mydriatics and cycloplegics. **All dilating agents are stocked with red caps**. **Mydriatic agents directly dilate the pupil while cycloplegics paralyze the ciliary muscles. Cycloplegic agents should not be used in patients who require serial neurologic examinations.** Choose a noncycloplegic mydriatic agent such as phenylephrine to dilate the pupils of a patient requiring serial examinations. The duration of action is significantly shorter than that of a cycloplegic agent. **Phenylephrine is systemically absorbed and may be inappropriate for patients with hypertension or cardiac conditions.** A combination of a mydriatic agent (e.g., phenylephrine) and a shorter-acting cycloplegic agent (e.g., cyclopentolate) is optimal when maximal dilation is necessary or when a single agent is ineffective.

Most Emergency Departments stock or have access to five dilating agents. The choice of agents depends upon the length of time required for dilation, the need for a cycloplegic agent, and the need for a mydriatic agent. Atropine (Isopto Atropine) produces cycloplegia lasting 5 to 10 days and mydriasis lasting 7 to 14 days. Cyclopentolate (Cyclogyl, AK-Pentolate, Pentolair) produces cycloplegia lasting 6 to 24 hours and mydriasis lasting 24 hours. Homatropine (Isopto Homatropine) produces cycloplegia and mydriasis lasting 1 to 3 days. Phenylephrine (Neo-Synephrine, Mydrin, Relief) produces mydriasis lasting 5 hours. Tropicamide (Mydriacyl) produces mydriasis lasting 4 to 6 hours.

THE FUNDOSCOPIC EXAMINATION

A fundoscopic examination is an essential part of every eye evaluation. It is particularly helpful when the patient complains of visual disturbances or visual loss. Examine the patient's right eye first. Hold the ophthalmoscope in the right hand and use the right eye to examine the patient's right eye. Remember "right eye to right eye and left eye to left eye" or the Emergency Physician may otherwise find themself in an awkward nose-to-nose position with the patient.

Instruct the patient to focus the eye not being examined on a fixed object over the Emergency Physician's shoulder and approximately 6 to 8 feet away. It is important that the patient maintain their focus on the object throughout the complete examination of the eye.

Set the ophthalmoscope initially at 0. Adjust the dial as the examination begins to adjust for refractory errors. Moving the dial into the red numbers moves the point of focus forward toward the red retina. Moving the dial into the black numbers moves the point of focus closer to you. Approach the eye from a slightly lateral position to quickly identify the medial position of the optic disk. Position the ophthalmoscope as close as possible to the patient's eye without making contact. Imagine looking at the fundus through a peephole. The closer you get, the wider the view on the other side. By the same analogy, the larger the peephole the better the view on the other side. Thus, dilate the patient's pupils to obtain the best results from the ophthalmoscope examination.

Adjust the diameter of the light down to the size of the patient's pupil in order to avoid the bright reflection off of the iris if dilation is not possible. This bright reflection is a common reason for inadequate visualization of the fundus. The patient's eyes are often moving if the structures seem to move in and out of focus. Remind the patient to focus on one point in the distance.

Inspect the eye grounds for uniformity. The normal color of the fundus is creamy peach to pink, but may be pigmented in darker skinned people. A pale fundus with a small cherry-red spot in the region of the macula suggests an infarction generally associated with a retinal artery occlusion. The optic disk is located on the nasal aspect of the fundus. If the optic disk does not come into view, follow the blood vessels that extend from the disk to the periphery of the retina. The disk margin should be sharp with the exception of the nasal aspect that may appear slightly blurred in a normal eye. Papilledema appears as diffusely blurred disk margins. Papilledema may be the result of localized inflammation of the optic nerve or may be the result of elevated intracranial pressure.

The veins will appear darker and wider than the arteries. Evaluate the blood vessels for evidence of hemorrhages and irregularities. Acute hemorrhages may be helpful in the diagnosis of a variety of problems such as a hypertensive emergency or the shaken baby syndrome. Give careful consideration to the clinical setting. A helpful finding in the patient suspected of having increased intracranial pressure is the presence or absence of venous pulsations. Venous pulsations are best seen as the veins cross into the optic cup. The presence of venous pulsations is a normal finding. The first sign as the intracranial pressure rises is a loss of venous pulsations followed later by papilledema. The green light or red filter helps to provide a sharper image when evaluating the retinal vessels in detail.

Examine the fovea and the surrounding macula. This area is located approximately two to three disk diameters (DD) lateral to the optic disk. Instruct the patient to look directly into the light to bring the fovea and macula into view. The target setting on the ophthalmoscope is helpful for this purpose. Look into the patient's eye with the ophthalmoscope turned to the target. Instruct the patient to look directly into the center of the target. The fovea will be found at the center of the target in your view as well.

Examine the vitreous chamber for evidence of a vitreous hemorrhage when a retinal detachment is suspected or when the patient complains of floaters. The fluid within the vitreous chamber is gelatinous so blood within it does not dissipate quickly. Blood within this chamber appears as clouds, spots, or veils to the patient and the examiner. Their color is typically described as black or red. Set the ophthalmoscope to +10 to move the point of focus anteriorly toward the examiner's eye to evaluate the vitreous. Dial the ophthalmoscope down as the examination proceeds. Each click results in focusing a little deeper within the vitreous chamber until the point of focus is upon the retina at the posterior aspect of the chamber.

INTRAOCULAR PRESSURE MEASUREMENT

The measurement of intraocular pressure should be included in the eye examination. It is particularly important in patients with eye pain and visual loss. Refer to Chapter 156 regarding the complete details of ocular tonometry.

SUMMARY

Approach all eye complaints with a detailed history that includes a chief complaint, the duration of symptoms, and the natural history of their evolution. It is important to inquire about exposures and trauma. The past medical history must include the patient's baseline visual acuity and any history of eye problems. Perform a complete examination on all patients with eye complaints. Always document an accurate visual acuity and carefully inspect all of the eye structures. A thorough approach in all patients with eye complaints improves diagnostic accuracy. The end result is decreased morbidity and long-term complications in this vital sensory apparatus.

154 Contact Lens Removal

Dino P. Rumoro

INTRODUCTION

The Emergency Physician must be familiar with the proper technique of removing both soft and hard contact lenses from patients who are unable to do so on their own for various reasons. Patients with altered mental status are at particular risk of corneal damage if contact lenses are allowed to remain in place. Healthy individuals who wear contact lenses overnight experience a 4- to 15-fold increase in the risk of corneal injury over those who remove their contact lenses daily.[1] The explanation for this increased risk of injury is based on the development of corneal hypoxia and an immune response to antigens present on the lens surface, both of which lead to an inflammatory response and susceptibility to infectious organisms.[1] This results in an increased incidence of ulcerative keratitis, *Pseudomonas aeruginosa* infection, and corneal neovascularization.[2,3]

ANATOMY AND PATHOPHYSIOLOGY

Contact lenses rest on a three-layer tear film (outer lipid, middle aqueous, and inner mucus layer) that covers the corneal and conjunctival epithelium. This tear layer provides oxygen and nutrients to the avascular cornea. The cornea also receives nutrition from blood vessels at the limbus and the aqueous humor. It is believed that contact lenses increase tear evaporation and disrupt the three-layer tear film, leading to the lack of corneal oxygenation and the symptoms of dry eye.[4] A dry eye causes discomfort and corneal edema with resultant hazy vision. The normal blinking action initiates contact lens movement and a "fresh" flow of oxygenated tears over the cornea in an awake patient. This blinking action is not present in the sleeping or comatose patient.

The normal resting position of the contact lens is over the cornea. It may occasionally drift from the center of the eye and

relocate over the sclera or in various parts of the eye, including under the upper eyelid. Thorough exploration of all aspects of the eye is essential when evaluating an individual for the presence of contact lenses prior to their removal. This evaluation should include inspection under the lower eyelid margin as well as eversion of the upper eyelid. Failure to adequately perform this examination can lead to the mistaken belief that a contact lens does not exist. In turn, a contact lens that remains in place acts as a foreign body and can lead to chronic irritation, inflammation, and development of a mass. Mass development from a retained contact lens typically occurs in the upper fornix of the eyelid and requires double eversion of the eyelid for identification and retrieval.[5]

INDICATIONS

Contact lenses must be removed from any patient who is unconscious or suffers an ocular injury. Contact lenses should not be left in place if fluorescein stain is to be used to examine the eye. Fluorescein can permanently stain the contact lens material. Give patients the opportunity to remove their own contact lenses if there are no contraindications (i.e., immobilization or ocular trauma). Patients are usually quite adept at removing their own contact lenses. Remove the contact lenses if the patient is unable to remove them or cannot remove them.

CONTRAINDICATIONS

The only absolute contraindication to removing a contact lens would be in the case of a ruptured globe. Leave the contact lens in place for the Ophthalmologist to remove at the time of their examination and/or surgical repair. Extreme caution must be exercised to avoid unnecessary pressure on the eye itself so as not to complicate the injury when severe ocular damage has occurred. Place an eye shield and not an eye patch to avoid pressure on the globe with resultant exacerbation of the injury (Chapter 161).

EQUIPMENT

- Normal saline
- Two cups, labeled "left" and "right"
- Hard lens remover suction cup device, optional
- Soft lens remover device, optional
- Cotton-tipped applicators

PATIENT PREPARATION

Explain to the patient, if they are awake, that their contact lenses must be removed. A signed consent is not required to remove a contact lens. Place the patient sitting or supine, whichever is most appropriate for the current clinical situation. Place several drops of a saline solution onto the eye and wait 5 to 10 minutes to allow the saline to penetrate the lenses. This maximally moistens the contact lenses to the point where they can be seen to slide easily over the surface of the eye when the patient blinks.

All contact lenses should be centered over the cornea for ease of removal by gentle manipulation of the eyelids. The lenses may often become displaced from the cornea. Care must be taken to search for the lens in other parts of the eye. Shine a penlight at an angle to the eye to aid in the search. A common location for a displaced contact lens to migrate is under the upper eyelid. **Evert the upper eyelid if a contact lens cannot be found elsewhere to complete the search before assuming either that the lens fell out or the patient is not wearing contact lenses.** Instill fluorescein into the eye if the patient still insists that it is present. The fluorescein will pool around the edges of the contact lens and make it easy to locate. **Warn the patient that fluorescein may permanently stain their contact lens.**

Prepare the equipment. Locate the equipment required to remove the contact lenses. Label two cups, "left" and "right," to place the lenses in after they are removed. Fill the cups with enough saline to cover the contact lenses. The person performing the procedure should wear powderless gloves to prevent the powder from irritating the eye. Wipe powdered gloves clean with a saline or a water-moistened towel to remove the powder. Powdered gloves can also be placed under running water to flush away the powder.

HARD CONTACT LENS REMOVAL TECHNIQUES

A hard contact lens can be identified by its small size (6 to 10 mm). It is smaller than the cornea. Center the hard contact lens on the cornea. Place the index finger (or thumb) of one hand at the base of the eyelashes of the upper eyelid and the index finger (or thumb) of the opposite hand at the base of the eyelashes of the lower eyelid (**Figure 154-1A**). Gently, but firmly, approximate the eyelids by moving them toward the center of the cornea until the margins of the eyelids touch the edges of the hard contact lens (**Figure 154-1B**). Press slightly harder on the lower eyelid until the bottom edge of the

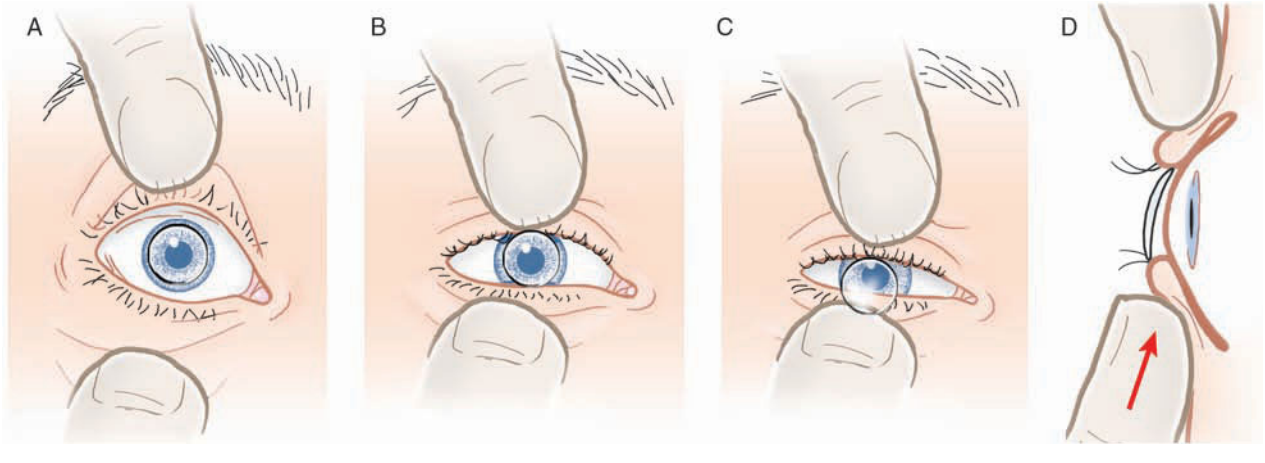

FIGURE 154-1. Hard contact lens removal. **A.** Use both thumbs to open the eyelids. **B.** Close the eyelids until the edges of the eyelids just contact the lens. **C.** Push the edge of the lower eyelid under the edge of the contact lens to pop it off the eye. **D.** Lateral view of the lower eyelid pushing the contact lens off the eye.

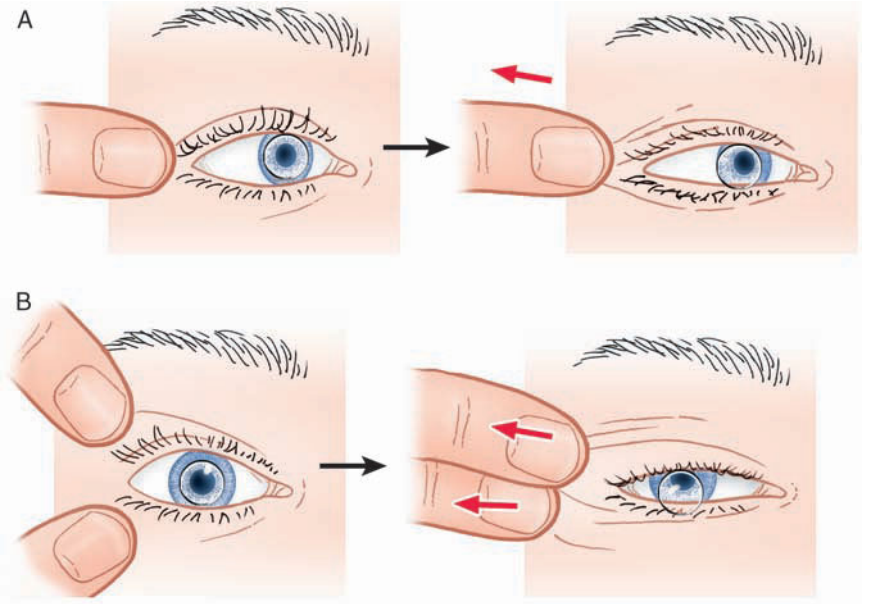

FIGURE 154-2. Alternative hard contact lens removal techniques. These methods do not apply pressure onto the globe. Apply laterally directed pressure to the skin lateral to the eyelids (**A**) or to the eyelids (**B**) to "catch" the contact lens and pop it off the eye.

hard contact lens lifts off the cornea utilizing the edge of the lower eyelid as a fulcrum (**Figures 154-1C & D**). Continue to push the eyelids together until the hard contact lens is lifted completely off the cornea and can be easily grasped.[6,7]

The patient who is awake and alert may not like the Emergency Physician's fingers near their eyes. Pull the skin of the lateral margin of the eyelids laterally with an index finger (**Figure 154-2A**). Alternatively, place one finger on the lateral edge of the upper eyelid and one finger on the lateral edge of the lower eyelid and pull laterally (**Figure 154-2B**). Instruct the patient to look downward and inward toward their nose. The hard contact lens will pop off the cornea. Grasp and remove the contact lens. This technique does not put as much pressure on the globe as the previous technique, an advantage if the patient has ocular trauma.

A commercially produced suction cup-like rubber device, resembling a golf tee, can be used to remove hard contact lenses if available (**Figure 154-3**). Moisten the surface of the device with a drop of saline. Gently touch the suction cup to the center of the hard contact lens. Suction will form and result in the hard contact lens adhering to the device. Lift the device and the attached contact lens from the cornea. **Slide the hard contact lens sideways to remove it from the suction cup. Do not attempt to pull the hard contact lens off the suction cup as this may damage the contact lens.**

A final technique involves the use of a cotton-tipped applicator (**Figure 154-4**). Moisten the cotton with saline. Place the cotton-tipped applicator over the lower edge of the hard contact lens (**Figure 154-4A**). Carefully and gently slide the hard contact lens off the cornea and onto the sclera with the moistened cotton-tipped applicator. Gently press the cotton-tipped applicator into the sclera and under the edge of the hard contact lens (**Figure 154-4B**). Lift the hard contact lens from the sclera. **Do not use the cotton-tipped applicator to elevate the hard contact lens from the cornea as this can result in a corneal abrasion.**[8]

SOFT CONTACT LENS REMOVAL TECHNIQUES

Soft contact lenses can be identified by their larger sizes (12 to 14 mm). They usually extend to, or just beyond, the corneal-scleral junction. There are numerous techniques to remove a soft contact lens (**Figures 154-5** to **154-7**). The easiest and simplest method is to remove it manually (**Figure 154-5**). To remove the contact manually, retract the lower eyelid with the nondominant index finger

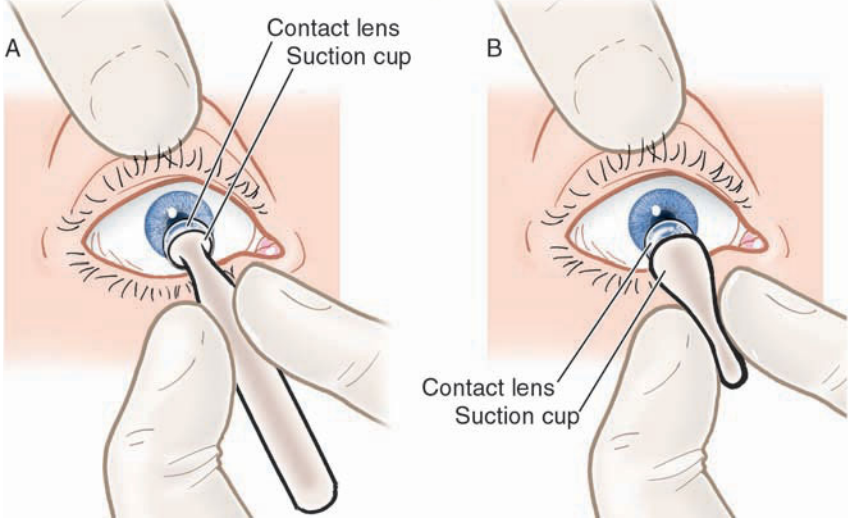

FIGURE 154-3. Suction cup removal of hard contact lenses. **A.** Suction cup on a plastic handle. **B.** Fingertip held suction cup.

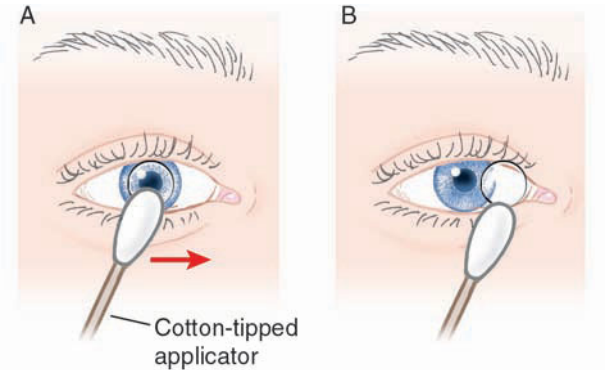

FIGURE 154-4. A cotton-tipped applicator to remove a hard contact lens. **A.** Place a cotton-tipped applicator against the lower edge of the hard contact lens. Push the hard contact lens onto the sclera. **B.** Push the cotton-tipped applicator under the edge of the contact lens to lift it off the eye.

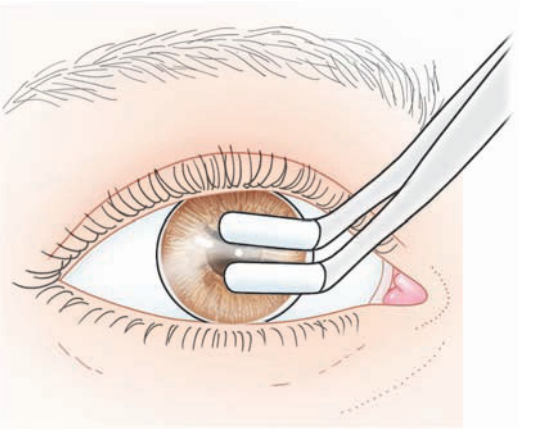

FIGURE 154-6. A tweezer-like device to grasp and remove the soft contact lens.

(**Figure 154-5A**). The soft contact lens will slide partially onto the conjunctival surface of the lower sclera. Gently grasp the soft contact lens between the thumb and index finger of the dominant hand. Pinch the fingers together and remove the soft contact lens.

A second technique to remove soft contact lenses is illustrated in **Figure 154-5B**. Gently place the index finger and thumb of the non-dominant hand on the upper and lower eyelids, respectively. Retract the eyelids. Gently grasp the soft contact lens between the thumb and index finger of the dominant hand. Slide the soft contact lens inferiorly. Gently pinch the fingers together to pull the soft contact lens from the eye.[6]

A third technique to manually remove a contact lens uses the patient's eyelids (**Figure 154-5C**). Place the thumb of the non-dominant hand and dominant hand on the upper and lower eyelid, respectively. Retract the eyelids until the edges of the contact lens are fully visible. Close both eyelids against the superior and inferior edges of the soft contact lens. Continue to close the eyelids until the contact lens pops off the eye. Grasp and remove the soft contact lens with the dominant hand.

A commercially available rubber tweezer-like device can be used to remove soft contact lenses. Place the rubber tips of the device onto the center of the soft contact lenses (**Figure 154-6**). Gently

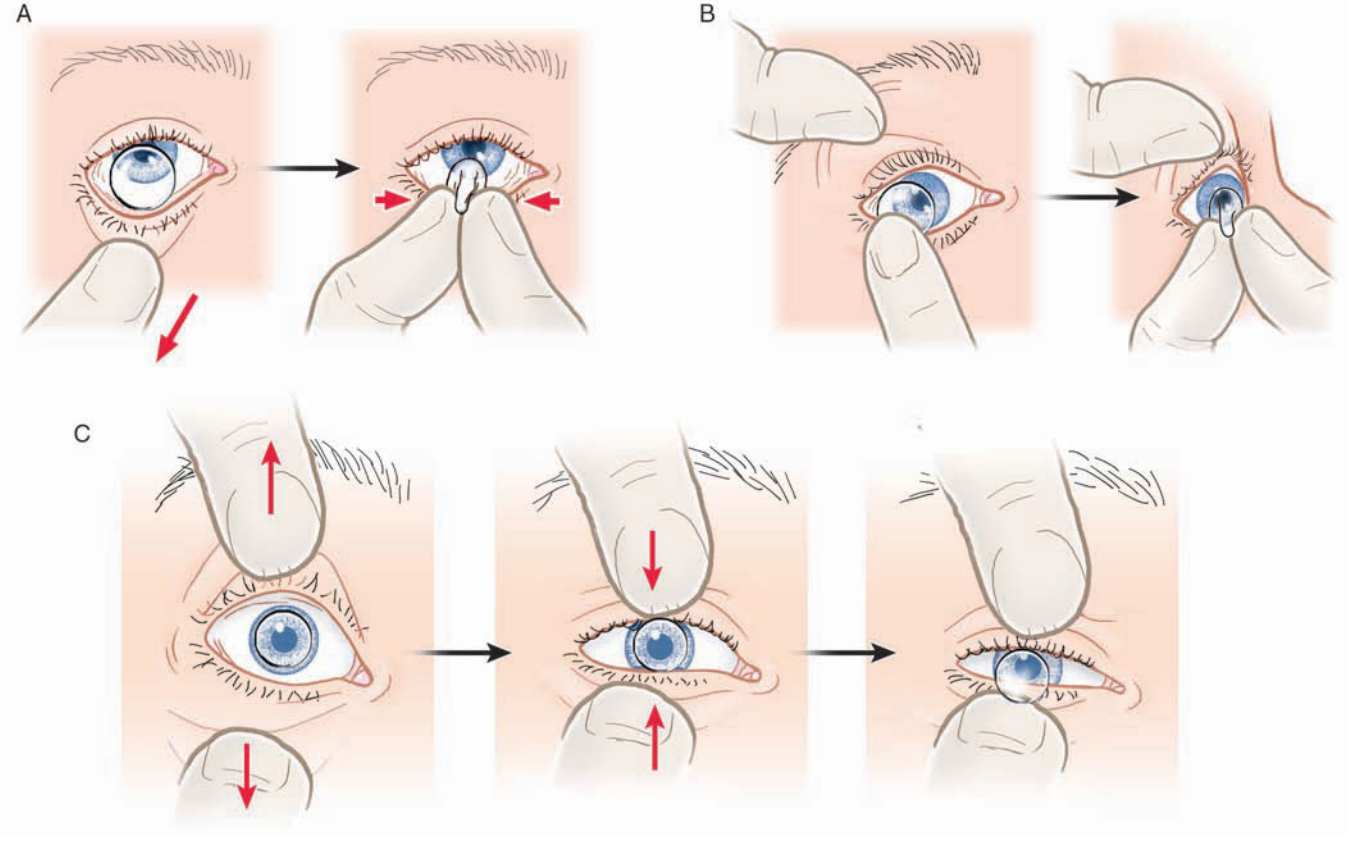

FIGURE 154-5. Manual soft contact lens removal techniques. **A.** Pull the lower eyelid downward and grasp the contact lens. **B.** Retract the eyelids. Slide the soft contact lens off the cornea and onto the sclera. Grasp and remove the contact lens. **C.** Use the patient's eyelids to pop the contact lens off the eye.

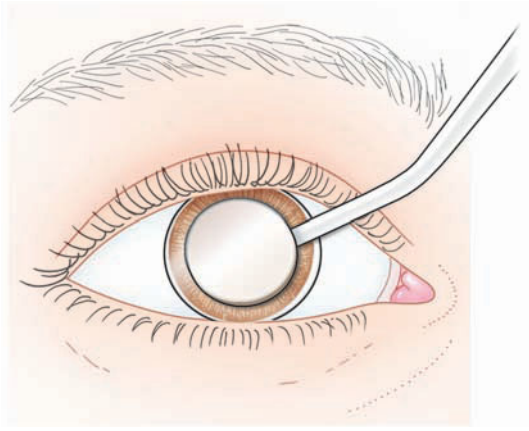

FIGURE 154-7. A rubber pad to remove a soft contact lens.

squeeze the tweezers closed using minimal pressure. The soft contact lens will fold and lift off the eye. Remove the soft contact lens from the eye.

A commercially available rubber disc on a stick can be used to remove soft contact lenses. Place the rubber disc over the center of the soft contact lens (**Figure 154-7**). Apply gentle pressure to slide the soft contact lens onto the sclera. Lift the stick to remove the attached soft contact lens. The rubber disc may occasionally not stick to the soft contact lens. Apply a drop of saline to the rubber disc and repeat the procedure. The drop of liquid will form a seal between the rubber disc and the soft contact lens.

SCLERAL LENS REMOVAL TECHNIQUES

The scleral lens is essentially a very large, soft contact lens. It is approximately the size of a quarter and covers the cornea and sclera. Remove the scleral lens using the same techniques described to remove a soft contact lens.

AFTERCARE

Place removed contact lenses in the appropriately marked container. Ensure that the contact lenses are covered completely with saline solution. Perform an eye examination using fluorescein eye drops if the patient complains of eye pain after contact lens removal. The procedure may have resulted in a corneal abrasion.

COMPLICATIONS

Any attempt to remove contact lenses with fingernails or other solid objects not approved for the removal of contact lenses can cause corneal abrasions. Their use must be avoided. Proper contact lens removal techniques can also result in corneal abrasions. Do not patch corneal abrasions resulting from contact lens removal in order to prevent an infectious process.[8] The suction cup of the hard contact lens remover may occasionally be inadvertently placed on the cornea. **Do not pull it off the cornea.** Slide it to the lateral corner of the sclera and remove it with a twisting motion.

Never remove a contact lens if there is concern for a potential globe perforation. The techniques described in this chapter are gentle yet put pressure on the globe while removing a contact lens. This pressure on the globe may result in extrusion of the intraocular contents (i.e., lens or vitreous) and cause permanent blindness. Use a suction cup device (hard contact lens) or a rubber disc (soft contact lens) if the contact lens must be removed before the Ophthalmologist arrives.

Additional complications include the inability to remove the lens and damage to the contact lens itself.[8] Consult an Ophthalmologist or Optometrist if a contact lens cannot be removed from the cornea. Desiccated lenses that are not properly rehydrated prior to removal can result in the removal of the corneal epithelium and a corneal abrasion.[8] A properly hydrated lens will slide easily over the surface of the eye. Apply saline drops onto the eye to hydrate the contact lens prior to removal.

SUMMARY

Removal of contact lenses is a procedure that all Emergency Physicians must be able to perform on any patient who is unconscious, who has ocular trauma, or who cannot remove their own lenses. Failure to perform this simple procedure appropriately can result in serious ocular damage. The removal of a contact lens is easy, quick, simple, and straightforward. Never remove a contact lens if a globe perforation is suspected unless absolutely necessary.

155 Ocular Burn Management and Eye Irrigation

Steven J. Socransky

INTRODUCTION

Ocular burns are true emergencies and represent a significant minority (7.2% to 9.9%) of ocular trauma cases.[1,2] Chemical burns account for the large majority of ocular burns, with thermal burns being the second most common cause.[3] Most victims are young males.[2,4] The industrial workplace is the most common setting, although a significant number of cases occur in the home.[4] Assaults are a significant cause of ocular burns in the lower socioeconomic groups of large cities.[4,5]

Caustic agents are primarily responsible for the most severe chemical ocular burns. Most reports indicate that alkali burns are more frequent than acid burns.[1,3,4] Examples of more common alkalis and acids are listed in **Table 155-1**.[4,6–13] Ammonia causes the most serious alkali burns, while calcium hydroxide (lime) is the most common cause of alkali burns.[4] Hydrofluoric acid causes the most serious acid burns, while sulfuric acid is the most common cause of acid burns.[4] Fortunately, caustic agents account for only a minority of chemical ocular exposures.[1] Most chemical

TABLE 155-1 Common Caustic Agents and Their Sources

Substance	Class	Source
Ammonium hydroxide	Alkali	Fertilizers, refrigerants, and sparklers
Calcium hydroxide	Alkali	Mortar, plaster, and cement
Magnesium hydroxide	Alkali	Sparklers and fireworks
Potassium hydroxide	Alkali	Oven and drain cleaners
Sodium hydroxide	Alkali	Lye soaps, airbags, EMLA cream, and hair straightener
Sodium hypochlorite	Alkali	Bleaches and drain cleaners
Acetic acid	Acid	High vinegar concentrations
Chromic acid	Acid	Chrome plating
Hydrochloric acid	Acid	Household and pool cleaners
Hydrofluoric acid	Acid	Rust removers; glass, mineral, gasoline, and silicone industries
Sulfuric acid	Acid	Industrial cleaners and battery acid
Sulfurous acid	Acid	Bleach and refrigerants

ocular exposures are due to relatively innocuous noncaustic substances (e.g., shampoos, hair sprays, and personal defense sprays) and therefore do not cause significant or lasting damage.[1,14,15]

Ocular irrigation is a simple procedure that is commonly employed in the Emergency Department. It is potentially an eye-saving procedure in the setting of significant chemical ocular burns. Physicians, nurses, and emergency medical personnel who deal with ocular emergencies should be trained in ocular irrigation. When possible, first aid personnel in the workplace should be familiar with the use of ocular irrigation.[16] **Most importantly, ocular irrigation must be employed rapidly.[1,17] Delays in irrigation can limit its effectiveness and increase morbidity.[3]**

ANATOMY AND PATHOPHYSIOLOGY

The anterior surface of the globe is the major target of toxins in ocular burns (**Figure 155-1**). The eyelids are the most important protective structure for the eye. The orbicularis oculi muscle is innervated by branches of the facial nerve and closes the eyelids in response to noxious stimuli. The cornea provides little in the way of protection from chemical agents. The cornea is composed of five convex and transparent tissue layers. The cornea's major function is the refraction and transmittance of light. Despite its avascularity, the cornea is exquisitely sensitive to pain. Paradoxically, more extensive burns may be less painful due to destruction of corneal nerve endings and resultant anesthesia.[18] The cornea merges with the sclera to form the limbus at its outer margins. Stem cells at the level of the limbus are responsible for regeneration of the corneal epithelium. The corneal epithelium is unable to regenerate when the limbus is damaged. Although tougher than the cornea, the fibrous sclera is also susceptible to chemical injury.

The sclera is covered by the bulbar conjunctiva, which becomes the palpebral conjunctiva as it reflects onto the inner surface of the eyelids. These areas of reflection are referred to as the superior and inferior fornices of the upper and lower eyelids, respectively. The spaces between the eyelids and the globe are referred to as the superior and inferior conjunctival sacs (also known as palpebral sulci). Posterior to the cornea lies the anterior chamber, which contains the aqueous humor. The anterior and posterior chambers are separated by the iris, ciliary body, trabecular meshwork, and lens.[19]

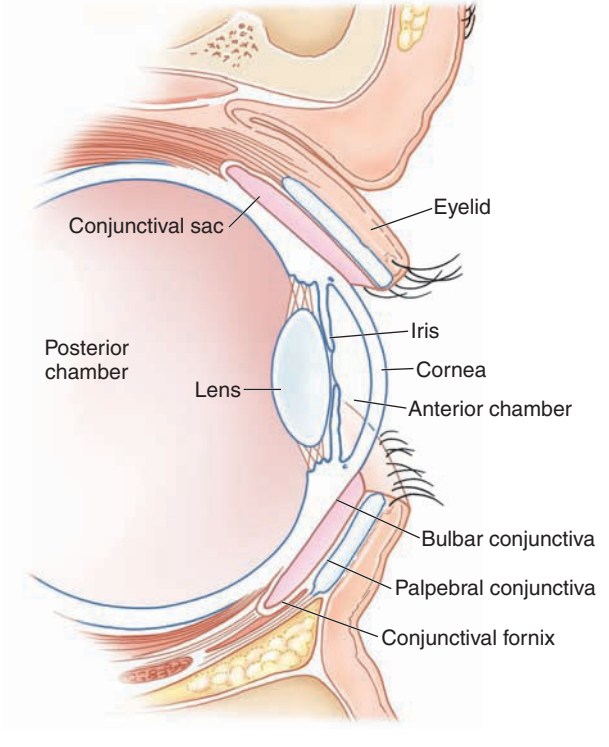

FIGURE 155-1. Cross-sectional anatomy of the eye and surrounding structures.

The damage produced to the eye by toxins depends on several factors: duration of contact; anion or cation concentration; and amount, pH, and inherent toxicity of the chemical.[17,20] **Alkalis generally produce the most damage.** Alkalis release hydroxyl ions that combine with tissue fatty acids and proteins, causing liquefaction necrosis.[11] The resultant degradation of corneal tissue allows for easy passage of the chemical into the anterior chamber. This causes a rapid rise (within a few seconds to a few minutes of contact) in aqueous humor pH and consequent damage to the iris, lens, ciliary body, and other ocular structures.[4,18,21] Damage to these structures and the cornea results in decreased visual acuity, secondary glaucoma, and cataracts. This damage can continue as the anterior chamber pH may remain elevated for hours. **Measurement of tear film pH immediately after irrigation will often yield a normal pH.[7,8] This may be falsely reassuring.** It may either reflect the pH of the irrigant or a transient neutralization of the tear film pH.[18] Alkalis may diffuse from the anterior chamber to the anterior ocular surface several minutes after irrigation has been discontinued, causing the tear film pH to rise again.

In general, acids cause less damage than alkalis. Acids lead to coagulation necrosis and protein precipitation, which usually prevents penetration beyond the cornea.[11] Exceptions include acids in higher concentration (particularly sulfuric acid) and hydrofluoric acid, which behaves more like an alkali.[4,5,18] These acids, like alkalis, can cause damage to deeper structures. Ocular burns caused by weaker acids can progress if treatment is delayed.[18]

Most noncaustic chemical eye exposures involve nontoxic agents that do not penetrate the cornea and cause only mild and self-limited irritation. Notable exceptions include surfactants and high-concentration lacrimators, both of which can cause damage to deeper structures.[10,18] Lacrimators in low concentration (e.g., tear gas) stimulate corneal nerve endings, causing pain and tearing, but they do not cause deeper injury.[18] Surfactants can cause significant damage that is often minimally symptomatic.[10] Although most solvents can cause sizable superficial corneal defects, reepithelialization is the rule and deeper tissues are spared.[10,18] Corneal injuries with capsicum (i.e., pepper spray) usually cause self-limited injuries, but significant corneal defects requiring Ophthalmology follow-up do occur occasionally.[22]

INDICATIONS

The treatment of chemical exposures to the eye is the primary indication for ocular irrigation. In this setting, irrigation has three principal objectives: immediate dilution of the offending agent, removal of the agent, and normalization of anterior chamber pH.[18] Nonembedded foreign bodies that are too small or too numerous to be removed adequately with a forceps or a cotton-tipped applicator can usually be removed with irrigation. Foreign bodies that are suspected but cannot be visualized may be removed with irrigation. Certain ocular infections are treated with antibiotics delivered by eye irrigation, although this is not a usual indication in the Emergency Department.

CONTRAINDICATIONS

There are no true contraindications to ocular irrigation. **An irrigating lens (e.g., Morgan Lens) should not be used if a deep corneal injury or a foreign body is suspected.[23] This lens may cause the foreign body to further injure the cornea or penetrate the globe. It is preferable to carefully employ the traditional method of**

irrigation using intravenous tubing and eyelid retraction rather than commercial devices that contact the globe in the setting of an actual or potential globe penetration or rupture.

EQUIPMENT

- Topical ophthalmic anesthetic agent, 0.5% proparacaine or 0.5% tetracaine
- Towels and a basin to collect fluid runoff
- Bags of crystalloid solution
- Intravenous tubing
- Gauze pads
- Cotton-tipped applicators
- Lid retractors, paper clip or Desmarres
- Commercial irrigation device, Morgan Lens or Eye Irrigator
- Protective eyewear, gloves, and gowns for healthcare personnel

PATIENT PREPARATION

Patients with ocular chemical burns may also have upper respiratory tract injuries, gastrointestinal tract injuries, and facial burns.[1] Nonchemical traumatic injuries are also possible. Airway, breathing, and circulatory problems should take priority. Significant ocular burns will need to be dealt with early and simultaneously with other problems. Initially, irrigation of the periocular skin should be performed with ocular irrigation itself such that residual toxin does not enter the eye causing further chemical injury.

Patients with isolated ocular injuries often have severe pain that requires parenteral narcotics. If this is the case, a monitored setting is appropriate. Intravenous sedatives and analgesics may facilitate ocular irrigation in a patient with severe pain and blepharospasm. Place the patient supine. Place towels and a basin under the patient's head to collect the runoff irrigant solution. Due to the speed with which ocular irrigation must be started, an explanation of the risks and benefits of the irrigation procedure should be offered to the patient while preparing for and initiating irrigation. Healthcare personnel and first-aid workers in the workplace are at risk for injury themselves. Protective equipment is essential and should be easily and rapidly accessible. Contaminated clothes should be removed and bagged in plastic until they can be cleaned or discarded.[15]

TECHNIQUES

A topical ophthalmic anesthetic agent, if immediately available, should first be instilled into the inferior conjunctival sac. Commonly available topical anesthetics include tetracaine and proparacaine. Proparacaine causes less irritation than tetracaine.[24] Each has a duration of action of approximately 10 minutes. Frequent readministration of the topical anesthetic may be necessary every 5 to 10 minutes to ease patient discomfort and facilitate irrigation. An alternative to readministration of local anesthetic would be to add 10 cc of 1% lidocaine to 1 L of crystalloid solution. Compared to an initial instillation of two drops of tetracaine alone, O'Malley et al found that lidocaine added to the irrigant in this way decreased the discomfort of irrigation when the irrigation lasted more than 10 minutes.[25]

OCULAR IRRIGATION

Hang the bag of crystalloid solution at a height of 70 to 200 cm above the patient's head in order to obtain an adequate flow rate.[26,27] The traditional eye irrigation technique involves directing the flow of crystalloid solution over the globe at a wide open rate

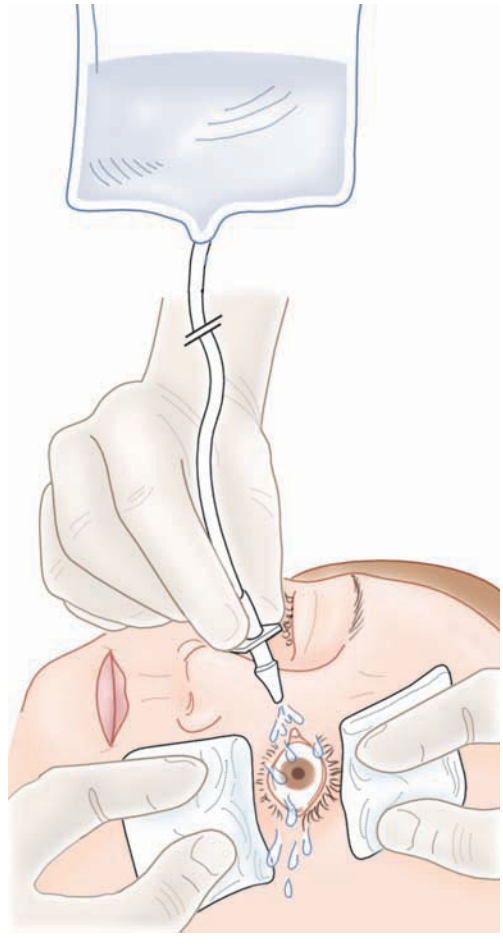

FIGURE 155-2. Standard ocular irrigation setup using intravenous tubing. An assistant retracts the eyelids using gauze pads or lid retractors. Complete irrigation of the conjunctival sacs is crucial.

(**Figure 155-2**). Hold the end of the intravenous tubing 3 to 5 cm above the patient's eye to avoid blunt injury to the ocular surface. An assistant is usually needed to hold the eyelids open. Dry gauze pads will facilitate one's ability to maintain a grip on the slippery eyelids and keep them open. Direct the flow of crystalloid solution at the entire surface of the globe, including into the conjunctival sacs and down to the conjunctival fornices.[18,28] Having the patient look in a direction opposite to where the irrigant is directed helps in this regard.[29] Although one can point the stream directly at the conjunctiva, it is better to direct it across the cornea in order to reduce the potential for further corneal injury.[23]

Manual retraction of the eyelids with gauze pads does not always allow for adequate irrigation of the conjunctival fornices. In these instances, eyelid retractors (Desmarres or bent paper clip) must be employed (**Figure 155-3**). **The eye must be well anesthetized when using eyelid retractors, and care must be taken to avoid further ocular injury.** Desmarres retractors are preferred to paper clips. Many paper clips are coated with nickel or silver that, when the paper clip is bent, can flake off, resulting in iatrogenic foreign bodies.[30] The use of a Water-Pik or handheld drench hose has been described but offers no definite advantages over intravenous tubing.[31,32]

Two commercially available devices exist which are less labor-intensive and facilitate ocular irrigation. The Morgan Lens (MorTan Inc., Missoula, MT) is a scleral contact lens-type device that is designed to fit over the anterior ocular surface (**Figure 155-4A**). Connect the proximal end of the device to intravenous tubing and

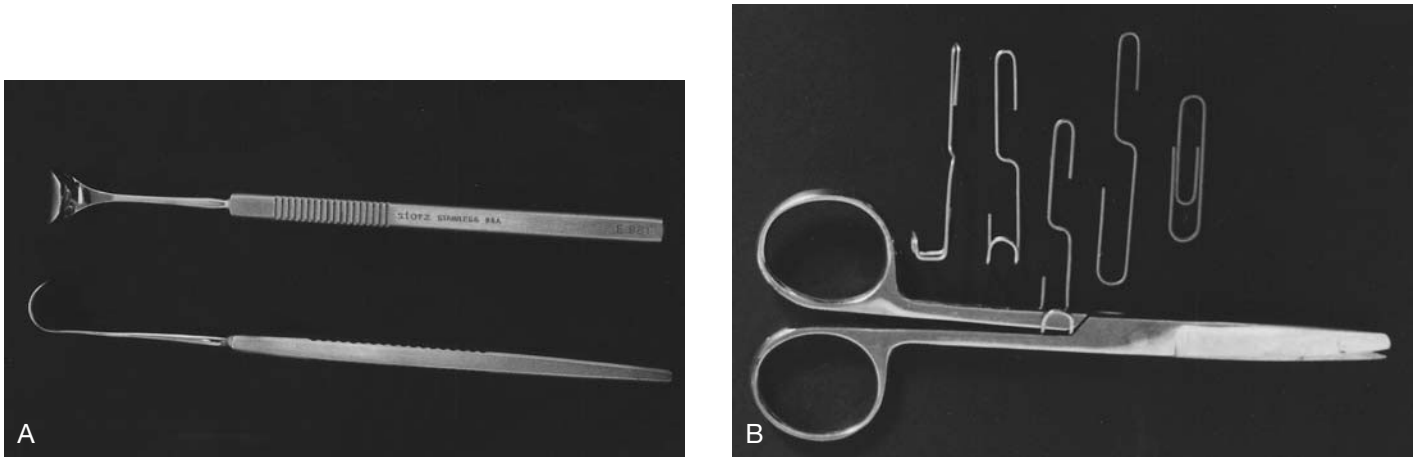

FIGURE 155-3. Eyelid retractors. **A.** The Desmarres eyelid retractor. **B.** An eyelid retractor fashioned from a paper clip.

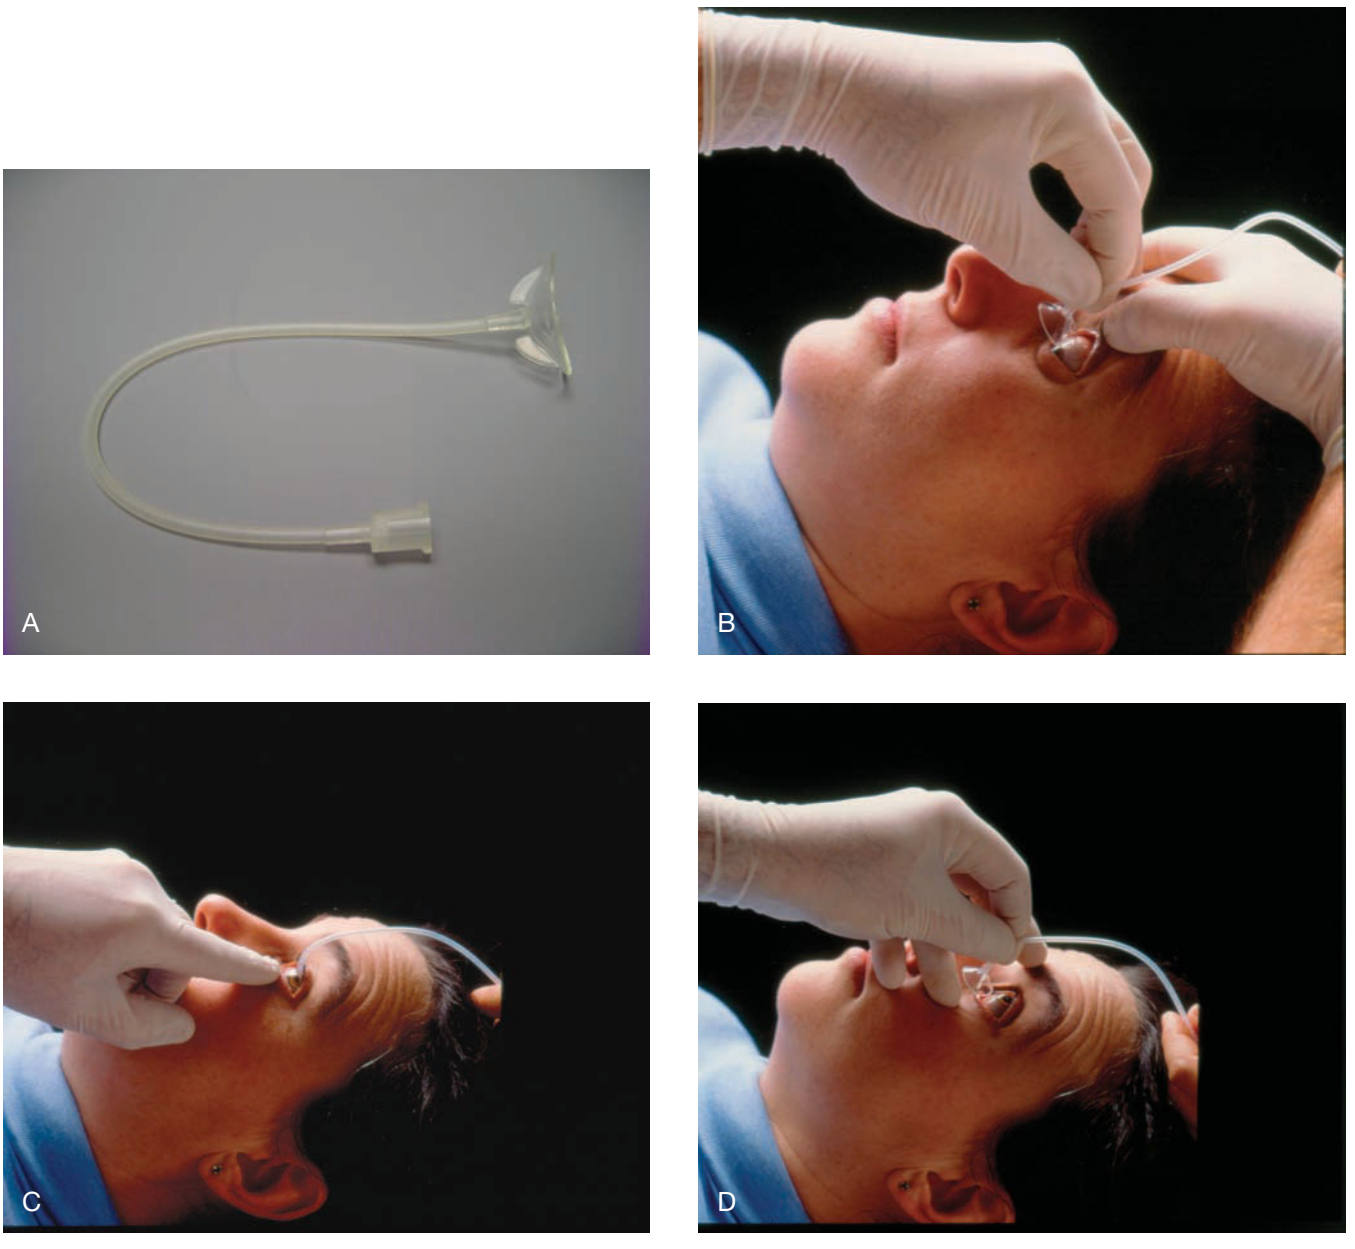

FIGURE 155-4. Eye irrigation with the Morgan Lens. **A.** The Morgan Lens. **B.** Placement of the lens under the upper eyelid. **C.** Placement of the lens under the lower eyelid. **D.** Removal of the lens. (Photos **B–D** courtesy of MorTan Inc., Missoula, MT.)

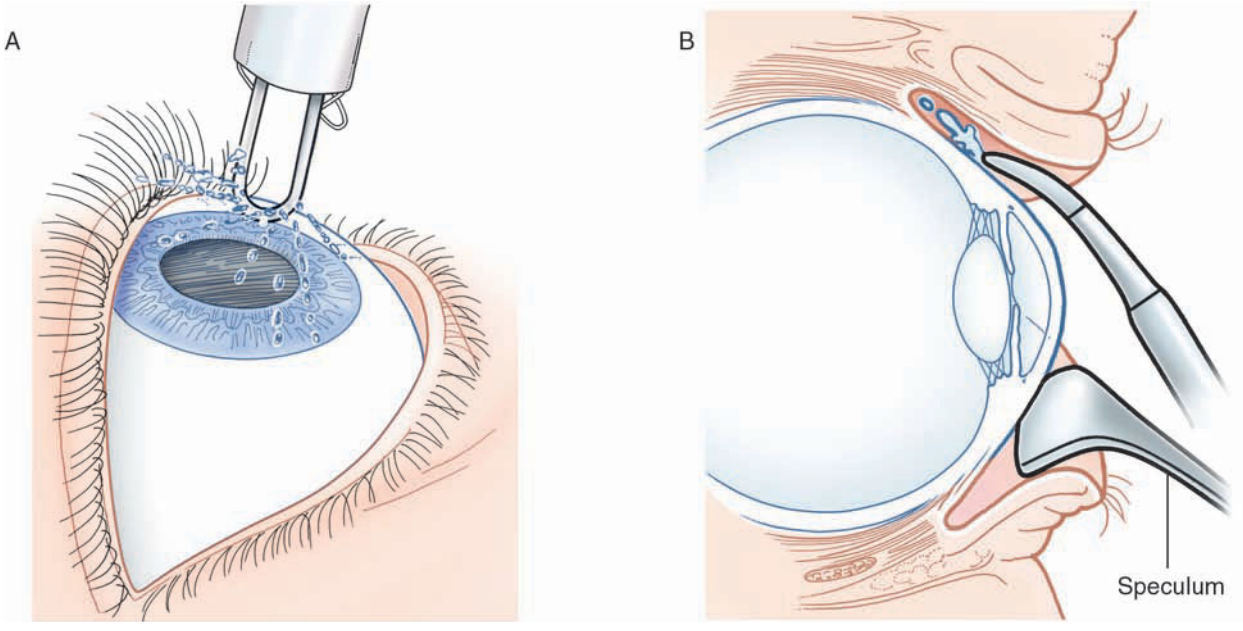

FIGURE 155-5. Eye irrigation with the Eye Irrigator. **A.** The Eye Irrigator. **B.** Cross section of the orbit with the Eye Irrigator under the upper eyelid and a speculum opening the lower eyelid.

start a minimal flow of irrigant solution through the Morgan Lens. Retract the upper eyelid and ask the patient to look down. Insert the lens under the upper eyelid (**Figure 155-4B**). Retract the lower eyelid and ask the patient to look upward. Insert the lower part of the lens under the lower eyelid (**Figure 155-4C**). Increase the flow of the irrigant solution through the lens. Remove the lens by reversing these steps (**Figure 155-4D**).

The Eye Irrigator (American Health & Safety, Madison, WI) delivers the irrigant via a U-shaped cannula with multiple perforations through which the irrigant flows (**Figure 155-5A**). Insert a speculum into the inferior conjunctival sac and retract the lower eyelid (**Figure 155-5B**). Insert the Eye Irrigator under the upper eyelid (**Figure 155-5B**). These steps are reversed for removal of the device. This device is somewhat similar to irrigating systems reported both by Yamabayashi and Terzidou.[26,27]

The EyeCap (Splash Medical Devices LLC, Atlanta, GA) is a simple device to irrigate an eye (**Figure 155-6**). The unit is quick to set up by just screwing it onto a bottle of sterile saline. The base of the unit has universal threads to attach to a bottle of sterile saline (**Figure 155-6**). The other end is wide and contoured to fit over the orbit. The device allows the saline to deflect off its sidewalls and pool over the eye. The patient can open their eye "under water" to gently allow high volume eye irrigation. This device cannot be used for foreign bodies embedded in the cornea, penetrating injuries, or if a ruptured globe is suspected.

SOLID PARTICLES

Ocular burns can be caused by chemicals that are primarily in the solid form (e.g., lime). **Prior to irrigation, attempt to remove as much solid as possible using a moistened cotton-tipped applicator while everting and retracting the eyelids. Quickly proceed to irrigation once most of the solid material has been removed or if removal is limited by blepharospasm.** Copious irrigation is often successful in removing any residual solid material.[17] Proceed directly to irrigation when solid material is not suspected in significant quantity and inspect the conjunctival sac for foreign material once the initial irrigation has been completed.

CONTACT LENSES

Concern that contact lenses may trap chemicals between them and the cornea appears to be unfounded. Contact lenses may, in fact, be protective and act as a shield between the chemical and the cornea.[33,34] **Irrigation should not be delayed in order**

FIGURE 155-6. The EyeCap device attached to a bottle of sterile saline. (Photo courtesy of Joseph Schultz, M.D. and BSN Medical Inc.)

to remove a contact lens unless it appears that a contact lens can be removed easily and quickly. This is the case even when commercial irrigation devices are used. Contact lenses can be removed once an initial period of irrigation has been completed. Refer to Chapter 154 regarding the details of contact lens removal. The contact lenses should be discarded as the chemical may be absorbed by the contact lens, only to be released onto the surface of the cornea if reused.[15,33]

IRRIGATION FLUID

The choice of irrigation fluid is much less important than the speed with which irrigation is started.[18,21] Tap water is perfectly acceptable at the scene of the chemical exposure, although there may be problems with patient discomfort.[17] Normal saline and Ringer's lactate solution are both acceptable during ambulance transport and in hospital. It has been thought that the more neutral pH of Ringer's lactate solution (pH 6.0 to 7.2) should cause less patient discomfort than normal saline (pH 4.5 to 6.0). Similarly, balanced salt solutions (e.g., BSS Plus, Alcon Laboratories, Fort Worth, TX) should theoretically cause less patient discomfort due to its enhanced buffering capacity, physiologic osmolarity, and physiologic pH. These theories have yet to be clearly substantiated.[14,35,36] **Use the irrigant fluid that is most readily available.** Balanced salt solutions should be used only in patients who require prolonged irrigation and for whom other irrigants are unsuitable due to their expense and time-consuming preparation (requiring reconstitution in glass bottles).[14,35]

The use of warmed irrigation fluid appears to increase patient comfort.[37] Ernst et al have reported an optimal irrigant temperature of 32.2 to 37.8 °C (90 to 100 °F). Werwath et al found that 120 seconds were required to heat 1 L bags of normal saline and Ringer's lactate solution to a temperature of 101 °F in a microwave oven set at the highest cooking intensity.[38] **This cannot be routinely recommended, as microwave ovens vary and overheated irrigant fluid will cause secondary injury. Irrigation should not be delayed while an irrigant fluid is being warmed despite the potential value of warmed fluid.** Commence irrigation with room temperature crystalloid solution and switch to a warmed crystalloid solution once prepared. Although not experimentally validated, Rost et al has suggested that cooler liquids at the beginning of irrigation may help reduce the heat of the reaction, thus limiting chemical injury.[21] Saidinejad and Burns has put forward the unproven theory that using a cold irrigant may provide cold anesthesia.[39]

There is probably no chemical ocular burn for which crystalloid irrigants are contraindicated.[18] Metallic sodium, metallic potassium, and white phosphorus may react violently. Remove any visible solid particles with a cotton-tipped applicator prior to irrigation. Irrigation with copious amounts of crystalloid probably dissipates the heat of the initial reaction more than it initiates a thermochemical reaction.[18]

SPECIFIC ANTIDOTES

The mainstay of treatment for chemical ocular burns is early and copious irrigation. Although specific antidotes usually play little role in the treatment of most ocular exposures, there are some instances where antidotes can be helpful once the initial irrigation has been performed. **Consultation with a poison center or Toxicologist should be considered in cases of exposure to unusual agents.**[23]

EDTA may be helpful in removing adherent calcium hydroxide corneal deposits from lime exposures that cannot be removed with a cotton-tipped applicator or toothless forceps.[1,10,23] A 0.05 M neutral solution of EDTA can be prepared by diluting 20 mL of Endrate disodium (150 mg/mL) with 180 mL of normal saline.[10] A cotton-tipped applicator soaked in the EDTA solution can be used to loosen such deposits. EDTA may also be useful in exposures to potassium permanganate and zinc chloride.[10]

Ascorbic acid may be useful in potassium permanganate exposures. A 5% solution can be prepared by dissolving a 500 mg tablet of ascorbic acid in 25 mL of normal saline. The resultant manganese oxide deposits can be dissolved by dripping the solution into the eyes from a moistened piece of gauze.[40]

Numerous other miscellaneous antidotes can be used for specific exposures. Copper sulfate (3% solution) can be used to negate the effects of embedded white phosphorus.[10,23] Polyethylene glycol may be useful in phenol exposures.[41] Mineral oil has been suggested in the removal of cyanoacrylates.[23] Calcium gluconate solutions have no beneficial effect in ocular exposures to hydrofluoric acid.[42]

DURATION OF IRRIGATION

Irrigation should be continued for 20 minutes in the home or workplace prior to patient transport. Emergency medical technicians should continue irrigation during ambulance transport until hospital arrival. The duration of any further irrigation in the Emergency Department depends on the severity of the exposure and the nature of the agent.

Minor exposures with nontoxic substances need not undergo copious irrigation. Irrigation with crystalloid solution using a squeeze-type bottle may be sufficient. In fact, irrigation that had been performed either in the home or in the workplace may be all that is needed. However, treatment should proceed as for caustic agents if the chemical nature of the substance is unknown. **Assume that any previous irrigation was inadequate and that further irrigation is necessary in the Emergency Department.**[4]

Although no definite standard duration for ocular irrigation is available in the literature, most would agree that patients who are significantly symptomatic or who have received a caustic exposure should have their eyes irrigated with a minimum of 1 to 2 L of crystalloid solution over 20 to 30 minutes.[17,43] Exposures to noncaustic agents, milder acid burns, and very mild alkali burns will usually not need further irrigation. Moderate to severe acid burns and anything more than a mild alkali burn will likely require more prolonged irrigation.

The duration of irrigation for caustic exposures is in part governed by pH measurement. After the initial irrigation, measure the pH of the inferior conjunctival sac using wide-range pH paper (i.e., accurate in the pH range of at least 2 to 10) or litmus paper.[10] Litmus paper with a narrower range and urine dipsticks may not be adequate. **If the pH is abnormal, continue irrigation and recheck the pH at 10 to 15 minute intervals until it normalizes.**[10,23] If the pH has reached the near-normal range (i.e., 7 to 8), discontinue irrigation and recheck the pH in 10 to 30 minutes to ensure that it continues to remain normal.[18,23] **In clinically severe caustic burns, regardless of the ocular pH, irrigation should be continued until the patient is evaluated by an Ophthalmologist. Alkali burns are more likely to require prolonged irrigation than acid burns.** In fact, several hours of irrigation may be required for severe alkali burns. In this instance, the Ophthalmologist may opt to perform a regional nerve block to incapacitate the orbicularis oculi muscle, thus limiting blepharospasm and improving patient comfort.[11]

ASSESSMENT

Ocular assessment should be limited to observation of gross injury, assessment of ocular pH, and quick verification of visual acuity until irrigation is complete. These assessments

should not be prolonged and should not delay initial irrigation. A full ophthalmologic assessment is required once irrigation has been discontinued. This should include a recheck of visual acuity, measurement of intraocular pressures, and a slit lamp examination to evaluate for corneal injury, uveitis, and globe perforation.

AFTERCARE

The extent of aftercare required is dependent upon the severity of the injury. Minor exposures to innocuous agents and very mild caustic exposures without corneal changes should be reevaluated in 24 hours if the patient is asymptomatic. Some exposures (e.g., gases, vapors, and fumes) can result in delayed evidence of corneal injury on slit lamp and fluorescein exams.[10] Thus, patients with apparently minor exposures should be cautioned to return to the Emergency Department if their symptoms worsen or do not improve.

Patients with mild exposures that result in corneal defects should be treated with topical antibiotics that have antistaphylococcal and antipseudomonal activity.[10] Ascertain the patient's tetanus immune status and administer prophylaxis as indicated. Analgesics or an eye patch may be offered if patient discomfort is significant.[1,10] Cycloplegics should be prescribed in order to decrease the pain resulting from ciliary spasm and to decrease the risk of the formation of posterior synechiae if anterior chamber involvement is suspected.[10,28] After a chemical burn, patients chronically using phosphate buffer-containing eye drops (e.g., timolol and latanoprost) are at greater risk of corneal calcification.[44] Telephone consultation with an Ophthalmologist is recommended. Ophthalmology follow-up should occur within 24 hours.

Moderate to severe ocular burns require admission and acute evaluation by an Ophthalmologist. Medical treatment of secondary glaucoma may be required. Anterior chamber paracentesis and lavage may be needed early in the course of severe alkali burns in order to decrease the anterior chamber pH as well as intraocular pressure.[1,10,23,41] Necrotic tissue will have to be debrided.[4] The goals of longer-term therapy include the prevention of corneal ulceration, prevention of scarring of the anterior ocular structures, prevention of globe perforation, and the promotion of corneal reepithelialization.[23] Steroids, nonsteroidal anti-inflammatory agents, frequent lubrication, and soft contact lenses may help in this regard.[1,4] Ascorbic acid and collagenase inhibitors are experimental. More severe injuries require surgical intervention due to the loss of stem cells at the limbus and thus the loss of potential corneal reepithelialization.[4]

COMPLICATIONS

Pain and discomfort are common after ocular exposure to chemicals. These can be minimized with topical ophthalmic anesthetic agents, parenteral sedatives, and parenteral narcotics in the Emergency Department. Corneal injury is usually the result of the primary chemical injury. Corneal injury may result from the irrigant or irrigating device, particularly if improper technique is used. Frequent use of topical ophthalmic anesthetic agents can lead to corneal injury. Extrusion of ocular contents is possible in the setting of a globe penetration. The diving reflex is a rare but possibly significant complication. This reflex is mediated by the ophthalmic branch of the trigeminal nerve and the vagus nerve. It is triggered by a cold water stimulus to the face and results in bradycardia without hypotension. The diving reflex is more common in infants and children. Its clinical importance is greatest in patients with significant comorbid disease. Continuous cardiac monitoring is wise in these subsets of patients. Irrigation with warm water may limit this reflex.[45,46]

SUMMARY

Ocular irrigation is an eye-saving procedure in the setting of significant ocular burns. For trained personnel, it is an easy and safe procedure to perform. First-aid workers, emergency medical technicians, and Emergency Department personnel should be trained in its use. Ocular irrigation should be performed rapidly with the most available nontoxic irrigant, as delays of even seconds can limit its effectiveness.

156 Intraocular Pressure Measurement (Tonometry)

Michelle M. Verplanck, Mark A. Rolain, and Aaron D. Cohn

INTRODUCTION

This chapter is designed to help the Emergency Physician know when it is necessary to measure intraocular pressure (IOP) and reviews several reliable methods of tonometry to measure IOP. There are multiple traumatic, pathologic, and postsurgical causes of altered IOP. The clinical signs and symptoms of elevated IOP are similar regardless of the etiology. Digital palpation is the oldest and simplest form of tonometry and remains useful in select situations. Schiøtz indentation tonometry is discussed for historical purposes but is still an accurate method to measure IOP. The nonportable Goldmann or applanation tonometer serves as the standard for measuring accurate IOP. It requires the use of a slit lamp and can be difficult to master. The handheld Perkins and Kowa tonometers are based on the same principle as the Goldmann and require experience to use effectively. The electronic Tono-Pen is best known to most Emergency Physicians and is discussed at length. It is useful to become comfortable with one or more of these techniques because early detection of abnormal IOP can prevent irreversible vision loss.

ANATOMY AND PATHOPHYSIOLOGY

Aqueous humor is produced by the ciliary body in the posterior chamber of the eye, directly behind the iris (**Figure 156-1**). Most of the aqueous humor flows forward, through the pupil, into the anterior chamber. It drains out of the eye through the trabecular meshwork located at the angle where the cornea and iris meet. This is the area referred to in open angle, narrow angle, and angle closure glaucoma. In healthy eyes, aqueous humor production is equivalent to outflow. IOP reflects the pressure of the ocular contents and by convention is expressed in millimeters of mercury or mmHg.[1] The mean IOP in the general population is 16 mmHg with a standard deviation of 3 mmHg.[2] Therefore, normal pressure is considered to range from 10 to 22 mmHg.

Aqueous humor production and outflow can be dramatically affected by disease or injury of the eye. Even small changes in IOP over long time periods can be vision threatening. However, significant increases in pressure can cause rapid and irreversible damage to vision in just a few hours. Nontraumatic conditions that result in an elevation of IOP include primary angle-closure glaucoma and secondary angle-closure glaucoma. Traumatic conditions associated with elevated IOP include retrobulbar hemorrhage, hyphema, and traumatic iritis. Conditions associated with low IOP that threaten vision include penetrating trauma and postsurgical complications.

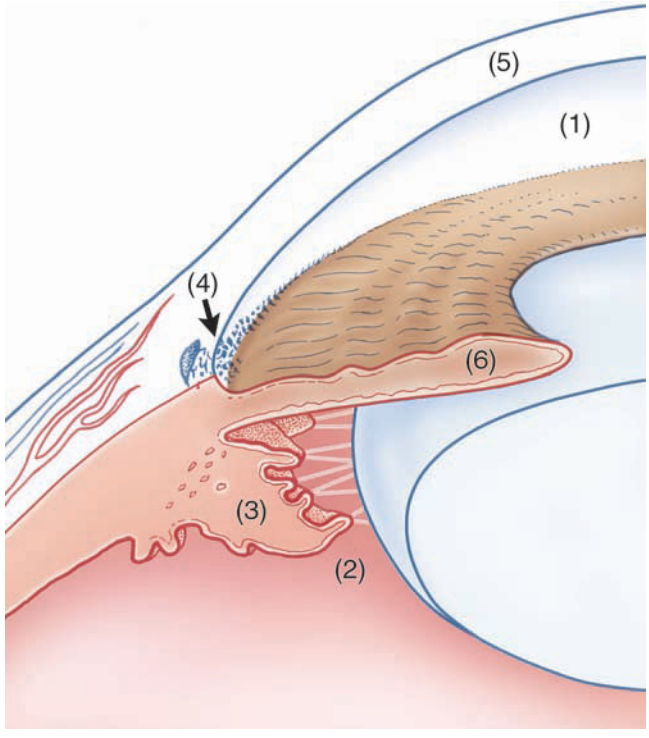

FIGURE 156-1. Anatomy of the anterior segment of the eye: (1) anterior segment; (2) posterior segment; (3) ciliary body; (4) trabecular meshwork; (5) cornea; and (6) iris.

Patients with primary or secondary acute angle-closure glaucoma often present with ocular pain and decreased vision, usually in one eye. They may describe a headache in the brow region, with or without associated nausea and vomiting. External examination frequently reveals that the conjunctiva is erythematous, the cornea appears milky or hazy, and the pupil is slightly dilated with a sluggish response to light (**Figure 156-2**).

Traumatic retrobulbar hemorrhage can result in markedly elevated IOP. Patients will present with a painful proptosis and fullness of the periorbital tissues. There is usually restricted movement of the eye in one or more fields of gaze. Acute onset of retrobulbar inflammation will present the same way, but there is no history of trauma. A spontaneous nontraumatic retrobulbar hemorrhage can occur in patients with a coagulopathy. Refer to Chapter 162 regarding the complete details and management of a retrobulbar hemorrhage.

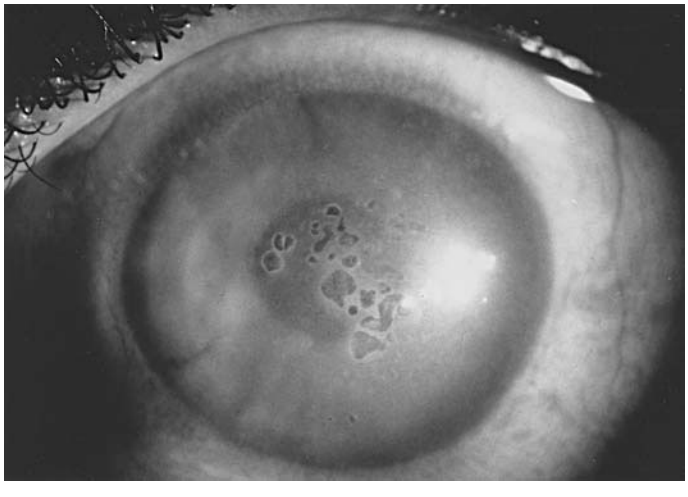

FIGURE 156-2. A high magnification of an eye with angle-closure glaucoma and a markedly elevated IOP. Note the corneal edema and the mid-dilated pupil.

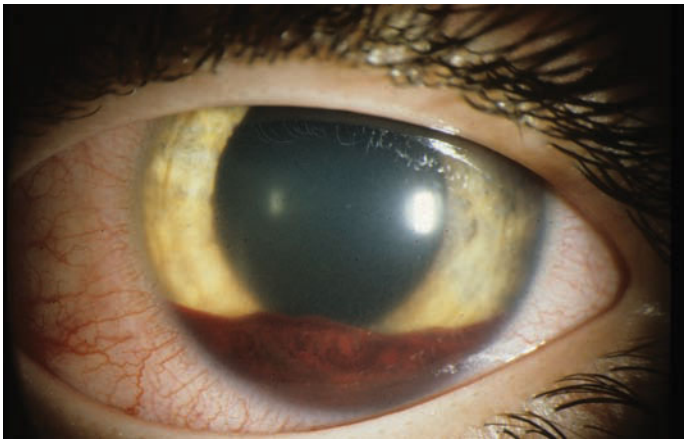

FIGURE 156-3. A traumatic hyphema with 10% to 15% layered blood in the anterior chamber.

Traumatic iritis may result in an elevated or a reduced IOP. Traumatic iritis presents following blunt, nonpenetrating trauma to the eye. Inflammatory cells circulating in the anterior chamber may impede aqueous outflow resulting in high IOP. Iritis may also affect the ciliary body causing a decrease in the production of aqueous humor and a lower IOP. These patients present with eye pain and photophobia. They usually describe their vision as slightly blurred and give a history of trauma within the last 48 hours. The history of recent trauma and light sensitivity is important given that the external examination of the eye may appear normal. The cornea will be clear and a slit lamp examination is usually necessary to identify the inflammatory cells in the anterior chamber.

A hyphema is visible blood that layers out in the anterior chamber between the iris and the cornea (**Figure 156-3**). A microhyphema is diffuse blood circulating in the anterior chamber. These patients present with decreased vision, photophobia, and blood in the anterior chamber. A common cause of blood in the anterior chamber is blunt, nonpenetrating trauma to the eye. A patient with blood in the anterior chamber and a history of sickle cell disease or trait is at a higher risk of elevated IOP.[3] Consult an Ophthalmologist if a sickle cell patient presents with blood in the anterior chamber.

INDICATIONS

Patients presenting with a painful eye and/or decreased vision, and no history of ocular trauma, should have their IOP measured and documented. Do not measure IOP if there is a history of blunt trauma associated with these symptoms. Some of the common presentations that require documentation of the IOP are reviewed in the previous section. This includes confirming the clinical diagnosis of acute angle-closure glaucoma, determining IOP after blunt ocular trauma, and determining IOP in a patient with iritis.

CONTRAINDICATIONS

It is essential to rule out a ruptured globe before tonometry is performed when a patient relays a history of trauma. Tonometry should be strictly avoided if there is evidence of a ruptured globe

or the suspicion of a ruptured globe. A ruptured globe from penetrating trauma to the anterior segment of the eye, including corneal or scleral lacerations, is usually obvious upon clinical examination. However, blunt trauma resulting in a ruptured globe may be very difficult to see on examination. Any blunt force (e.g., closed fist) causing an anteroposterior compression of the globe can result in a scleral rupture posterior to the attachment of the extraocular muscles. This is rarely obvious on external examination or a nondilated slit lamp examination. The clue here is that the patient has dramatically reduced vision and prominent swelling of the periorbital tissues.

Viral conjunctivitis is one of the most common ocular conditions seen in the Emergency Department. Conjunctivitis is so highly infectious that it is a relative contraindication to performing tonometry. These patients may present with ocular pain and decreased vision just like patients with angle-closure glaucoma. Conjunctivitis symptoms are usually binocular and the pain is not as severe. Acute angle-closure glaucoma almost always presents in one eye. It is reasonable to proceed with tonometry to rule out increased IOP as an etiology of a painful red eye if the diagnosis of conjunctivitis is uncertain. **Clean the instrumentation carefully to prevent spreading the infection to the contralateral eye.** The instrument of choice in cases of suspected infection is the Tono-Pen as it uses disposable, single-use, latex covers for the instrument.

EQUIPMENT

Topical Ophthalmic Anesthetic Agents

- Proparacaine hydrochloride 0.5% (Alcaine, Ocu-Caine, Ophthaine, Ophthetic)
- Tetracaine hydrochloride 0.5% (AK-T-Caine, Altacaine, Opticaine, Protocaine)

Topical Stain for Tear Film

- Fluorescein sodium 1 mg strips (Fluorets, Fluor-I-Strip-AT, Ful-Glo)
- Fluorescein ophthalmic solution (Fluress, Fluorescein Sodium)

Tonometers

- Goldmann applanation tonometer
- Handheld applanation tonometer (e.g., Tono-Pen)
- Schiøtz indentation tonometer

Antiseptic

- >70% isopropyl alcohol solution/swabs
- 3% hydrogen peroxide solution

PATIENT PREPARATION

Inform the patient of the need to measure the pressure in their eye. Explain that an instrument will contact their tear film directly over the cornea. Reassure the patient that tonometry is not painful. It is not necessary to have the patient sign a consent form, as tonometry is part of a routine eye examination. One may choose to document the discussion with the patient for completeness.

Remove all contact lenses before the instillation of any topical ocular anesthetic agent or fluorescein. Measuring IOP through a contact lens is unreliable. The fluorescein dye will permanently stain contact lenses and clothing.

Instill one drop of a topical ophthalmic anesthetic agent in both of the patient's eyes. The contralateral eye is used as the control, even if only one eye is of concern. Topical ophthalmic anesthetic agents begin working within 30 seconds and remain effective for 10 to 20 minutes. The drops may burn when applied and may cause a transient drying of the cornea. Instruct the patient not to touch or rub their eyes until the anesthesia wears off.

Instill fluorescein when using any prism applanation tip, such as in Goldmann, Perkins, or Kowa tonometers. Fluorescein is not needed when using the Tono-Pen or the Schiøtz tonometer. Fluorescein is available on strips or in solution. Fluorescein strips are applied to the tear film on the inner layer of each lower eyelid. Dampen the strip with a drop of topical anesthetic before application if the eye is extremely dry. If using fluorescein solution, instill a drop of fluorescein in the cul-de-sac of each lower eyelid.

All plastic prism applanation tonometer heads and the metal plunger of the Schiøtz need to be sterilized to prevent cross contamination. **Do not use sterilization solution on electronic tonometer tips.** Replace the disposable cover over the tip of the tonometer after each use. To sterilize the tip of a tonometer, use a prepackaged 70% alcohol swab or gauze soaked in 70% alcohol. Apply the alcohol to the tip of the prism for 10 seconds and allow it to air dry. Gauze soaked in 3% hydrogen peroxide may also be used. Rinse the tip with sterile saline to wash off the 3% hydrogen peroxide before application to prevent iatrogenic corneal abrasions. These described methods effectively disinfect for common bacteria and viruses, adenovirus, herpes simplex, and HIV.[4,5]

TECHNIQUES

DIGITAL PALPATION

Digital palpation is not as accurate as applanation tonometry. Digital palpation has been an informal means of judging IOP, as there is a built-in comparison with the contralateral eye. Studies examining this technique have shown inexperienced examiners can improve their accuracy with a short training session to within 5 mmHg of the actual IOP 88% of the time.[6] **Digital palpation should not be attempted if there is any potential for a ruptured globe.**

Place the patient supine or in a reclined position. Ask the patient to close their eyes and look straight ahead through the closed eyelids. Stand next to the patient's torso and facing them. Place the right thumb over the patient's left eye and left thumb over the patient's right eye. Place the remaining fingers of both hands on the patients' temples for stability. Apply gentle alternating pressure to each globe. The Emergency Physician should be able to ascertain any difference in pressure between the two eyes using the patient's contralateral eye as a control. The Emergency Physician may also gently palpate their own globe as a normal control. This qualitative measurement is often sufficient to determine a significantly elevated IOP.

SCHIØTZ TONOMETRY

The Schiøtz tonometer estimates IOP by measuring the indentation of the globe caused by a known weight.[7] The Schiøtz tonometer is a sturdy, low maintenance, and affordable instrument. It is gravity dependent and requires the patient to be supine or have their head fully extended to get an accurate reading. The Schiøtz tonometer case contains the Schiøtz tonometer, a calibration scale, weights, and a calibration platform (**Figure 156-4**).

The tonometer consists of a plunger and a hammer device connected to a needle (**Figure 156-5**). The needle is calibrated to a scale, with each unit measuring 0.05 mm on the scale. The plunger, the hammer, and the needle weigh 5.5 g. This can be increased to 7.5, 10, or 15 g by adding known weights to the tonometer. The weighted plunger is heavy and has a large contact area that causes significant indentation of the cornea with each measurement. **The**

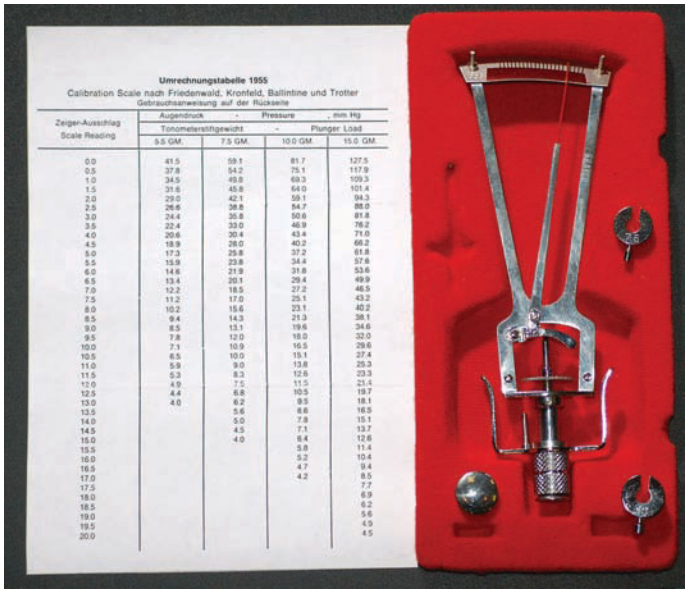

FIGURE 156-4. The contents of the Schiøtz tonometer case.

more weight it takes to move the needle on the scale or indent the cornea, the higher the IOP. The scale reading is converted to IOP in mmHg by a conversion chart supplied with each Schiøtz tonometer (**Figure 156-4**).

Place the patient supine or sitting with their head fully extended. Ensure that the patient is comfortable. A tight collar, flexed neck, breath-holding, squeezed eyelids, looking toward the nose, or accommodation results in a falsely elevated reading. Place two drops of a topical ophthalmic anesthetic agent onto each eye.

Calibrate the tonometer by placing the footplate of the plunger on the platform provided in the case (**Figures 156-4 & 156-5**). **The scale reading must be "0" while the footplate is on the platform. The instrument requires repair if it does not read zero while on the platform.**

Instruct the patient to look at a fixation target directly overhead and to open both eyes as wide as possible. Spread the eyelids with the nondominant index finger and thumb if necessary. Grasp the Schiøtz tonometer by its handle. **Ensure that the fingers holding the eyelids open are pushing on the orbital rim and not the globe, falsely elevating the IOP.** Place the footplate of the Schiøtz tonometer directly over the pupil and gently lower it onto the tear film (**Figure 156-6**). Note the reading on the scale. Add more weight if the scale reading is less than three units. **Do not push down on the cornea with the Schiøtz tonometer. This will cause a false elevation in the IOP reading.** Repeat the measurement several times or until three readings are within 0.5 scale units. Convert the scale reading to IOP with the conversion chart (**Table 156-1**).[8]

Clean the tonometer immediately after each use. Clean the barrel with two pipe cleaners, the first soaked in 70% isopropyl alcohol and the second one dry. Clean the plunger with an alcohol swab. Allow the instrument to air dry 1 to 2 minutes before being used in the contralateral eye so that the alcohol evaporates and is not transferred to the corneal surface.[10]

GOLDMANN (APPLANATION) TONOMETRY

The Goldmann tonometer is considered the clinical standard for measuring IOP. This method of tonometry is based on the Imbert-Fick principle.[4] It states that the pressure inside an ideal dry, thin-walled sphere equals the force necessary to flatten its surface divided by the area of the flattening ($P = F/A$; where P = pressure, F = force,

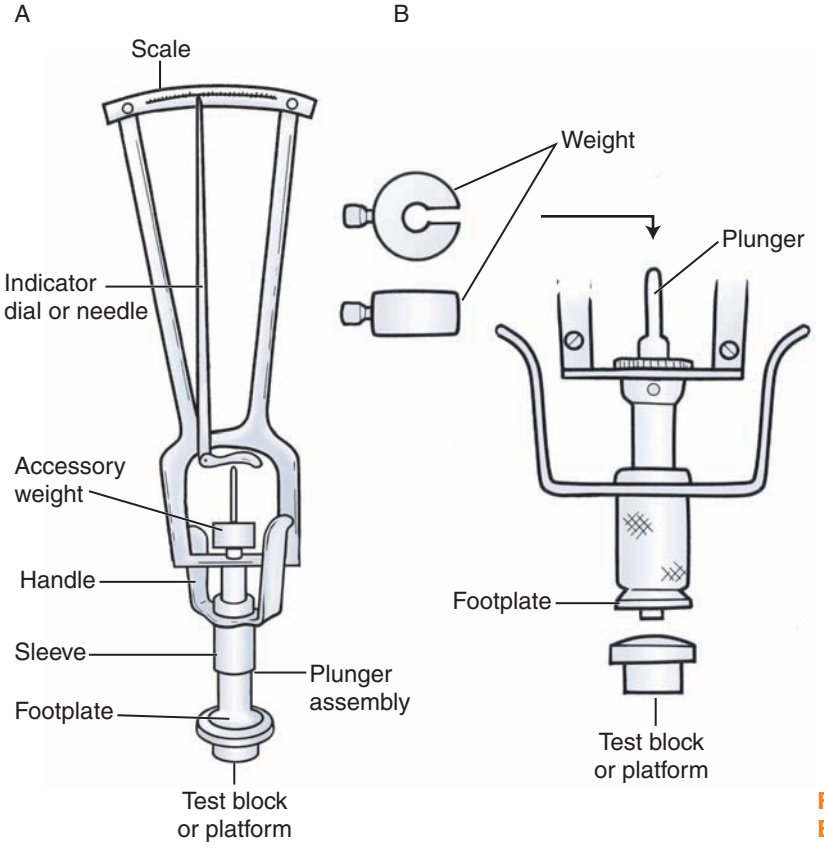

FIGURE 156-5. The Schiøtz tonometer. **A.** Schematic of the tonometer. **B.** Schematic of the plunger assembly.

FIGURE 156-6. The Schiøtz tonometer positioned on the cornea.

TABLE 156-1 The Schiøtz Tonometer Scale

Tonometer reading	5.5 g load	7.5 g load	10 g load	15 g load
0.0	41.5	59.1	81.7	127.5
0.5	37.8	54.2	75.1	117.9
1.0	34.5	49.8	69.3	109.3
1.5	31.6	45.8	64.0	101.4
2.0	29.0	42.1	59.1	94.3
2.5	26.6	38.8	54.7	88.0
3.0	24.4	35.8	50.6	81.8
3.5	22.4	33.0	46.9	76.2
4.0	20.6	30.4	43.4	71.0
4.5	18.9	28.0	40.2	66.2
5.0	17.3	25.8	37.2	61.8
5.5	15.9	23.8	34.4	57.6
6.0	14.6	21.9	31.8	53.6
6.5	13.4	20.1	29.4	49.9
7.0	12.2	18.5	27.2	46.5
7.5	11.2	17.0	25.1	43.2
8.0	10.2	15.6	23.1	40.2
8.5	9.4	14.3	21.3	38.1
9.0	8.5	13.1	19.6	34.6
9.5	7.8	12.0	18.0	32.0
10.0	7.1	10.9	16.5	29.6
10.5	6.5	10.9	15.1	27.4
11.0	5.9	9.0	13.8	25.3
11.5	5.3	8.3	12.6	23.3
12.0	4.9	7.5	11.5	21.4
12.5	4.4	6.8	10.5	19.7
13.0	4.0	6.2	9.5	18.1
13.5		5.6	8.6	16.5
14.0		5.0	7.8	15.1
14.5		4.5	7.1	13.7
15.0		4.0	6.4	12.6
15.5			5.8	11.4
16.0			5.2	10.4
16.5			4.7	9.4
17.0			4.2	8.5
17.5				7.7
18.0				6.9
18.5				6.2
19.0				5.6
19.5				4.9
20.0				4.5

Use the tonometer scale reading and the weight applied to the plunger (gram load) to determine the IOP reading in mmHg.

and A = area). The Goldmann tonometer determines the force necessary to flatten or applanate an area of the cornea 3.06 mm in diameter. The degree of flattening is determined while viewing the cornea through a split prism device in the tonometer head. Fluorescein is used to stain the tear film in order to distinguish the cornea from the tear film. The eye is viewed through the cobalt blue filter causing the fluorescein-stained tear film to appear yellow-green. The technique is described below.[5]

The Goldmann tonometer is not portable. It requires the patient to be cooperative, the patient to sit upright, and a working knowledge of the slit lamp. The Goldmann tonometer in combination with a slit lamp examination provides the clinician with the most detailed information about the patient's ocular condition.

Place two drops of a topical ophthalmic anesthetic agent onto each eye. Place fluorescein dye in the eye. Position the tonometer head and cobalt filter on the slit lamp. Set the tension knob at 10 mmHg. It is more accurate to measure IOP by increasing rather than decreasing the force of applanation. Seat the patient in front of the slit lamp. Support the patient's chin in the chin rest and place their forehead firmly against the strap (**Figure 156-7**).

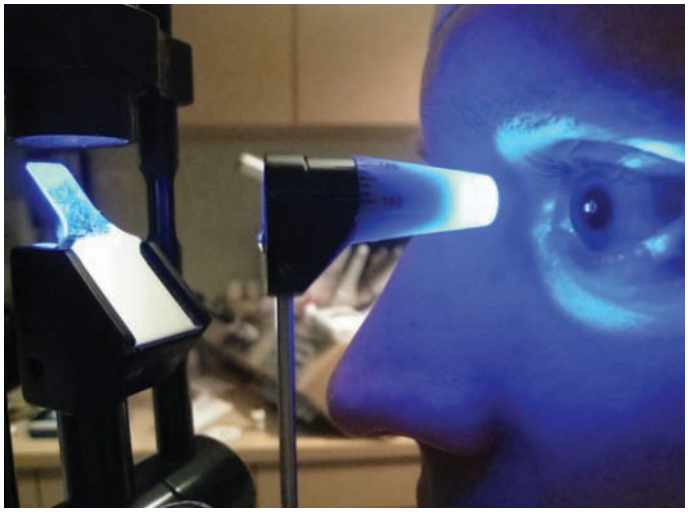

FIGURE 156-7. A patient positioned in the slit lamp with a Goldmann tonometer in position to be advanced onto the cornea.

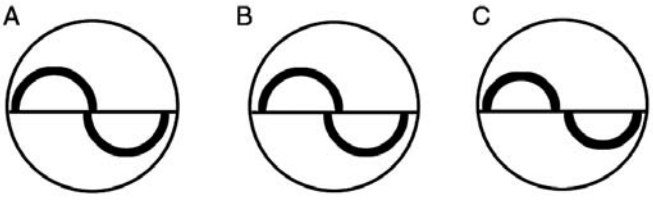

FIGURE 156-8. Semicircles as seen through the Goldmann tonometer. **A.** The inner edges of the semicircles are touching signifying the correct IOP reading. **B.** Semicircles are not touching because the pressure reading on the tension knob is too low. **C.** Semicircles are overlapping because the pressure reading is too high.

Instruct the patient to look straight ahead and open both eyes as wide as possible. Spread their eyelids with a thumb and forefinger if necessary. **Do not put pressure on the globe while holding the eyelids open.**

Move the tonometer head within one-half inch of the cornea. Use the control stick on the slit lamp to center the applanation head directly over the pupil. Look for two semicircles on the ocular surface as the tonometer head is advanced onto the corneal tear film (**Figure 156-8**). Ensure that the tension knob is set at 10 mmHg. The semicircles will not be touching if the patient's pressure is above 10 mmHg (**Figure 156-8B**). Turn the tension knob clockwise to raise the reading and counterclockwise to lower the reading. Turn the tension knob up until the inside borders of the fluorescein rings are touching (**Figure 156-8A**). Read the IOP on the tension knob. The semicircles will overlap if the pressure is below 10 mmHg (**Figure 156-8C**). Turn the tension knob down until the inside borders of the fluorescein rings are touching (**Figure 156-8A**). Read the IOP on the tension knob.

Clean the tonometer head with an alcohol swab immediately after use. Let it air dry 1 to 2 minutes so that the alcohol evaporates and is not transferred to the corneal surface. Repeat the procedure on the contralateral eye.

HANDHELD TONOMETRY

The Tono-Pen XL and the Tono-Pen Avia (**Figure 156-9**) are lightweight, simple to operate, and can record IOP with the patient in any position. The small contact area is useful in patients with eyelid swelling and corneal surface irregularities. The Tono-Pen calculates IOP using a strain gauge that creates an electronic signal as the 1.5 mm footplate flattens the cornea.[10] A single microprocessor chip analyzes each application of the footplate and averages 4 to 10 valid measurements to form one reading. The instrument should be stored in its case when not in use. An Ocu-Film cover should remain over the tip when it is stored and changed with each new patient (**Figure 156-9**). **The Ocu-Film covers are made of latex. Ask the patient about latex allergies prior to using this device. The tip of the Tono-Pen is very sensitive, is easily damaged, and should never be touched.**

The Tono-Pen XL unit is internally calibrated, thus the instrument calibration should be checked before the first use each day or in the event of unanticipated readings. Calibration should also be performed whenever it is indicated by the LCD display, when batteries are replaced, or after unsuccessful calibration. If the word "bAd" appears in the LCD window, it needs to be calibrated. The Tono-Pen is not used or calibrated daily in the Emergency Department. Thus, it is necessary to check the calibration prior to each use.

The display of "Good" in the LCD window indicates that the Tono-Pen is functioning properly. Press the operation button once. The Tono-Pen will display [8.8.8.8] in the LCD window, followed by a single row of dashes [----], and then a double row of dashes [= = = =]. This indicates that the Tono-Pen is ready to measure IOP.

FIGURE 156-9. The Reichert Tono-Pen XL and Reichert Tono-Pen Avia. The Tono-pen XL has an Ocu-Film cover in place.

To calibrate the Tono-Pen aim the transducer end straight down. Depress the operation button twice within 1.5 seconds. The Tono-Pen will beep and display "CAL" in the LCD window. Wait for the Tono-Pen to beep and display "UP" in the LCD window. This can take as long as 15 seconds. Immediately and quickly invert the Tono-Pen so that the transducer end is pointing straight up. The Tono-Pen will beep and display "Good" in the LCD window if it is functioning properly. Repeat the calibration procedure if "bAd" is displayed in the LCD window.

Place the patient in a seated or supine position. Instruct the patient to look straight ahead. Place two drops of a topical ophthalmic anesthetic agent onto each eye. Fluorescein is not necessary when using the Tono-Pen. Grasp the Tono-Pen like a pencil and hold it perpendicular to the corneal surface (**Figure 156-10**). Gently contact the cornea directly over the pupil or central cornea (**Figure 156-10**). Make contact with the cornea in a series of light taps. **The Tono-Pen should not indent the cornea if used properly, reducing the risk if there is an unidentified ruptured globe or a hyphema.** The Tono-Pen chirps each time a valid IOP measurement is obtained. The microprocessor sounds a final beep after it receives four valid readings. The mean IOP will be displayed in the LCD window. A single row of dashes [----] indicates that an insufficient number of valid readings were collected. Obtain additional measurements after pressing the operation button.

FIGURE 156-10. The Tono-Pen positioned in front of the cornea.

ALTERNATIVE DEVICES

There are many additional handheld tonometers of varying cost, ease of use, and availability. The Perkins MK-2 (Haag-Streit, Essex, UK) and the Kowa HA-2 (Kowa Optimed, Inc., Torrance, CA) are two handheld tonometers utilizing the Goldmann prism technique (i.e., aligning the semicircular images). They are portable, but require a familiarity with Goldmann applanation. The Accupen (Accutome, Malvern, PA) is similar to the Tono-Pen with a few differences. These include ease of use, longer battery life, and not requiring calibration before every use. The Diaton transpalpebral handheld tonometer (Bicom Inc., Long Beach, NY) is designed to measure IOP through a patient's closed eyelids.[11] The Pulsair IntelliPuff (Keeler, Brownhill, PA) is the only portable, handheld, noncontact tonometer. The iCare Rebound (Tiolat Oy, Helsinki, Finland) uses a smaller zone to indent the cornea and claims not to require topical anesthesia.[12] This would be particularly useful for the Emergency Department should it prove to be reliable.

ASSESSMENT

The normal range for IOP is 10 to 22 mmHg. A baseline IOP is specific to each patient and the patient's contralateral eye can serve as a control. We can make general assumptions about certain ranges of IOP in order to make rapid clinical assessments and facilitate patient care. Readings of 0 to 9 mmHg should be discussed with an Ophthalmologist, especially if there is a history of recent eye surgery or recent eye trauma. Readings of 10 to 21 mmHg are normal. Readings of 22 to 25 mmHg should be followed up with an Ophthalmologist within 2 to 3 days. IOP readings greater than 26 mmHg require an emergent consultation with an Ophthalmologist.

COMPLICATIONS

Infectious agents can be transferred via tonometer heads.[9] **It is essential to properly clean each instrument before use, before using it on the contralateral eye, and after use.** The use of a 70% isopropyl alcohol swab is an effective disinfectant for the Goldmann and the Schiøtz tonometers. The Tono-Pen has single-use disposable latex covers.

Incorrect IOP measurements can occur for a variety of reasons. An improperly working plunger on the Schiøtz tonometer can result in falsely low measurements. IOP will be elevated if measured while the examiner's hand is holding the eyelids open and inadvertently pressing on the underlying globe. Measurement during eye movements, blinking, or eyelid movements will elevate IOP. Maneuvers that increase intracranial pressure (e.g., valsalva or breath holding) also increase IOP.

Corneal abrasions can occur while using contact tonometers. It is very important to have a cohesive tear film to avoid cornea abrasions. Instruct the patient to blink several times just prior to tonometry to spread the tear film. Apply artificial tears in patients with extremely dry eyes. The Schiøtz tonometer puts significant weight on the cornea and must be applied very gently. Warn the patient that their eye may be uncomfortable when the anesthetic wears off if a small abrasion is suspected after measuring the IOP. Instruct the patient to instill artificial tears every 4 to 6 hours. Treat larger abrasions with a topical ocular antibiotic of choice and schedule a follow-up visit.

SUMMARY

The practice of tonometry is essential in guiding appropriate eye care. The Goldmann, Tono-Pen, or Schiøtz contact tonometers are readily available in most Emergency Departments. The literature frequently debates the comparative accuracy of each instrument. The Goldmann applanation tonometer is generally considered the clinical standard.[11,12] However, all three instruments are useful for screening IOP in the Emergency Department. Factors such as the patient's ability to ambulate and the presence of periorbital swelling will influence the choice of an instrument. The Emergency Physician should select a tonometer that feels comfortable and use it routinely. The Emergency Physician will be able to measure IOP rapidly and reliably with repeated use of the tonometer.

157 Digital Globe Massage

Carlos J. Roldan and Eric F. Reichman

INTRODUCTION

Digital globe massage has been considered a heroic measure to salvage vision in cases of central retinal artery occlusion (CRAO), an ophthalmologic emergency.[1–8] CRAO is one of several diagnoses to consider in the patient with acute painless loss of vision or a visual field. The typical patient is older, between the ages of 50 and 80 years of age, and with significant systemic illnesses. The CRAO is most likely an embolic event secondary to atherosclerotic disease. The vision loss is sudden, monocular, and painless. The outcome for CRAO is poor if treatment is delayed more than 2 hours. Spontaneous remission and recovery of visual function is rare. This condition requires an emergent consultation with an Ophthalmologist for medical management and the consideration of an anterior chamber paracentesis (Chapter 158). Digital globe massage can be used in an attempt to relieve the obstruction or break up the embolus so it moves distally to restore some blood flow to the retina.

ANATOMY AND PATHOPHYSIOLOGY

The ophthalmic artery is a branch of the carotid artery (**Figure 157-1**). The first branch of the ophthalmic artery is the central retinal artery. This vessel runs along the optic nerve and enters the optic nerve. The central retinal artery is the main blood supply to the retina. The macula has an independent blood supply from

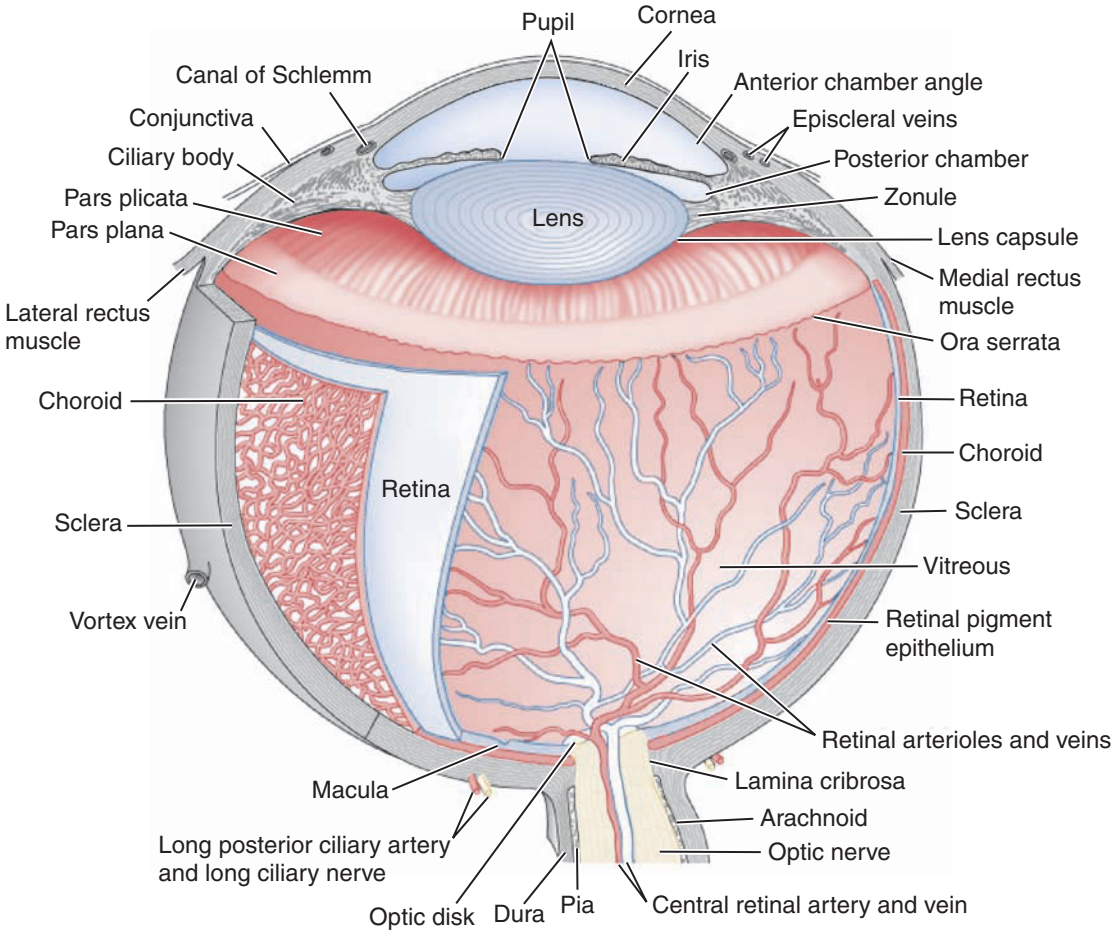

FIGURE 157-1. The anatomy of the eye. (Used with permission from: Riordan-Eva P, Whitcher JP (eds): *Vaughan & Asbury's General Ophthalmology*, 17th ed. New York: McGraw-Hill, 2008.)

other branches of the ophthalmic artery. An area between the macula and the optic nerve receives collateral circulation from the central retinal artery and the ciliary arteries in a small percentage of the population. This explains why a patient with a complete CRAO may have a normal appearing macula and occasionally an area of perfusing retina adjacent to the optic nerve area.

The individual etiology remains unclear in many cases. The main cause of retinal arterial occlusions is an embolic event lodging in the central retinal artery where it narrows to pass through the lamina cribrosa, or in a smaller distal branch arteriole. The embolism may be comprised of aggregated fibrin and platelets arising from an ulcerated vessel wall thrombus, cholesterol from an ulcerated carotid artery plaque, material from cardiac valvular disease, or thrombus formation from giant cell arteritis. The embolus may also result from an invasive procedure such as cardiac angioplasty, carotid angioplasty and stenting, or a carotid endarterectomy.

Abnormal cardiac rhythms are considered an etiology for intracardiac blood clot formation. These may embolize and lodge in the ophthalmic artery or distally in one of the branch arteries. Retrobulbar masses (e.g., a hematoma, neoplasm, or retrobulbar injection) may also lead to an optic nerve and central retinal artery compression.[1]

PHYSICAL EXAMINATION FINDINGS

The patient may display vision compromise ranging from a small visual defect to a decreased ability to finger count or perceive light, and to complete blindness. Grossly, the eye appears normal. However, an afferent pupillary defect may be evident with little or no reaction to direct light and a normal reaction to consensual light. The initial fundoscopic examination may show a near-normal retinal appearance (**Figure 157-2A**). This soon progresses to a pale retina, bloodless or attenuated arterioles, and "boxcar" segmentation of the retinal veins (**Figure 157-2B**). The fundoscopic exam will then reveal a milky and edematous retina with a cherry-red macula if the entire central retinal artery is occluded. If the cilioretinal artery flow is not occluded, there will be an area of perfusion between the optic disc and the macula (**Figure 157-2B**). An embolus may be visible in the vasculature of the optic disc in rare cases. If a branch retinal artery is occluded, an embolus may be visible in the vessel with ischemia and infarction distal to the occlusion.

It has been shown experimentally that the retinal damage is irreversible after 100 minutes of nonperfusion.[3] There is anecdotal evidence that heroic measures to salvage vision after a CRAO have sporadically resulted in the return of vision. A large study showed that the average final visual acuity in patients with a CRAO treated with heroic measures compared to those untreated was only a one-quarter line improvement in Snellen chart visual acuity. If the underlying cause of the CRAO is giant cell arteritis, up to 10% of the cases progress rapidly to bilateral vision loss if the arteritis is left untreated.

MEDICAL MANAGEMENT

Various methods have been employed to reduce intraocular pressure or to dilate the artery in an attempt to facilitate dislodgement

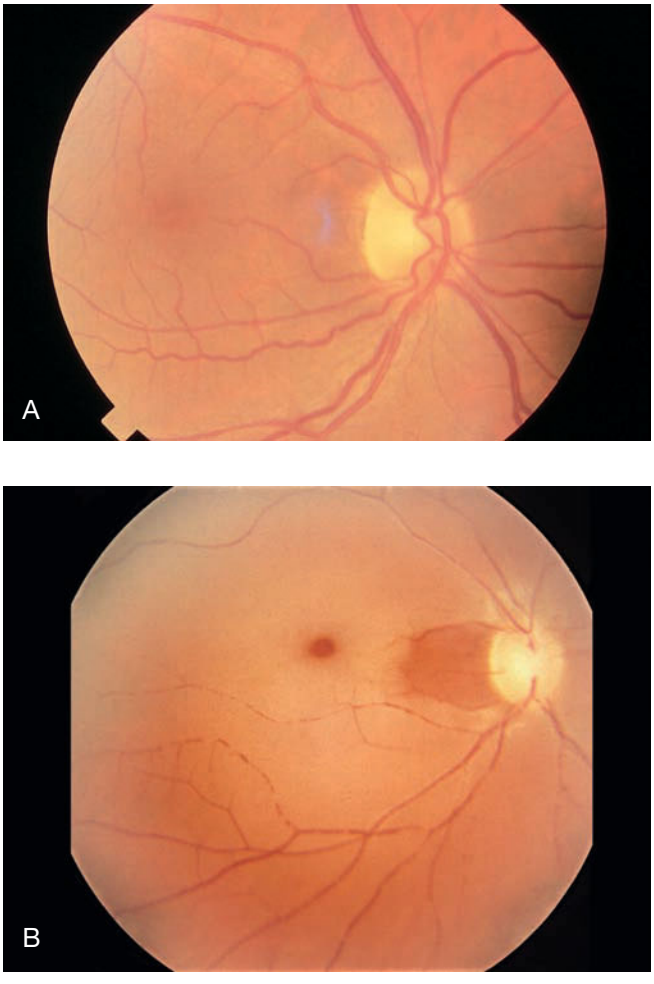

FIGURE 157-2. Fundoscopic images of the eye. **A.** Normal examination. **B.** CRAO with cilioretinal vessel sparing. (Used with permission from: Knoop KJ, Stack LB, Storrow AB, et al: *The Atlas of Emergency Medicine*, 3rd ed. New York: McGraw-Hill, 2010.)

of the embolus.[1–8] None of these have been proven to be of benefit in the management of a CRAO.[6] On the other hand, none of these have been proven to be harmful. Thus, they may prove to be useful in saving the patients vision. The following interventions should be considered as coadjuvants to digital globe masses. Oral nitrates (0.5 or 0.4 mg nitroglycerin pills or spray) may vasodilate the retinal artery. Instruct the patient to breathe into a paper bag to increase blood carbon dioxide levels and induce vasodilation. If available, administer carbogen (95% oxygen and 5% carbon dioxide) by face mask instead of using the paper bag. Oral and intravenous carbonic anhydrase inhibitors (500 mg Diamox or acetazolamide) will reduce intraocular pressure and decrease ophthalmic arterial vascular resistance to forward flow. Intravenous mannitol (1 g/kg of a 20% solution) may cause intraocular fluid to exit the eye and decrease intraocular pressure. Hyperbaric oxygenation treatment can compensate to prevent retinal hypoxemia and ischemia in some cases while awaiting the restoration of arterial flow.[3] Intra-arterial fibrinolysis with urokinase or recombinant tissue plasminogen activator (rTPA) can be successful in improving vision and shows promise.[1,5]

INDICATIONS

Digital globe massage can be performed in cases of CRAO where medical management is contraindicated or not successful. It can also be performed simultaneously with medical management. Treat the patient if they present to the Emergency Department within 24 hours of symptom onset.[7] It should be performed ideally within 90 minutes of the CRAO.

CONTRAINDICATIONS

Digital globe massage is contraindicated if the patient has had ocular surgery. Consult an Ophthalmologist in these cases before performing the procedure. Digital globe massage is contraindicated if there is the possibility of a perforated globe. There are otherwise no contraindications to digital globe massage in a nontraumatic CRAO.

EQUIPMENT

No special equipment is required to perform a digital globe massage.

PATIENT PREPARATION

Perform a fundoscopic examination and visual acuity testing. Document these results in the medical record. Explain the procedure, its risks, and benefits to the patient and/or their representative. This potentially vision-saving procedure should not be delayed. Verbal consent is adequate and the conversation documented in the medical record. Place the patient supine or in a reclining position.

TECHNIQUE

Stand next to the patient's torso and facing them. Instruct the patient to tightly close the eyelids of the affected eye. Place the dominant thumb over the patient's eyelids. Apply firm and steady pressure with the thumb for approximately 5 seconds. Abruptly release pressure by quickly lifting the thumb of the eyelids. Repeat the procedure several more times.[2]

ASSESSMENT

Immediately perform a repeat fundoscopic examination and visual acuity testing. Document and compare these to the preprocedural evaluations. It should be noted that the fundoscopic examination may show improvement while the visual acuity has changed very little or not at all. Depending on the ischemic time, visual acuity may never improve. Repeat the digital globe massage if there is little or no improvement in the fundoscopic examination. If significant improvement is noted, the procedure may be repeated in the hope of further improvement.

AFTERCARE

All patients must be evaluated by an Ophthalmologist in the Emergency Department. If one is not available, consider transferring the patient to another facility to be evaluated by an Ophthalmologist. These patients require inpatient admission for further evaluation and management.

Patients with a CRAO usually have significant comorbidities such as hypertension, atherosclerosis, or diabetes. These patients are at risk for additional morbidity and require prompt medical referral to determine the etiology of the CRAO. Medical testing should include blood pressure evaluation, electrocardiography, echocardiography, blood glucose management, lipid and cholesterol testing, and hyperviscosity studies. Any irregularities or abnormal studies will require further evaluation. Patients over the age of 60 need an immediate erythrocyte sedimentation rate (ESR) test in consideration of the possibility of giant cell arteritis.

COMPLICATIONS

If properly performed, digital globe massage has few immediate complications. Over vigorous digital globe massage can result in a lens dislocation or a ruptured globe.[4] Mechanical trauma can result in injury to the cornea, retinal detachments, and intraocular hemorrhage (e.g., hyphema and intravitreal hemorrhage).

SUMMARY

A central retinal artery occlusion is a true ophthalmologic emergency. The patient will present with sudden, painless, and unilateral loss of vision. Immediate management is required in an attempt to restore the patient's vision. This includes medical management, anterior chamber paracentesis, and digital globe massage. These techniques attempt to reduce intraocular pressure or break up the embolus in order to allow the embolus to move downstream and restore at least partial blood flow to the retina. Despite these interventions, the patient's vision may not recover.

158 Anterior Chamber Paracentesis

Rene Pineda Carizey

INTRODUCTION

Anterior chamber paracentesis is the removal of fluid from the anterior chamber, the area just anterior to the iris and lens, and immediately posterior to the cornea. Although not often formally taught nor performed in the Emergency Department, an anterior chamber paracentesis is a fairly quick, simple, and safe procedure with important diagnostic and therapeutic roles.[1–20] The long-term prognosis is directly related to the duration of symptoms for disease states that present with increased intraocular pressure, such as acute closure glaucoma and central retinal artery occlusion. In a sense, "Time is Eye." The Emergency Physician should become familiar with this technique. Its use can potentially prevent irreversible vision loss, especially when medical management is not sufficient in lowering intraocular pressure.

ANATOMY AND PATHOPHYSIOLOGY

The eye is a fluid-filled, closed system with a one-way valve. Aqueous humor is produced by the ciliary body and flows from the posterior chamber to the anterior chamber. Once in the anterior chamber, the aqueous humor then travels through a fine trabecular meshwork at the anterior chamber angle (the one-way valve) and leaves via the canal of Schlemm.

Intraocular pressure normally measures between 10 and 22 mmHg. This represents the balance between the production and outflow of aqueous humor.[3] Tonometry is used to measure intraocular pressure (Chapter 156). An increase in aqueous humor production, resistance to the outflow of aqueous humor, or additional fluid (e.g., pus or blood) in the vitreous body can severely increase intraocular pressure, potentially causing permanent visual loss due to ischemia. In addition to medical therapies, removing fluid via an anterior chamber paracentesis will reduce intraocular pressure to help prevent further ischemia.

Central retinal artery occlusion (CRAO), usually from an atherosclerotic embolic event, is another potential cause of visual loss that may benefit from an anterior chamber paracentesis in combination with digital ocular massage (Chapter 157) and medical management.[4] Decreasing intraocular pressure increases retinal perfusion in an attempt to propagate the embolus distally and minimize the amount of visual loss. Traumatic retrobulbar hemorrhages and other extraocular causes of elevated intraocular pressure do not benefit from an anterior chamber paracentesis.

INDICATIONS

An anterior chamber paracentesis will immediately reduce intraocular pressure but is not a treatment that resolves the underlying cause of the elevated intraocular pressure. Medical management is usually initiated first to lower intraocular pressure before attempting an anterior chamber paracentesis. An anterior chamber paracentesis is indicated whenever elevated intraocular pressure threatens visual loss and medical management is not successful in lowering intraocular pressure. Reducing the intraocular pressure acutely with an anterior chamber paracentesis in disease states such as acute angle closure glaucoma, uveitis, hyphema, central retinal artery occlusion, and suppurative endophthalmitis will help prevent further irreversible vision loss, especially if used in conjunction with other medical modalities.[5–7]

There are numerous nonemergent indications for an Ophthalmologist to perform an anterior chamber paracentesis. Diagnostically, an anterior chamber paracentesis can be used for aqueous humor sampling for a suspected infection, lymphoma, and intravitreal drug level monitoring.[8,9] It is also performed for isotonic saline injection for flattened anterior chamber reformation and numerous ophthalmologic surgical procedures.

CONTRAINDICATIONS

There are no absolute contraindications to performing an anterior chamber paracentesis since the patient's vision is at risk. Consult an Ophthalmologist prior to the procedure if a ruptured globe is suspected. Relative contraindications include uncooperative patients, patients with allergies to topical ocular anesthetics, and if the Emergency Physician is not comfortable performing the procedure. The patient's airway, breathing, hemodynamic status, and other life-threatening events should always be addressed prior to the procedure.

EQUIPMENT

- Sterile povidone iodine solution
- Topical ophthalmic anesthetic drops, e.g., 0.5% proparacaine or tetracaine
- Broad-spectrum topical antibiotic eye drops, e.g., fluoroquinolone
- Sterile saline minim
- 15° super sharp micro blade
- 1 mL tuberculin syringe
- 27 to 30 gauge, 5/8 inch needle[1,8,11,12]
- Slit lamp

PATIENT PREPARATION

Inform the patient of the reasons for performing an anterior chamber paracentesis, including its risks and benefits. Obtain a signed procedural consent and place it in the medical record. Reassure the patient that a "pressure sensation" might be felt during the procedure but they should not experience pain.

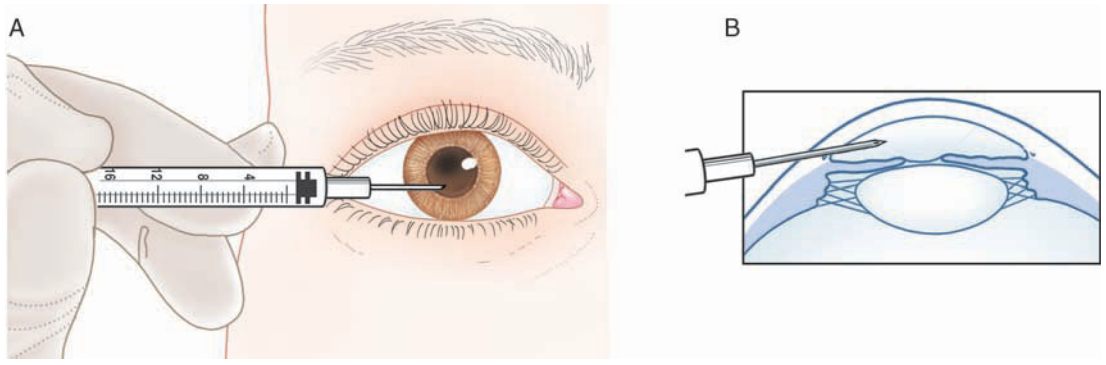

FIGURE 158-1. The hypodermic needle technique. **A.** The needle is inserted obliquely at the limbus. **B.** Transverse view of the eye. The needle enters the cornea at the limbus and is directed anteriorly into the anterior chamber.

Remove all contact lenses prior to placing any topical ocular medications or using fluorescein. **Perform a visual acuity assessment and an intraocular pressure measurement prior to any intervention to document the patient's baseline status and for serial comparisons after the procedure.** If the patient's tetanus status is unknown or their last tetanus booster has been greater than 10 years, administer a tetanus booster intramuscularly. Administer antiemetic and pain medication if the patient is symptomatic. Retching and vomiting increases intraocular pressure and complicates the procedure. Instill one to two drops each of the topical ophthalmic anesthetic and the broad-spectrum ophthalmic antibiotic onto the affected eye. Some Ophthalmologists instill two drops of sterile povidone iodine solution onto the cornea followed by topical ophthalmic anesthetic drops to dilute it.[17,18,20] Place the patient comfortably in a chair. Position their chin on the slit lamp chin rest. Attempt to comfortably immobilize the patient's head. Use an assistant if needed. Check for proper anesthesia by softly brushing the cornea with cotton-tipped swab or rechecking intraocular pressure.

TECHNIQUES

Numerous techniques have been described to perform an anterior chamber paracentesis. The quickest, simplest, and easiest to perform are the hypodermic needle and saline minim techniques. The surgical technique is often performed by an Ophthalmologist.

HYPODERMIC NEEDLE TECHNIQUE

Anesthetize the cornea and position the patient in the slit lamp as described above. Arm a tuberculin syringe with a 27 to 30 gauge needle. Slightly withdraw the plunger to break the bead on the syringe. Position the tip of the needle at the limbus, somewhere between the 4 o'clock and 8 o'clock position (**Figure 158-1A**). **Gently insert the needle through the cornea and angled anteriorly. This will ensure that the tip of the needle will enter the anterior chamber and not injure the ciliary body, iris, or lens (Figure 158-1B).** The anterior chamber holds approximately 0.3 mL of fluid. Slowly withdraw the plunger and aspirate 0.1 mL of fluid from the anterior chamber. Withdraw the needle. Apply topical ophthalmic antibiotic drops immediately after the procedure.

SALINE MINIM TECHNIQUE

A saline minim attached to a hypodermic needle is an alternative to using a syringe (**Figure 158-2**). This technique is simpler to perform when compared to using a hypodermic needle.[11,12,15] A saline minim is a single use, soft sided, disposable container containing 0.5 mL of sterile saline.

Anesthetize the cornea and position the patient in the slit lamp as described above. Prepare the minim. Twist off and discard the tip of the minim. Firmly apply a 27 to 30 gauge needle to the open end of the minim. Grasp the needle-minim unit with the thumb and index finger of the dominant hand. Gently squeeze the minim until one drop of sterile saline is expressed from the tip of the needle. Do not release pressure on the sides of the minim. Position the tip of the needle at the limbus, somewhere between the 4 o'clock and 8 o'clock position (**Figure 158-2**). **Gently insert the needle through the cornea and angled anteriorly. This will ensure that the tip of the needle will enter the anterior chamber and not injure the ciliary body, iris, or lens.** Slowly open the thumb and index finger to release the compression on the minim. The aqueous humor will flow from the anterior chamber into the minim. Do not withdraw enough fluid to dimple the cornea. Withdraw the minim until the needle exits the eye. Apply topical ophthalmic antibiotic drops immediately after the procedure.

SURGICAL TECHNIQUE

Anesthetize the cornea and position the patient in the slit lamp as described above. Position the tip of the 15° super sharp micro blade at the limbus, somewhere between the 4 o'clock and 8 o'clock position. **Gently insert the blade through the cornea and angled anteriorly. This will ensure that the tip of the blade will enter the anterior chamber and not injure the ciliary body, iris, or lens.** Withdraw the blade. Carefully and gently insert a 27 to 30 gauge needle on a tuberculin syringe through the incision. Aspirate 0.1 mL of fluid from the anterior chamber and withdraw the needle. As an

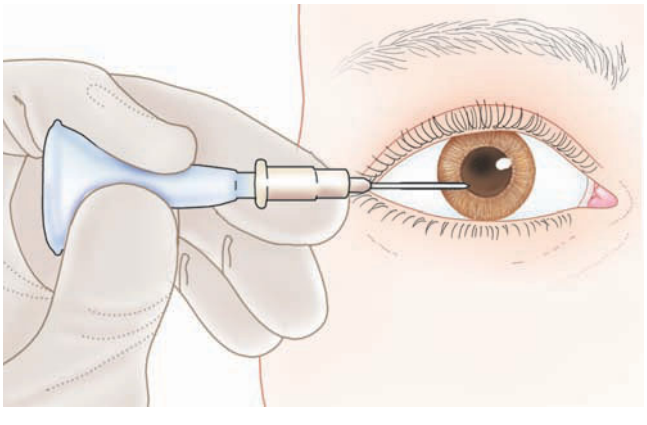

FIGURE 158-2. The saline minim technique.

alternative, a 27 to 30 gauge needle on a saline minim can be used. Apply topical ophthalmic antibiotic drops immediately after the procedure.

ASSESSMENT

After the procedure, immediately perform an intraocular pressure measurement with the same device used before the procedure to measure intraocular pressure. The intraocular pressure and symptomatic complaints should significantly decrease after the anterior chamber paracentesis procedure. Perform serial intraocular pressure measurements in 30-minute intervals for 2 hours to assess for any recurrence of elevated intraocular pressure. Perform and document a postprocedure visual acuity. Readdress any symptomatic complaints of eye pain, nausea, and headache. Significant decreases in intraocular pressure have been shown immediately, 2 hours, 2 days, and up to 2 weeks after an anterior chamber paracentesis with near resolution of symptoms.[5,6,19]

AFTERCARE

An Ophthalmologist should evaluate the patient in the Emergency Department. Immediate surgical intervention may be indicated if there is no improvement in the patient's symptoms or the intraocular pressure is persistently elevated despite medical management and an anterior chamber paracentesis. Patients can usually be safely discharged home once symptoms resolve and the intraocular pressure has normalized. Arrange close follow-up with an Ophthalmologist within the next 24 to 48 hours. Patients are typically discharged with broad-spectrum topical ophthalmic antibiotics, oral pain medications, oral antiemetics, and other antiglaucoma medications including oral acetazolamide, topical ophthalmic beta blockers, ophthalmic pilocarpine, and/or ophthalmic steroids.[10,15] The consulting Ophthalmologist will determine the proper medical management including the medications, their strength, and the frequency of administration. The patient should immediately return to the Emergency Department if they develop increased eye pain, severe nausea and/or vomiting, or any visual disturbances (e.g., decreased vision, photophobia, and halos around lights).

COMPLICATIONS

Mechanical injury to ocular structures (e.g., ciliary body, corneal abrasions, iris, or lens), infection, and bleeding comprise the most serious complications after an anterior chamber paracentesis.[13,14] Inadvertent injection of air into the anterior chamber occurs, but is typically a small amount and resolves spontaneously.[12] Allergic reactions to any of the medications used can also occur.

SUMMARY

Many types of disease pathologies can acutely elevate intraocular pressure and result in potential irreversible vision loss. Immediate reduction of the intraocular pressure by using medical treatments in conjunction with an anterior chamber paracentesis will reduce the amount of ischemic time, thereby reducing the amount of possible permanent visual impairment.

Multiple studies have repeatedly demonstrated the efficacy and safety of an anterior chamber paracentesis when used acutely to reduce intraocular pressure.[11,12] Although performing an anterior chamber paracentesis is often met with apprehension by the Emergency Physician, it is a procedure routinely performed in the office setting. Emergency Physicians should become familiar with an anterior chamber paracentesis because it is safe, simple, effective, relatively quick, and also has the potential to save a patient's vision.

159 Corneal Foreign Body Removal

Eric F. Reichman

INTRODUCTION

Corneal foreign bodies are a common complaint confronting Emergency Physicians and account for approximately 35% of all eye injuries seen.[1] Many objects have been implicated as a source of corneal foreign bodies including, but not limited to glass, metal, wood, dirt, dust, insects, and plant particles.[1] The majority of ocular foreign bodies require prompt removal. More than 75% of retained foreign bodies present on the eye surface are corneal in nature, and if left in place for more than 3 days will result in a keratitis.[2]

The prevailing symptom that forces patients to seek treatment is the sensation of an ocular foreign body or simply the pain associated with the foreign body. A variety of techniques exist for removal of ocular foreign bodies. A discussion of each of these techniques is necessary to determine the proper technique for a given situation.

ANATOMY AND PATHOPHYSIOLOGY

Many foreign bodies are diverted from the surface of the eye by the rapid blinking action of the eyelids and the eyelashes. A foreign body may not necessarily lodge itself into the cornea or the surrounding scleral surface if it is able to get past the eyelids and eyelashes. It may be washed to the inner canthus by a combination of blinking and tear flow. The foreign body may occasionally be carried away via drainage through the lacrimal ducts.[2] Objects that resist these means of diversion may be found in the upper or lower fornices, the channels created by the fold of the inner surfaces of the eyelids in communication with the conjunctival surface of the eye. The foreign body in the upper fornix is typically found lodged in the subtarsal groove on the inner surface of the upper eyelid, inferior to the tarsal plate.[2] Foreign bodies may also travel deeper into the respected fornices where they may be difficult to find. Foreign bodies may lodge themselves into the surface of the conjunctiva overlying the sclera or into the cornea itself, which obviously carries the most risk of serious injury or permanent scarring.

The cornea is <1 mm thick. It is comprised of five layers (from outer to inner layer): epithelium, Bowman's membrane, stroma, Descemet's membrane, and the endothelial layer that lies directly over the anterior chamber.[3] The surface epithelium itself has five layers of squamous cells. Most superficial corneal foreign bodies become embedded in this layer and do not result in scarring. Bowman's membrane has no regenerative capacity, and if injured, may result in scarring and permanent injury.[4] Foreign bodies that violate Bowman's membrane are considered deep corneal injuries. The stroma is composed of collagen and accounts for the largest portion of the cornea. Descemet's membrane is a basement membrane that can be regenerated if injured. The final component of the cornea is the endothelial layer that is composed of a single row of cuboidal cells that can regenerate if damaged.

Healthy cells adjacent to the injury slide over the damaged site and eventually replicate to the previous number of cells present when the corneal epithelium is injured.[3] Conjunctival epithelium migrates over the cornea to aid in its repair. This is true even if the entire surface epithelium of the cornea is removed.

Corneal innervation is provided by sensory nerve fibers located in the surface epithelium. These are concentrated primarily in the center of the cornea and sparsely located in the periphery.[5,6] Injuries

to the corneal epithelium produce pain, tearing, photophobia, and the sensation of a foreign body.[6] More pain occurs when the central portion of the cornea is affected due to the larger distribution of sensory nerves.[6]

Patients are fairly adept at identifying the location of an embedded foreign body due to the corneal innervation. A study evaluated 50 patients with corneal foreign bodies and their accuracy in identifying the foreign body location.[7] Eighteen patients (36%) were unable to identify the foreign body location, 14 (28%) were able to identify the exact location, and 18 (36%) were partially correct in identifying the location based upon vertical and horizontal components. **Always acknowledge the patient's sensation of an ocular foreign body and evaluate the area thoroughly.**

The presence of a metallic foreign body in the cornea can result in a rust ring. This is identified as a brownish ring surrounding the foreign body. **The rust ring, and the metallic foreign body, must be removed from the cornea.** The rust ring may be removed at the time of the foreign body removal or within 24 hours by an Ophthalmologist. Refer to Chapter 160 for the complete details of rust ring removal.

INDICATIONS

In general, all foreign bodies involving the eye must be removed. They do not all need to be removed immediately in the Emergency Department. Foreign bodies that are superficial and located on the cornea, sclera, eyelid, upper fornix, or lower fornix can safely be removed in the Emergency Department by the Emergency Physician. Metallic foreign bodies require prompt removal to avoid the formation of a rust ring. If a rust ring is also present, the foreign body should be removed in the Emergency Department and the rust ring can be removed by the Emergency Physician or by the Ophthalmologist at the 24-hour follow-up visit. Vertical abrasions on the cornea during the fluorescein examination are indicative of a foreign body under the eyelid. This requires the upper eyelid to be everted to evaluate for the presence of a foreign body under the eyelid.

CONTRAINDICATIONS

Corneal foreign bodies located in the direct axis of vision can cause permanent visual disturbances if improperly removed.[4] Consult an Ophthalmologist before removing these foreign bodies, as they often prefer to remove them. Deeply embedded objects or multiple foreign bodies that would require extensive debridement can result in significant scarring.[1] Consult an Ophthalmologist before attempting to remove these foreign bodies. **Avoid any manipulation of the eye if a perforated globe is suspected based upon either the direct examination of the eye or the mechanism of injury.** Foreign bodies embedded deeply within the cornea may be left in place if they are composed of an inert substance such as glass.[1] This will avoid the possibility of additional scarring from extensive debridement as long as the object is well below the corneal surface to allow for healing of the epithelium over the object. This decision must be made in conjunction with an Ophthalmologist. Consult an Ophthalmologist if an infection is associated with the foreign body (e.g., corneal edema, corneal clouding, or a purulent discharge). Refer injuries to an Ophthalmologist that are old, those in which the foreign body has been covered by epithelium, and foreign bodies resistant to removal. Do not attempt to extract a corneal foreign body if the patient is confused or uncooperative as this can result in a perforated globe. Consider the use of intravenous sedation, procedural sedation (Chapter 129), or general anesthesia to extract the foreign body in these patients after consulting an Ophthalmologist.

EQUIPMENT

- Slit lamp
- Cotton-tipped applicator
- Corneal spud
- Ringer's lactate solution or normal saline
- Intravenous (IV) tubing
- 25 or 27 gauge needle
- Tuberculin syringe with needle
- Topical ocular anesthetic solution (e.g., proparacaine and tetracaine)
- Topical ophthalmic antibiotic
- Cycloplegic agents (e.g., cyclopentolate, homatropine, and tropicamide)
- Fluorescein strips or liquid
- Electric burr drill and burrs
- Eye patches
- Adhesive tape
- Benzoin solution
- Wood's lamp (if slit lamp is not available)
- Eidolon BLUMINATOR® (Eidolon Optical LLC, Natick, MA) (if slit lamp is not available)

Having the availability of a slit lamp is preferred when removing a corneal foreign body. There are alternatives if a slit lamp is not available or the Emergency Physician does not feel comfortable with using a slit lamp. The Wood's lamp can provide the appropriate blue light required for fluorescein staining and rust ring removal. This portable device has a built in magnification lens. It has several disadvantages including having to be plugged into an outlet, an awkward shape, and a heaviness that must be balanced while using it. A newer device is the Eidolon BLUMINATOR®. It is small, handheld, self-contained, battery powered, and includes a 7× magnification lens.

PATIENT PREPARATION

Perform a complete eye examination prior to removing a foreign body. Measure visual acuities prior to any ocular procedure and following the procedure to document any changes. Refer to Chapter 153 for the complete details regarding the eye examination. Apply a topical ocular anesthetic agent into the affected eye. Note any irregularities in the contour of the eye, any loss of anterior chamber depth, prolapse of the iris through a corneal laceration, focal injection, a hyphema, or lens opacification. All of these signs may indicate a ruptured globe that requires an emergent Ophthalmology consultation.[4] Vary the beam of light from the slit lamp in its direction of illumination from direct exposure to indirect exposure, and even tangential exposure, to highlight any surface defects.[8] Examine the anterior chamber for cells and flare that occurs in older injuries as a result from a secondary iritis. The patient typically suffers from the discomfort of an anterior uveitis rather than the foreign body itself.[1]

Stain the eye with fluorescein dye. Fluorescein can permanently stain contact lenses and should not be used in their presence. Illuminate the eye with a cobalt blue light, looking for the green reflection of a corneal abrasion. Observe the site for the flow of fluorescein stain away from the site of a corneal puncture as anterior chamber fluid flows forth, otherwise known as the Seidel sign.[4,8] A positive Seidel sign indicates a ruptured globe. Irrigate

the fluorescein stain from the eye after the examination is complete to avoid any chemical-induced irritation.

Explain the process of ocular foreign body removal to the patient and/or their representative. Discuss the benefits and risks of the procedure. Obtain a signed informed consent to perform this procedure. Instill additional topical ophthalmic anesthetic solution as necessary.

TECHNIQUES

EYELID FOREIGN BODIES

Evert the upper eyelid.[8] Refer to Chapter 153 and **Figures 153-12** through **153-15** for the complete details regarding the eyelid eversion. Instruct the patient to look downward as a cotton-tipped applicator is used to gently press on the upper eyelid over the tarsal plate. Grasp the eyelashes with the thumb and index finger. Pull the upper eyelid outward, downward, and upward to evert it over the applicator. Examine the undersurface of the eyelid for foreign bodies. Remove any foreign bodies by sweeping the area with a saline-moistened cotton-tipped applicator (**Figure 159-1**). Double evert the eyelid by lifting the inferior edge of the eyelid created by the initial eversion. This is best accomplished by using a cotton-tipped applicator or an appropriate lid retractor. Examine the sclera and conjunctiva for foreign material. Allow the upper eyelid to return to normal. Release the eyelid and instruct the patient to blink their eyes.

Evert the lower eyelid by pulling the lower eyelashes forward while the patient looks upward.[4] Examine the area in similar fashion to the upper eyelid. Sweep the scleral and palpebral (eyelid) conjunctival area with a saline-soaked cotton-tipped applicator if the patient experiences a foreign body sensation but no debris can be visualized.

IRRIGATION

Superficial foreign bodies on the conjunctiva or the cornea can sometimes be removed by using an irrigation technique. A brief description is presented in this section. Refer to Chapter 155 for the complete details regarding eye irrigation. **Never use Morgan or Mediflow lenses for eye irrigation in the face of a foreign body as it may lodge the object further into the cornea.**

The most appropriate solution to use is Ringer's lactate solution followed by normal saline. Tap water can be used in the prehospital setting. Ringer's lactate solution causes less irritation because the range of its pH (6.0 to 7.2) is closer to the normal pH (7.4) of the eye in comparison to the pH (4.5 to 6.0) of normal saline.[4]

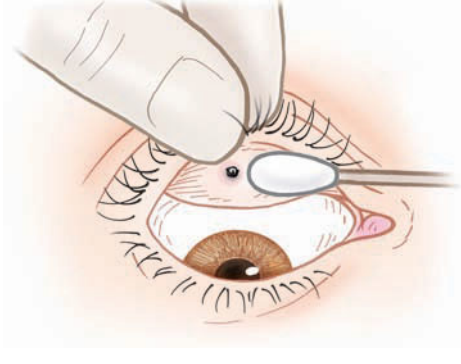

FIGURE 159-1. Evert the eyelids and remove the foreign body with a moistened cotton-tipped applicator.

Place the patient supine with their head tilted toward the side being irrigated to aid in proper runoff of the irrigant. Hang the IV fluid bag above the patient's head. Insert the IV tubing spike into the port on the IV fluid bag. Flush the patient's eye with sterile IV solution through the open end of the IV tubing while holding the patient's eyelids open. Flush from the scleral surface with the flow of solution directed over the cornea, thus washing the object out of the eye.[1,4,8] **Never direct the solution onto the object in order to avoid embedding it deeper into the soft underlying tissues. Never direct the flow directly onto the surface of the cornea to avoid secondary injury.** Use a forceps or cotton-tipped applicator to remove objects flushed onto the palpebral conjunctiva.[4] **Never use a forceps on the eye itself.**

COTTON-TIPPED APPLICATOR

Use a cotton-tipped applicator premoistened with saline to remove a foreign body from the conjunctiva overlying the sclera or the eyelids.[8] Gently touch the premoistened tip of the cotton-tipped applicator to the conjunctival surface and lift off the foreign body. **Do not use the cotton-tipped applicator to remove a foreign body from the cornea.[8]** It can result in a large corneal abrasion by removing the surface epithelium.

MANUAL EXTRACTION

Extract the foreign body with a corneal spud or hypodermic needle if it is not removed via irrigation or if it is embedded superficially into the corneal surface. A corneal spud is a stainless steel device that comes in a variety of shapes. It generally consists of a sharpened metal tip attached to a handle.[1] It is used to lift off or to carve out a corneal foreign body.[1] Many physicians prefer to use a tuberculin syringe. It allows for better control of the needle by using the syringe portion as the grip. The author always uses a saline-filled tuberculin syringe. This allows the Emergency Physician to apply saline drops to moisten the eye as well as to flush away the foreign body after it is dislodged from the cornea. An 18 gauge needle has been described for the removal of large foreign bodies because of its wide diameter.[1] The instrument used is physician dependent. **Proper explanation of the extraction procedure using a needle will often ease a nervous patient and ensure better compliance by limiting unexpected movements.**

Perform the procedure under direct visualization with the slit lamp. Place the patient seated at the slit lamp with their head firmly in place against the forehead rest to avoid any unexpected movement (**Figure 159-2A**). If a slit lamp is not available, the foreign body can be removed using the blue light of a Wood's lamp or Eidolon BLUMINATOR®. Hold the needle, or spud, between the thumb and index finger of the dominant hand as one would a pencil with the bevel facing the Emergency Physician. Stabilize the dominant hand on the patient or the slit lamp apparatus using the remaining fingers. Instruct the patient to focus their vision on a given point to avoid any eye movement.

Approximate the tip of the needle, or spud, to the foreign body with the naked eye before utilizing the slit lamp microscope in order to avoid inadvertent injury. Approach the foreign body from the periphery and not across the patient's field of vision (Figure 159-2B). Gently tease out the foreign body using the beveled edge of the needle, or spud, in a tangential direction in relation to the eye to avoid inadvertent deep puncture if the patient suddenly moves (Figure 159-2C). Use the tip to gently pry the foreign body loose if absolutely necessary, but extreme care must be exercised (Figure 159-2D). Remove the loose foreign body with a moistened cotton-tipped applicator or with gentle irrigation.

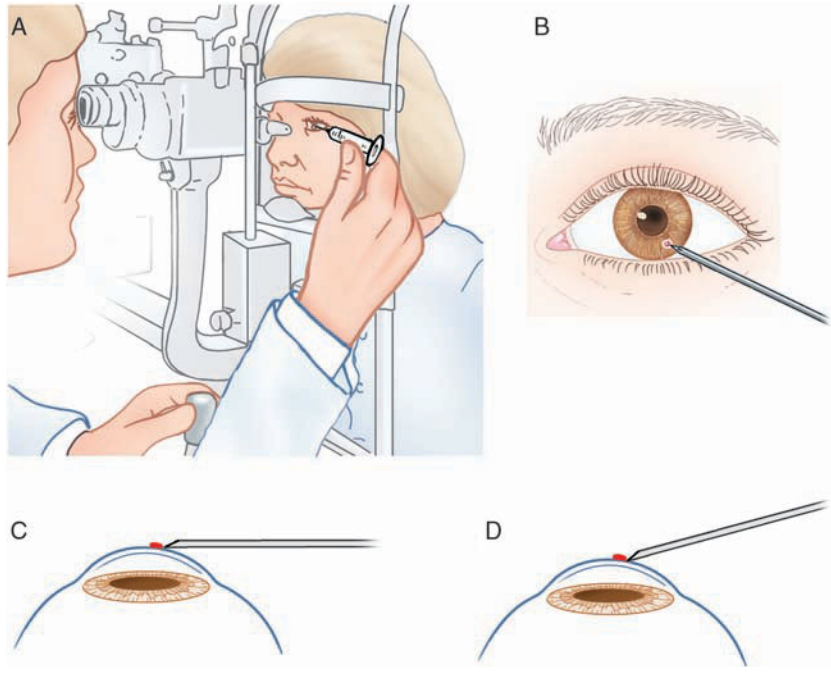

FIGURE 159-2. A hypodermic needle to remove a corneal foreign body. **A.** Position the patient in the slit lamp. Stabilize the hand holding the needle. **B.** Approach the foreign body from the periphery. **C.** Hold the needle tangential to the cornea to remove the foreign body. **D.** Slightly angle the needle to "pry" the foreign body off the cornea.

ELECTRIC BURR DRILL EXTRACTION

An electric battery powered drill equipped with various sized diamond dental burrs, if available, can be used for foreign body removal (**Figure 159-3**). Its use is typically associated with an increased tissue defect when compared to using a needle or a spud.[9] **Use caution as the burr drill can also embed the foreign body deeper into the cornea.**

Choose a burr size that is slightly larger than the diameter of the foreign body. Load the burr onto the drill. Grasp the device like a pencil using the thumb and middle finger. Press the finger bar on the drill with the index finger to turn on the drill and rotate the burr bit. Approach the foreign body tangentially to the eye (**Figure 159-4**). Gently place the rotating burr bit on the area to be debrided using short applications of one to two rotations of the burr. Lift the burr from the cornea after each application to examine the area and determine if the foreign body has been removed.

ASSESSMENT

Carefully examine the cornea under the slit lamp with and without the use of fluorescein dye. Ensure that the foreign body is completely removed. Consult an Ophthalmologist if the foreign body has broken off, is deeply embedded within the cornea, or is associated with a rust ring. Measure and record the patient's visual acuity after the extraction procedure. Compare this to the pre-extraction visual acuity. Consult an Ophthalmologist if there is a difference in the pre-extraction and post-extraction visual acuity.

AFTERCARE

A corneal abrasion will be present upon removal of the foreign body. The defect is usually larger than the original foreign body and should be treated as a typical corneal abrasion. Place a broad-spectrum ophthalmic antibiotic ointment (e.g., an aminoglycoside) on the eye. Instruct the patient to instill topical broad-spectrum antibiotics every 4 hours if the eye is not patched.[1,4,5,8] The ophthalmic nonsteroidal anti-inflammatory drugs are safe to use and provide effective pain relief.[12–14] Currently available are bromfenac, diclofenac, and ketorolac.

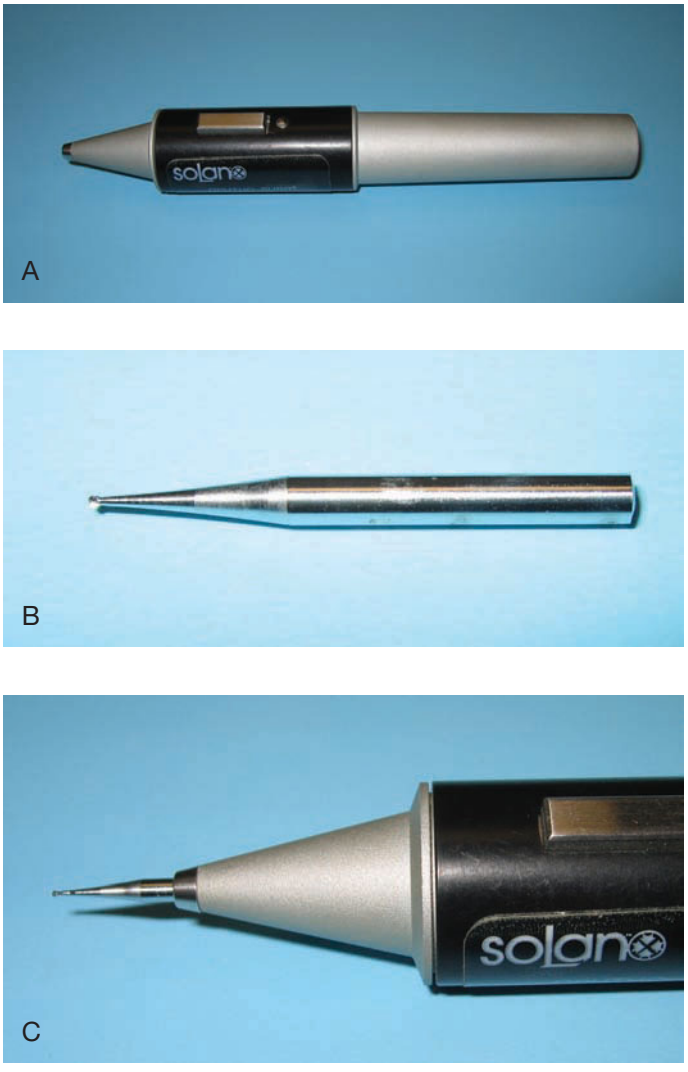

FIGURE 159-3. The burr drill used to remove a corneal foreign body. **A.** The drill. **B.** The burr bit. **C.** The burr drill with a burr bit inserted.

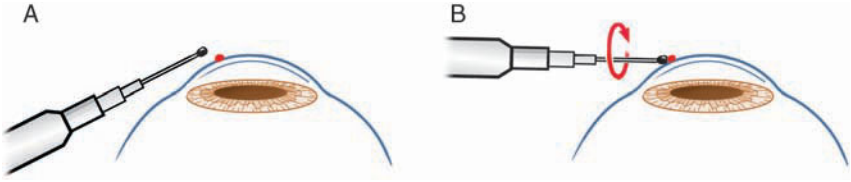

FIGURE 159-4. Removal of a corneal foreign body with a burr drill.

The use of an eye patch is controversial and usually not required. Refer to Chapter 161 regarding the complete details of eye patching. **The use of eye patches should be considered cautiously as they may be associated with additional discomfort, delayed healing, and the conversion of a corneal abrasion into a corneal ulcer.[10] Consider patching the eye closed if the defect is large and painful. Avoid pressure patching the eye in the case of small, superficial, or minimally painful abrasions. Avoid the use of eye patches in cases of organic foreign bodies and in patients who wear contact lenses, as the bacterial milieu is favorable for the development of a local infection.[4] Since most patients will not need eye patching, it is best to consult an Ophthalmologist before patching an eye.**

The proper method of applying an eye patch is to first administer all necessary medications. Instruct the patient to close both eyes. Apply a folded patch to the affected eye (rounded edge pointed downward) over which is placed an unfolded patch. Prep the skin with a benzoin solution to aid with tape adherence. Apply strips of tape from the medial aspect of the forehead, over the patch, and to the lateral cheek. Apply the tape tightly enough to prevent eye opening but lightly enough to not cause discomfort. Apply strips of tape repeatedly over the patch until it is entirely covered. Apply the final pieces of tape over the center of the patch while holding the cheek soft tissue superiorly. This will ensure that the cheek, when released, will pull the bandage taut and avoid loosening.[4,8]

Cycloplegics (e.g., 1% cyclopentolate) can be used to alleviate pain or to limit pain in cases of significant corneal defects or an anterior uveitis.[1] **Topical steroids have no place in the treatment of traumatic corneal defects.[1]** Oral analgesics are appropriate in cases of persistent discomfort. **Do not prescribe topical ocular anesthetic agents due to their abusive potential and the direct deleterious effects of the anesthetic on the corneal epithelium.[4]**

Refer all patients to an Ophthalmologist for reexamination in 24 hours, especially if an eye patch has been applied. A rust ring can be removed by the Ophthalmologist at the follow-up visit. Instruct the patient not to operate a vehicle if the eye is patched closed. These instructions also hold true if the eye is not patched but a procedure was performed to remove a foreign body.

Many eye injuries occur while at work due to failure to comply with wearing eye protection, resulting in a significant loss of working hours.[6,7,11] Take the time necessary to explain the importance of wearing safety goggles if the injury occurred while at work, gardening, or participating in hobbies (e.g., woodworking, drilling, auto repair, etc.).

COMPLICATIONS

A foreign body will occasionally not be able to be removed in the Emergency Department. Refer the patient to an Ophthalmologist for definitive treatment before further attempts at removal result in severe ocular injury and the potential for violation of the anterior chamber (i.e., perforation of the globe). **Notify an Ophthalmologist immediately if inadvertent puncture of the globe occurs from attempts at foreign body removal as a surgical emergency now exists.**

Improper placement of eye patches can cause a corneal ulcer or delayed corneal healing.[8] Caution the patient against driving while the eye is patched due to impaired depth perception.[8]

Continued discomfort at the 24-hour follow-up may indicate the foreign body was not completely removed, a corneal rust ring from a metallic object has formed, a penetrating eye injury, anterior uveitis, or an infection.[1] Contaminated corneal foreign bodies or those consisting of vegetative material can also lead to corneal ulceration from the introduction of bacteria.[1]

Corneal defects will not always be completely healed at the 24 hour follow-up. The eye may require one additional day of patching if the defect is still a significant size. Treat the defect by applying a topical antibiotic for several more days if the defect is markedly smaller than the original injury.[1]

Care must be taken to avoid further damage to the eye when treating children or patients who are uncooperative. Intravenous sedation and analgesia can be used in these situations. Consult an Ophthalmologist for treatment under general anesthesia if sedation is contraindicated or if the Emergency Physician is not comfortable with removing the foreign body under procedural sedation.[4]

SUMMARY

Corneal foreign bodies are routinely encountered in the Emergency Department. They must be definitively treated in order to avoid long-lasting ocular disability. Documentation of a complete history and physical examination of the eye is mandatory before attempting to remove a foreign body. The most reliable method of corneal foreign body removal is the use of a hypodermic needle or corneal spud, taking care to avoid additional ocular trauma. Administer appropriate antibiotics and/or cycloplegics after removal of the foreign body. The application of an eye patch is not required after the foreign body is removed in most cases. The decision to apply an eye patch is best done in consultation with an Ophthalmologist. Refer the patient to an Ophthalmologist in 24 hours for evaluation of proper healing and the immediate treatment of any evolving complications.

160 Corneal Rust Ring Removal

Eric F. Reichman

INTRODUCTION

Corneal rust rings occur commonly when metallic foreign bodies become embedded in the cornea. Removal of the rust ring is imperative to avoid permanent staining of the cornea, persistent inflammation, or disruption of corneal integrity (necrosis) with loss of stromal substance.[1–3] Two techniques for the removal of rust rings are discussed: hypodermic needle extraction and corneal burr drill

removal. The use of topical deferoxamine as a chemical chelator should only be used by an Ophthalmologist and is mentioned only for the sake of completeness.

ANATOMY AND PATHOPHYSIOLOGY

The cornea is approximately 0.5 mm thick. It is comprised of five layers (from outer to inner layer): epithelium, Bowman's membrane, stroma (largest layer), Descemet's membrane, and the endothelial layer which lies directly over the anterior chamber. Corneal rust rings are formed from the oxidation of iron present in metallic foreign bodies. As little as 3 hours of corneal contact are required to form the brown stain of a rust ring.[1]

INDICATIONS

All corneal metallic foreign bodies require prompt removal to avoid the possibility of rust ring formation. A rust ring requires complete removal in a timely fashion in order to avoid the damaging effects of rust on the cornea. While foreign bodies should be removed in the Emergency Department, the rust ring can be left for the Ophthalmologist to remove within 24 to 48 hours if the Emergency Physician does not feel comfortable removing the rust ring.

CONTRAINDICATIONS

Corneal foreign bodies and rust rings that are located in the direct axis of vision can cause permanent visual disturbances if improperly removed.[2] Consult an Ophthalmologist before removing these, as they often prefer to remove them. Do not attempt to extract a rust ring if the patient is a young child, confused, or uncooperative as this can result in a perforated globe. These patients may require the use of intravenous sedation, procedural sedation, or general anesthesia to extract the rust ring.

EQUIPMENT

- Slit lamp
- 25 or 27 gauge needle
- Tuberculin syringe with a needle
- Burr drill
- Burr bits
- Topical ocular anesthetic agent (e.g., proparacaine or tetracaine)
- Topical ophthalmic antibiotic
- Cycloplegic agents (e.g., cyclopentolate, homatropine, or tropicamide)
- Ringer's lactate solution or normal saline
- Fluorescein strips or liquid
- Wood's lamp (if slit lamp is not available)
- Eidolon BLUMINATOR® (Eidolon Optical LLC, Natick, MA) (if slit lamp is not available)

Having the availability of a slit lamp is preferred when removing a corneal rust ring. There are alternatives if a slit lamp is not available or the Emergency Physician does not feel comfortable with using a slit lamp. The Wood's lamp can provide the appropriate blue light required for fluorescein staining and rust ring removal. This portable device has a built-in magnification lens. It has several disadvantages including having to be plugged into an outlet, an awkward shape, and a heaviness that must be balanced while using it. A newer device is the Eidolon BLUMINATOR®. It is small, hand-held, self-contained, battery powered, and includes a 7× magnification lens.

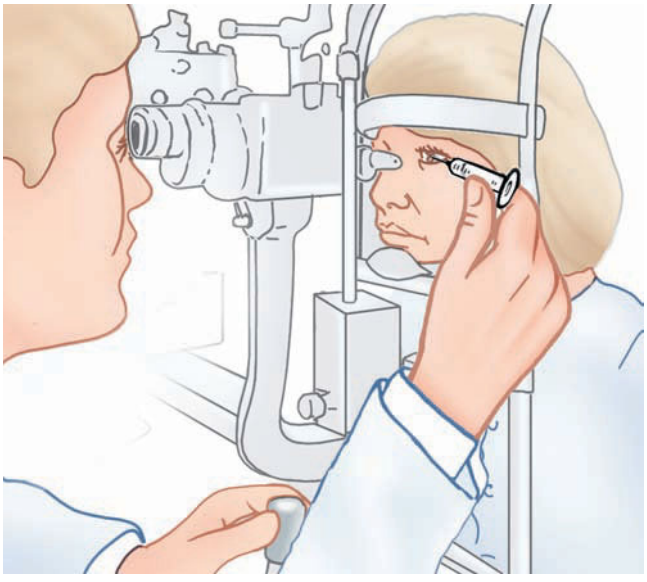

FIGURE 160-1. Positioning of the patient and the examiner's hand.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent to perform this procedure. Apply a topical ocular anesthetic agent into the affected eye. Determine the patient's visual acuity in the affected eye. Seat the patient at the slit lamp with their head firmly in place to avoid any unexpected movement (**Figure 160-1**). Examine the eye via the slit lamp and rule out the possibility of an intraocular foreign body with a corneal perforation. Perform a complete eye examination to rule out any other ocular problems. Remove the foreign body, if still present, with the hypodermic needle or tuberculin syringe. Refer to Chapter 159 for the complete details regarding corneal foreign body removal. The rust ring will often be removed simultaneously with the metallic foreign body. Make an attempt to remove the rust ring if it remains after removal of the foreign body.

TECHNIQUES

MANUAL EXTRACTION

Scrape out the rust ring in a similar fashion to the removal of a metallic foreign body (**Figure 160-2**). Refer to Chapter 159 for the complete details regarding corneal foreign body removal. **The entire area of rust stained epithelium must be completely removed without any residual rust.**

Extract the rust ring with a corneal spud or hypodermic needle. A corneal spud is a stainless steel device that comes in a variety of

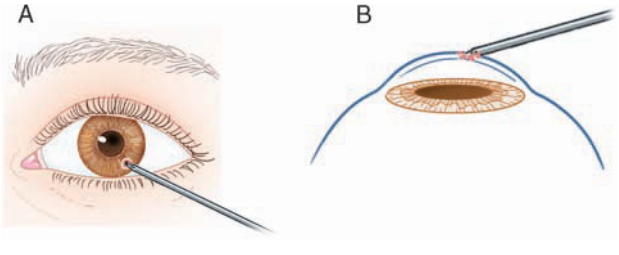

FIGURE 160-2. Manual extraction of the rust ring.

shapes. It generally consists of a sharpened metal tip attached to a handle.[1] It is used to lift off or to carve out a corneal foreign body or rust ring.[1] Many physicians prefer to use a tuberculin syringe. It allows for better control of the needle by using the syringe portion as the grip. The author always uses a saline-filled tuberculin syringe. This allows the Emergency Physician to apply saline drops to moisten the eye as well as to flush away the rust ring after it is dislodged from the cornea. The instrument used is physician dependent. **Proper explanation of the extraction procedure using a needle will often ease a nervous patient and ensure better compliance by limiting unexpected movements.**

Perform the procedure under direct visualization with the slit lamp. Place the patient seated at the slit lamp with their head firmly in place against the forehead rest to avoid any unexpected movement (**Figure 160-1**). If a slit lamp is not available, the foreign body can be removed using the blue light of a Wood's lamp or Eidolon BLUMINATOR®. Hold the needle, or spud, between the thumb and index finger of the dominant hand as one would a pencil with the bevel facing the examiner. Stabilize the dominant hand on the patient or the slit lamp apparatus using the remaining fingers. Instruct the patient to focus their vision on a given point to avoid any eye movement.

Approximate the tip of the needle, or spud, to the rust ring with the naked eye before utilizing the slit lamp microscope in order to avoid inadvertent injury. Approach the rust ring from the periphery and not across the patient's field of vision (Figure 160-2A). Gently tease out the rust ring using the beveled edge of the needle, or spud, in a tangential direction in relation to the eye to avoid inadvertent deep puncture if the patient suddenly moves. Use the tip to gently pry the rust ring loose if absolutely necessary, but extreme care must be exercised (Figure 160-2B). Remove the loose rust ring with a moistened cotton-tipped applicator or with gentle irrigation.

ELECTRIC BURR DRILL EXTRACTION

An electric battery-powered drill equipped with diamond burrs, if available, can be used for rust ring removal (**Figure 159-3**). The burr bit cuts away corneal tissue very slowly. Corneal rust rings were induced in rabbits and comparisons were made between manual extraction versus electric drill extraction.[1] Both were equally effective for rust ring removal, but the burr caused a deeper corneal defect. **Use caution when using an electric burr device.** There was no difference in corneal scarring between the two techniques. The burr drill can also be used to extract rust in the bulbar conjunctiva.[4]

Choose a burr size that is slightly larger than the diameter of the rust ring. Load the burr onto the drill. Grasp the device like a pencil using the thumb and middle finger. Press the finger bar on the drill with the index finger to turn on the drill and rotate the burr bit. Approach the rust ring tangentially to the eye (**Figure 160-3**). Gently place the rotating burr bit on the area to be debrided using short applications of one to two rotations of the burr. Lift the burr from the cornea after each application to examine the area and determine if the rust ring has been removed. **Thoroughly inspect the base of the crater to ensure that it is free of rust.**[4] Continue the process until the rust ring is removed. Use a slightly larger burr bit if rust still remains along the periphery of the crater.

DELAYED REMOVAL

The rust ring may be removed after it ages.[2,8] Allow the rust ring to remain for 24 to 48 hours. During this time the iron deposits will kill the surrounding corneal epithelial cells. The rust ring will "soften" and be easily removed in one piece with a needle, spud, or burr drill. **Do not allow the rust ring to remain for longer than 24 to 48 hours, ideally 24 hours, as it can cause significant damage to the cornea.**

CHEMICAL CHELATION

Topical deferoxamine has been used experimentally for the nonsurgical removal of rust stains on the cornea.[6] It has been shown to remove rust, though perhaps not as reliably as the methods previously described. The potential exists for resultant eye irritation, corneal ulceration, or persistence of the rust stain.[6] The clinical use of deferoxamine should be limited for use only in very select situations such as children with multiple lesions or when the central axis of vision is involved.[7] This technique is reserved for the Ophthalmologist and is therefore not described in this text.

ASSESSMENT

Measure and document visual acuities before and after the procedure. Consult an Ophthalmologist if the postprocedural visual acuity is different from the preprocedural visual acuity.

AFTERCARE

A corneal defect resembling a corneal abrasion will be present after the rust ring is removed. The defect is usually larger than the original foreign body and should be treated as a typical corneal abrasion. Apply topical ocular antibiotic ointment in the eye. The use of an eye patch is controversial but considered by most as unnecessary. Instruct the patient not to operate a vehicle. Administer cycloplegics to alleviate pain from an actual or potential anterior uveitis.[2] Oral analgesics are appropriate in cases of persistent discomfort. Consider prescribing topical nonsteroidal anti-inflammatory drugs (e.g., bromfenac, diclofenac, or ketorolac) for pain relief. Refer the patient to an Ophthalmologist for reexamination in 24 hours. The patient requires daily follow-up and corneal staining to ensure proper healing.[12]

Instruct the patient on the importance of safety goggles.[5] Many eye injuries occur while at work due to failure to comply with wearing eye protection, resulting in a significant loss of working hours.[5,9,10] Take the time that is necessary to explain the importance of wearing safety goggles if the injury occurred while at work, gardening, or participating in hobbies (e.g., woodworking, drilling, and auto repair). The prevention of ocular foreign bodies and rust rings is preferable to treating them.[11]

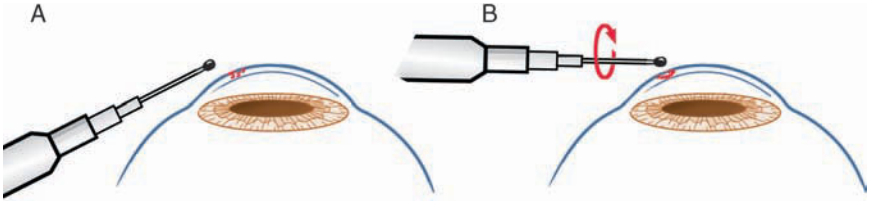

FIGURE 160-3. Burr drill extraction of the rust ring.

COMPLICATIONS

Abandon multiple attempts at removal of the rust ring to avoid severe ocular injury and the potential for violation of the anterior chamber if the depth of the rust cannot be determined or if repeated debridement is unable to completely remove the rust ring. The eye can be left unpatched for 24 hours and the patient referred to an Ophthalmologist for definitive removal the following day in these situations or in cases of hesitancy in removing a rust ring. Delayed removal is often easier than the initial attempts due to further oxidation and injury of the corneal epithelium resulting in "softening" of the rust. The "softened" rust ring is easily scraped out in 24 to 48 hours.[2] If not completely removed, the rust ring can lead to chronic inflammation, corneal necrosis, corneal vascularization, or permanent scarring.[3]

SUMMARY

Removal of corneal rust rings is imperative in order to avoid permanent ocular injury. It is best accomplished with a small gauge hypodermic needle or with an electric burr device. An alternative approach is to leave the rust for delayed removal by an Ophthalmologist in 24 hours when the rust has "softened." It is essential to completely remove the rust ring to prevent future ocular morbidity. The procedure is simple to perform with readily available equipment.

161 Eye Patching and Eye Shields

Rebecca R. Roberts

INTRODUCTION

Eye shields are used to protect the eye from further injury when the integrity of the globe is compromised or potentially compromised. The best results are obtained when early repair of globe disruption occurs, before any contents leak out or change position.[1,2] In contrast, eye patches are intended to prevent movement of the eyelid over an injured but intact cornea.[3,4] In the past, eye patching was performed to protect the eye from bright light, facilitate healing of a corneal abrasion, or protect the cornea from injury during sleep. While there have been no substantial changes in the indications for eye shields and their method of application, eye patching has become increasingly controversial.[5–8]

EYE SHIELDS

INDICATIONS

Eye shields serve as temporary protection for patients in whom a penetrated or ruptured globe is suspected.[9,10] The purpose is to prevent further injury, with resultant extravasation of the contents of the globe and resultant outcome of poor vision.[2,11] The signs associated with a ruptured globe include bloody chemosis, increase or decrease in the depth of the anterior chamber, irregular or peaked iris, positive Seidel test, vitreous hemorrhage, low intraocular pressure, hyphema, and loss of visual acuity.[9,10,12–14] **If a ruptured globe is suspected, further examination is contraindicated.** Instead, an eye shield is applied immediately and remains in place while other injuries are managed, tests are obtained (e.g., orbital computed tomography scans), and the consulting Ophthalmologist is contacted.[2,10]

CONTRAINDICATIONS

The only contraindication to the application of an eye shield arises when the surrounding face and orbits are so extensively damaged that the metal shield or its edges will directly injure the globe. The protective function of the shield relies on its edges being supported by the orbital rim, frontal bone, and maxillary bone.

EQUIPMENT

- Metal or plastic eye shield
- 1 inch tape

If commercially available eye shields are not available, a clean, disposable paper drinking cup may be used.[4,15] Use a scissors to make 3/4 to 1 inch deep cuts around the open end of the cup (**Figure 161-1**). Make approximately six to eight cuts around the circumference of the cup. Fold the flaps on the open end of the cup outward. Styrofoam cups are not suitable because the flaps can easily break off and cause further injury to the globe.

PATIENT PREPARATION

The first procedure in patients with a suspected globe disruption is the application of the eye shield.[10,13] There should be no preparations except to dry the area of skin that will receive the securing tape. Specifically, the eye should not be irrigated, no gauze or patch should touch the eye, and no antibiotic or anesthetic ointments or drops should be applied. Ocular tonometry is also contraindicated.[10] All of these are likely to cause further injury to the exposed globe.[2,16] Contact an Ophthalmologist immediately to expedite globe repair.[9,10,13]

TECHNIQUE

Apply the commercial eye shield (**Figure 161-2A**) or the one improvised from a paper cup (**Figure 161-2B**) over the injured eye. Ensure that its edges do not contact structures any closer to the eye than the orbital rim. Tear off four to six strips of 1 inch tape, each 4 to 5 inches long. Apply the strips of tape diagonally from the center of the forehead to the cheek above the mandible to hold the shield in place (**Figures 161-2A & B**).[15] **Care must be taken to avoid taping the nasolabial folds, lips, mustache (if any), and skin over the mandible.** Otherwise, mandibular movement may cause the eye shield to move and potentially injure the eye. If the patient requires

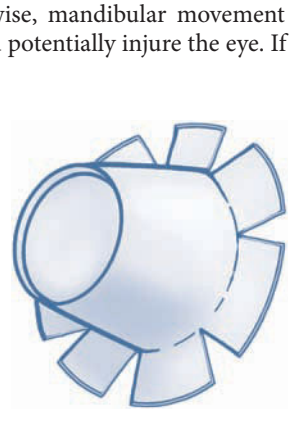

FIGURE 161-1. A paper cup may be used if a commercial eye shield is not available. The top of the cup is cut in multiple places and the resulting "flaps" are bent down to create a flat surface.

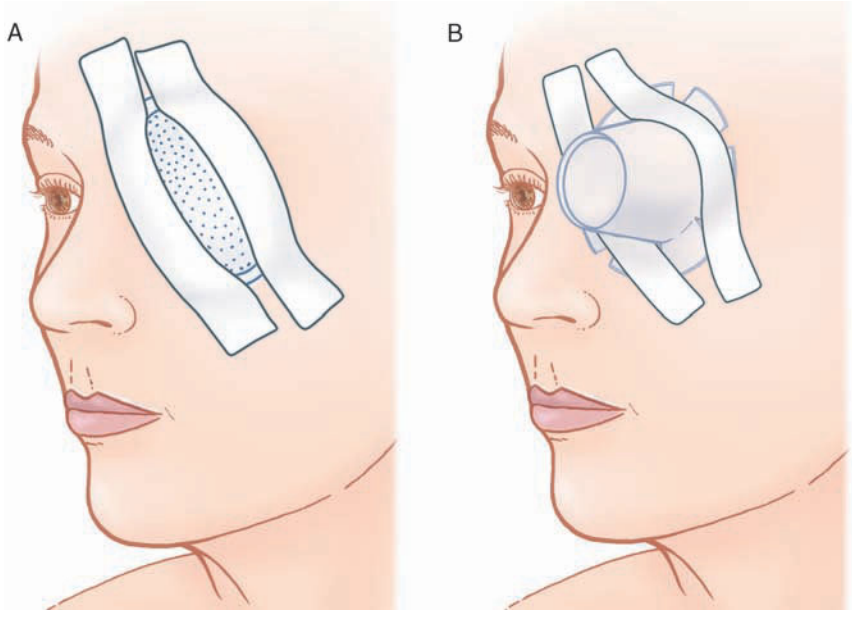

FIGURE 161-2. Eye shields. **A.** A commercial eye shield is applied. **B.** An improvised eye shield is applied.

the use of an oxygen mask, the mask must be trimmed around the eye shield to prevent it from displacing the eye shield and causing further eye injury.

AFTERCARE

The eye shield position should frequently be checked for any movement or loosening of the tape due to blood, perspiration, or other fluids. **The shield must remain in place until tests demonstrate that the globe is intact or the consulting Ophthalmologist arrives.** Do not allow the patient to eat or drink. Additional therapy includes tetanus prophylaxis, prophylactic intravenous antibiotics, and parenteral antiemetics for nausea, as vomiting will cause extrusion of the contents of the globe.[1,2,10,13,14,16] Ideally, position the patient with their head elevated if not contraindicated.

COMPLICATIONS

Poor positioning or shield movement can further injure the eye or cause extravasation of the globe contents. The patient must be handled gently at all times because even wincing or squinting of the eye can increase intraocular pressure sufficiently to cause the extravasation of the contents of the globe.

EYE PATCHING

INDICATIONS

The indications for eye patches are steadily being reduced as a growing body of literature shows no benefit and potential harm. In the past, patches were indicated for corneal injuries due to abrasions as well as to thermal, light, or chemical burns.[3] Patches were believed to promote healing and provide pain relief by decreasing movement of the eyelid across the recovering cornea.[3,4] Secondarily, patches block light in photophobic patients with ciliary spasm or reactive iritis due to corneal injuries.

Most of these assumptions are now questioned. Patching is believed to decrease corneal oxygenation, increase eye temperature, and increase corneal infection risk.[11,17,18] They can also cause injury if the eye opens underneath a pressure patch. A number of trials and meta-analyses comparing patients with corneal abrasions receiving patching versus no patching have found no difference in pain scores or healing time for small abrasions less than 10 mm in diameter.[5–8,19] There was a decreased healing time for patched patients with abrasions greater than 10 mm in diameter.[17,18] Therefore, patching is still recommended for those with large defects, but most authors also recommend further study in this group.[7] More recently, soft contact lens bandages have been used for patients who must maintain binocular vision.[20,21] Eye patches were also indicated during sleep to protect the cornea in patients with facial nerve palsy (e.g., Bell's palsy) and the inability to completely close their eyes.[22] Others are currently recommending ophthalmologic lubricants with or without an eye shield in this group.[23]

CONTRAINDICATIONS

Absolute contraindications to eye patching are corneal abrasions due to the wearing of contact lenses or from organic foreign bodies. There is an increased incidence of infection and more pathogenic bacteria harbored by contact lens wearers.[17] **Do not place an eye patch on any patient considered at risk for penetration or rupture of their globe.**[10] Eye patching will increase intraocular pressure and may cause extravasation of the contents of the globe. Patients must be carefully assessed for the presence of corneal ulcers masquerading as abrasions.[3] Eye patching of a corneal ulcer may place pressure on the ulcer, deepen the ulcer, perforate the cornea, or promote infection.

Relative contraindications are related to abrasion size and individual patient needs. Small abrasions heal well without patching. Patients who require binocular vision to function will benefit from not patching.[7,17,18] Patches that come loose and allow eyelid movement are more painful for patients than no patch. Contraindications to ophthalmoplegics used in conjunction with patches are patients with known glaucoma or narrow angles on physical examination.[3] Paradoxically, the contraindication to contact lens bandages is an abrasion in a patient who was wearing contact lenses or from organic foreign bodies, again because of the risk of infection.[9]

EQUIPMENT

- Cycloplegic drops to reduce photophobia, 1% cyclopentolate or 5% homatropine[4,11,17]
- Broad-spectrum antibiotic ointment or drops

- Cotton eye patches
- 1 inch tape
- Contact bandage, soft lens with minus 0.5 diopters of power[21]

PATIENT PREPARATION

Conduct a complete eye exam to ensure the integrity of the globe and the absence of an infection or foreign body. Document the visual acuity for both eyes.[15] Patients should receive tetanus prophylaxis if immunizations are not up to date.[4] Apply cycloplegic drops and antibiotic ointment to the affected eye.[3,4] Refer to Chapter 153, on the examination of the eye, for complete details regarding the instillation of drops and ointment into the eyes. For patients with small corneal abrasions, no further treatment is required.

EYE-PATCHING TECHNIQUE

After patient preparation as above, instruct the patient to close both eyes and to keep them both shut for the remainder of the procedure. Tear off four to six strips of 1 inch tape, each 4 to 5 inches long, and have them at the bedside. Obtain two cotton eye patches. Fold the first patch in half. Apply it to the affected eye (both eyes should remain closed). Place the second patch, unfolded, over the first patch (**Figure 161-3A**). Apply the pre-torn strips of tape diagonally from the center of the forehead to the cheek just above the mandible (**Figure 161-3B**).[3,4] Lift the lower cheek up slightly before securing the first two strips of tape to ensure the correct amount of pressure.[3,4] The patch will hold the eye more securely if the nasal and temporal strips are placed in a slight arc concave toward the center of the eye. Care must be taken to avoid taping the nasolabial folds, lips, mustache (if any), and the skin near the mandible.[3,4] Otherwise, eating and speaking will be uncomfortable for the patient and the patch will rapidly loosen. If the patient has a significant amount of facial hair, the tape may not stick.

SOFT CONTACT BANDAGE TECHNIQUE

For patients who require immediate use of both eyes, soft contact lenses can be applied as a corneal bandage.[20,21] Prepare the patient as described previously. Apply ophthalmic antibiotic drops rather than ointment to the affected eye. Remove the contact lens from the storage bottle. Rinse the storage solution from the contact lens. Place the contact lens on the index finger of the dominant hand. Using the nondominant hand, open the patient's eyelids. Instruct the patient to look straight ahead. Gently apply the contact lens directly to the cornea. The patient should remain in the Emergency Department for a recheck in 15 to 30 minutes to make sure that the contact lens fits properly and they are able to tolerate it.[21]

ASSESSMENT

Make sure that the patient with an eye patch does not feel the lid of the injured eye moving when they blink the unaffected eye.[4] Ensure that the tape does not interfere with the patient's speech, chewing movements, or smiling.

AFTERCARE

Instruct the patient to remove the patch if it becomes loose. Eye patches should be changed or removed after 24 hours to reduce the risk of infection.[3,4] Most patients will need oral pain medications for the first 24 hours in addition to the patch.[4] Topical nonsteroidal anti-inflammatory ophthalmic drops have been useful alone or in conjunction with a contact lens bandage for pain relief.[11,21,24,25] The patient must be reexamined in 24 hours by an Ophthalmologist for assessment of the healing process and to check for infection or other complications. They can expect complete resolution in 2 to 3 days. Instruct the patient not to drive or operate dangerous equipment due to the loss of binocular depth perception.[3,18] The elderly may need assistance even for walking, especially up or down stairs.[3] Discourage the patient from reading, as this will cause involuntary movement of the patched eye.

COMPLICATIONS

Infection is rare but is most likely to occur in contact lens wearers, from an abrasion from an organic foreign body, or in patients who have used a patch for a prolonged period.[3,4,9] Patches applied too tightly can raise intraocular pressure high enough to cause retinal artery occlusion, leading to retinal ischemia, infarct, and blindness. Allergy to ophthalmic medications, the patch, or the tape materials can occur. Falls, auto accidents, and injuries due to lack of binocular depth perception can occur.[3,4] Healing times may be prolonged with loose patches that allow movement of the eyelid over the cornea.[3,4] The eyelashes may get caught between the eyelids and the cornea and further abrade the cornea.[3] For all of these reasons, eye patching has fallen out of favor. Contact lens bandages can cause infective ulcerative keratitis or corneal revascularization.[21]

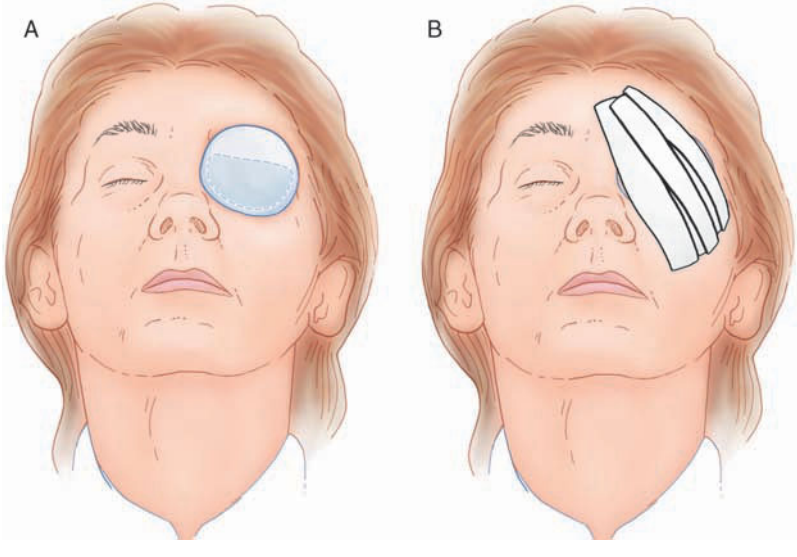

FIGURE 161-3. Eye patching. **A.** A folded patch is applied over the eyelid then covered by an unfolded patch. **B.** The patch is secured with tape.

SUMMARY

The eye is one of the most delicate and complex structures of the body. It is injured far more frequently than would be predicted based on its relative size.[26] Preservation of vision is essential to maintaining quality of life. In addition, the cornea is one of the most sensitive organs of the body. Tiny injuries to the cornea can result in significant pain and loss of function. It is therefore essential that the Emergency Physician be skilled in eye injury management. The application of an eye patch or eye shield is a simple, rapid, and straightforward procedure. Despite this, the improper application of these devices can result in significant morbidity.

162 Lateral Canthotomy and Cantholysis or Acute Orbital Compartment Syndrome Management

Jamil D. Bayram and Sami H. Uwaydat

INTRODUCTION

Acute orbital compartment syndrome is defined as an acute elevation of intraorbital pressure with resultant rapid ocular dysfunction. Patients typically present with ocular pain, proptosis, and blurry vision. Clinical signs of an acute orbital compartment syndrome include decreased visual acuity, elevated intraocular pressure (>40 mmHg), an afferent papillary defect, chemosis, mydriasis, diminished retropulsion of the affected globe to direct manual pressure, ophthalmoplegia, and fundoscopic signs of retinal ischemia (rare).[1–28]

Orbital compartment syndromes have been described in multiple clinical settings. The presentation that Emergency Physicians will most likely encounter is an acute posttraumatic retrobulbar hemorrhage leading to an orbital compartment syndrome, with subsequent rapid loss of vision.[1,2] Orbital compartment syndromes have been documented following blepharoplasty, retrobulbar anesthesia, orbital and sinus surgery, orbital fractures with intraorbital emphysema, spontaneous subperiosteal hemorrhages, and spontaneous retrobulbar hemorrhages.[3–9] Orbital compartment syndromes may also occur as the result of chronic and progressive disease processes (e.g., neoplasms, infections, and inflammations).[10]

Acute orbital compartment syndromes demand prompt recognition because irreversible loss of vision and even permanent blindness occurs without rapid treatment.[11] Once the diagnosis of an acute orbital compartment syndrome is made, emergent surgical intervention is indicated. An immediate lateral canthotomy and cantholysis are indicated within 1 hour of injury and ocular dysfunction. Medical interventions aimed at reducing intraocular pressure (e.g., mannitol, acetazolamide, topical beta-blockers, etc.) should be considered adjunctive therapy and not a substitute for surgical intervention.

ANATOMY AND PATHOPHYSIOLOGY

The orbit of the eye is a closed space posterior to the orbital septum and contained within the bony orbit. The lateral wall of the orbit is formed by the zygomatic bone. The posterior wall is formed by the sphenoid bone. The medial wall is formed by the ethmoid bone. The roof is formed by the frontal bone. The floor is formed by the maxillary bone. The globe is enclosed in a fascial envelope within the bony orbit.

The medial and lateral canthal tendons provide structural fixation of the eyelids to the orbital rim. The lateral canthal tendon (LCT) is located posterior and inferior to the lateral canthal fold (**Figure 162-1**). The LCT originates from the superior and inferior lateral tarsal plates (**Figure 162-1**) and attaches to the lateral orbital tubercle of the zygoma (**Figures 162-1 & 162-2**). The LCT consists of a superior crus from the superior tarsal plate and a inferior crus from the inferior tarsal plate. The LCT measures 10.6 mm (SD ± 0.9 mm) in length from its attachment site to the lateral canthal angle. It is 10.2 mm (SD ± 0.8 mm) in width at its origin at the lateral ends of the tarsal plates. It attaches 1.5 mm (SD ± 0.3 mm) behind the orbital margin and approximately 9.7 mm (SD ± 0.8 mm) below the frontozygomatic suture at the lateral orbital tubercle.[12] Immediately anterior to the LCT is Eisler's pocket, a collection of adipose tissue. Posterior to the LCT, at its attachment site to the lateral orbital tubercle is the check ligament of the lateral rectus muscle (**Figure 162-2**).

Any increase in intraorbital contents (e.g., retrobulbar hematoma, intraorbital emphysema, and retrobulbar abscess) will result in an elevation of intraorbital pressure because the orbit is a closed space. The globe itself may partially accommodate some of the elevation in intraorbital pressure by prolapsing forward (**Figure 162-3**). This will result in ocular pain and proptosis. The intraorbital pressure rises dramatically as the orbit approaches maximal distention. This rise in intraorbital pressure leads to a chemosis, elevated intraocular pressures, and compression of the intraorbital cranial nerves. If the compression is severe enough, the patient develops an ophthalmoplegia and an afferent papillary defect.

The exact mechanisms by which orbital compartment syndromes result in blindness remain speculative.[13–24] A common theory is that as the intraorbital pressure increases, orbital venous outflow is impeded and leads to diminished retinal and optic nerve arterial perfusion pressures. This results in an afferent pupillary defect, diminished visual acuity, and, rarely, fundoscopic signs of retinal ischemia. Over time, the elevated intraorbital pressure leads to irreversible optic nerve and/or retinal ischemia. Experimental studies have demonstrated that irreversible ischemic injury to the retina may occur within 90 minutes of vascular insufficiency.[18–21] Additional theories suggest that direct mechanical compression or

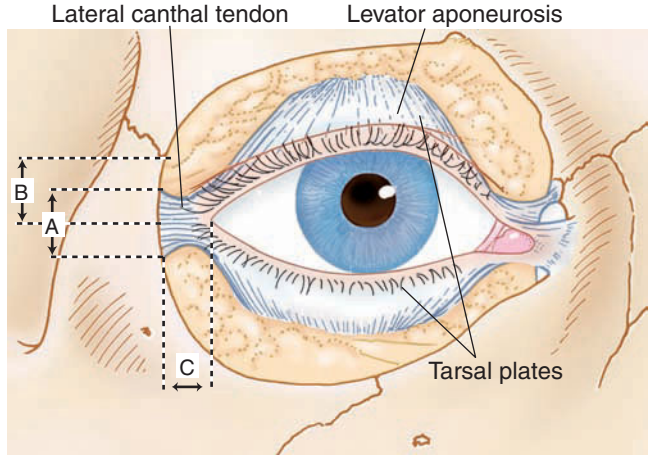

FIGURE 162-1. The lateral canthal tendon, or LCT (*A* = the vertical height of the LCT, *B* = the distance from the frontozygomatic suture to the midpoint of the LCT origin, and *C* = the length of the LCT as measured from the canthal margin to its origin).

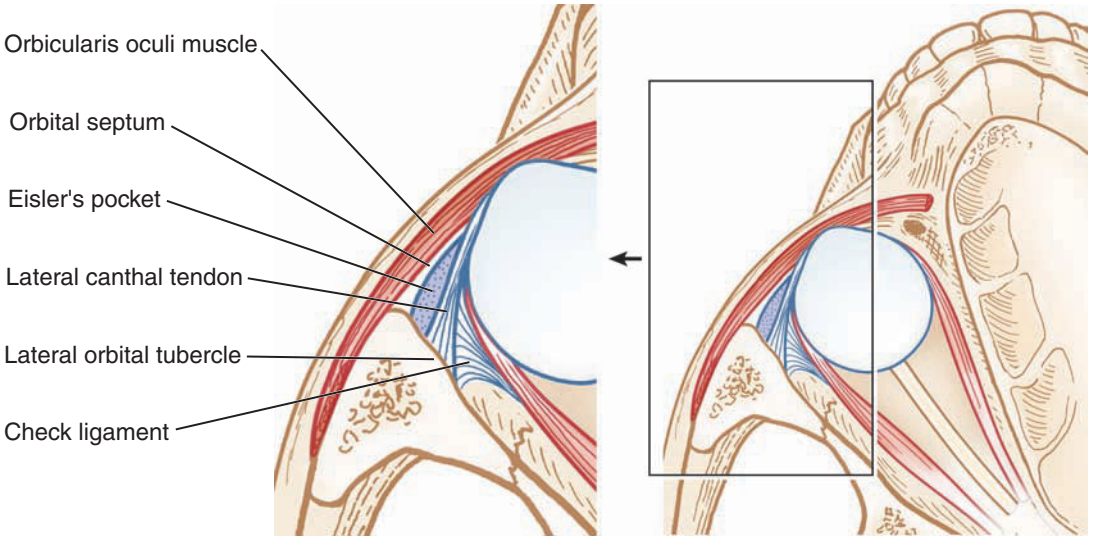

FIGURE 162-2. An axial view of the orbital contents. Identification of the LCT will require dissection of the conjunctiva and fascial tissues with a hemostat and iris scissors. A pocket of adipose tissue (Eisler's pocket) will be encountered beneath the superficial tissue layers. The LCT lies just posterior to this adipose tissue collection.

longitudinal traction on the optic nerve may contribute to the loss of vision in orbital compartment syndromes.[22,24] Elevated intraorbital pressure may also occur from large volume fluid resuscitation in patients without ocular trauma.[29]

A history of progressive loss of vision following orbital trauma suggests a reversible disease process (e.g., retrobulbar hemorrhage). If loss of vision is immediate and complete following orbital trauma, the chance of recovery of vision is poor.[25] This is because the loss of vision in the latter case is due to direct optic nerve, retinal, or vascular injury rather than an orbital compartment syndrome.

INDICATIONS

An acute orbital compartment syndrome is an indication for immediate orbital decompression.[23] Multiple case series have documented the efficacy of immediate orbital decompression in restoring visual acuity to affected patients.[24–28]

CONTRAINDICATIONS

There are no definite contraindications to performing this procedure, as permanent loss of vision may result from untreated acute orbital compartment syndromes. The patient's airway, breathing, circulation, and any life-threatening injuries must be addressed prior to performing this procedure. If the patient is very young, confused, or uncooperative, sedation and restraint or procedural sedation (Chapter 129) will be required to prevent iatrogenic injury to the globe.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Topical ocular anesthetic solution, proparacaine or tetracaine
- Lidocaine 2% with epinephrine

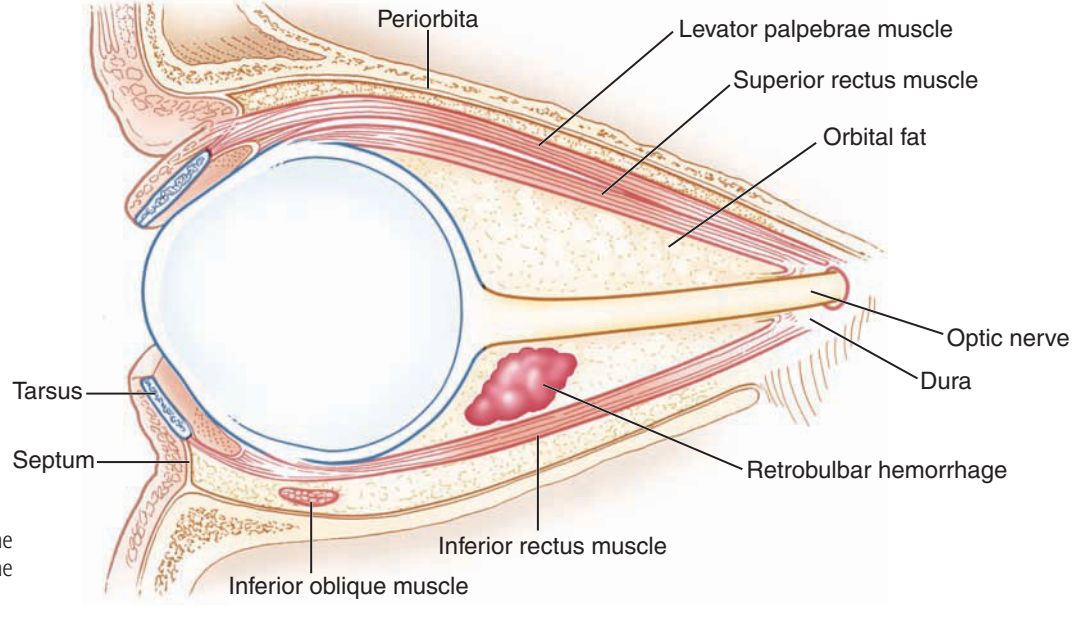

FIGURE 162-3. A sagittal view of the orbital contents. Note the location of the retrobulbar hemorrhage.

- 30 gauge 0.5 inch needle on a 3 cc Luer Lock syringe
- Ocular tonometer (applanation, Schiøtz, or Tono-Pen)
- Sterile saline or sterile water
- Straight mosquito hemostat
- Iris scissors
- Tissue forceps
- 2 × 2 gauze squares
- Topical ocular antibiotic ointment (e.g., bacitracin, ciprofloxacin, erythromycin, gentamicin, neosporin, polysporin, or sulfacetamide)
- #10 disposable scalpel (optional)
- Disposable hot tip cautery pen (optional)

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative, including the risks, benefits, and outcome if it is not performed. This is a painful procedure for the awake and alert patient, so lucid patients will require parenteral medications for analgesia and sedation in addition to local anesthetics. Consider the use of procedural sedation (Chapter 129) if not contraindicated. Measure and record the visual acuity. Perform a brief ophthalmologic examination. Apply topical ocular anesthetic solution to the conjunctiva of the affected eye. Measure and record the intraocular pressure.

TECHNIQUE

Place the patient supine. Clean the eyelids and surrounding skin of any blood, dirt, and debris. Apply povidone iodine or chlorhexidine solution to the eyelids and allow it to dry. Do not let these solutions drip into the eye. Irrigate the lateral canthal fold region with sterile saline or sterile water. Using aseptic technique, identify the lateral canthal fold (**Figure 162-4**). Inject 1 mL of local anesthetic solution with epinephrine subcutaneously using a 30 gauge, 0.5 inch needle on a 3 mL syringe along the lateral canthal fold. The goal is to anesthetize the tissue extending laterally from the canthal fold to the orbital rim. **Caution must be exercised to avoid inadvertent needle puncture of the globe.**

Insert a straight mosquito hemostat at the lateral canthal fold. Place one jaw of the hemostat anterior and one jaw posterior to the lateral canthal fold. Advance the tips of the hemostat laterally until the orbital rim is encountered. Clamp and compress the intervening tissue for approximately 1 minute. This will minimize any bleeding precipitated by the lateral canthotomy. Remove the hemostat. Cut all the tissue layers along the lateral canthal fold up to the orbital rim (lateral canthotomy) with an iris scissors (**Figure 162-4**). **All tissue layers, from the skin to conjunctiva, must be incised down to the orbital rim.** Use a #10 scalpel blade to cut the tissues in cases of severe distortion of the anatomy due to edema or if iris scissors are not readily available. A disposable hot cautery pen, if available, can be used to achieve hemostasis.

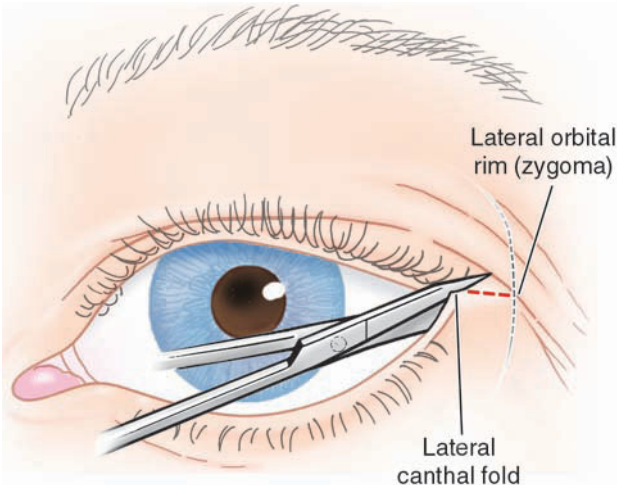

FIGURE 162-4. Illustration of lateral canthotomy. Iris scissors are used to cut all tissue layers along the lateral canthal fold up to the orbital rim.

Gently grasp the lower eyelid with a hemostat or forceps and retract it outward. Identify the LCT located just posterior and inferior to the lateral canthal fold (**Figures 162-1 & 162-2**). Dissect the conjunctiva and fascial tissues with a hemostat or iris scissors. A pocket of adipose tissue (Eisler's pocket) will be encountered beneath the superficial fascial planes (**Figure 162-2**). The LCT lies just posterior to this adipose tissue collection (**Figure 162-2**). Completely divide the LCT vertically at its midportion with an iris scissors or #10 scalpel (lateral cantholysis) to transect the inferior crus of the tendon.

ASSESSMENT

A successful lateral canthotomy and cantholysis will cause an immediate decrease in intraocular pressure to less than 40 mmHg. Recheck the intraocular pressure. **If the intraocular pressure remains elevated, reexplore the lateral canthal tendon region to make sure that the inferior crus has been completely transected. If transected, cut the superior crus of the tendon to transect it.** Occasionally, the intraorbital and intraocular pressures will remain elevated despite successful cantholysis. These refractory cases necessitate emergent decompression of the deep orbital wall.[7] Such decompressions call for operative techniques that are to be performed by Ophthalmologists and Otolaryngologists.

The resolution of proptosis, afferent pupillary defects, and restoration of visual acuity will usually not occur immediately. Patients who respond to surgical intervention will gradually regain their visual acuity over a period of hours to days.

AFTERCARE

Apply a topical antibiotic ointment along the canthotomy site. In orbital compartment syndromes, elevated intraocular pressures merely reflect elevated intraorbital pressures. Therefore, any attempts to decrease intraocular pressures will not reliably reduce retrobulbar optic nerve compression. Medical interventions decreasing intraocular pressure may be used following, or in conjunction with, a lateral canthotomy and cantholysis. These interventions are similar to those employed for the management of elevated intraocular pressures in patients with acute angle-closure glaucoma. This includes the use of topical beta-blockers, central acting alpha agonists, intravenous mannitol, and carbonic anhydrase inhibitors. **These medications are not a substitute for surgical orbital decompression.**

Many patients with an orbital compartment syndrome have other injuries requiring hospital admission following their Emergency Department evaluation and treatment. Ensure a timely Ophthalmologic consultation for a complete eye exam and possible repair of the canthotomy and cantholysis sites once the orbital compartment syndrome resolves. Repair of the lateral canthal fold and lateral canthal tendon is controversial. Many Ophthalmologists do not advocate suture repair, as a majority of wounds heal without complication by secondary intention. Patients with no other acute medical or surgical conditions,

restored vision, a normal ophthalmologic examination, and normal postprocedural intraocular pressures may be discharged after evaluation by an Ophthalmologist.

COMPLICATIONS

Time constraints, abnormal anatomy (resulting from traumatized tissue), and lack of familiarity with the lateral canthotomy and cantholysis techniques can make this a challenging procedure. Hemorrhage is often minimal and can be controlled with direct pressure. The use of a disposable cautery pen can be helpful. Mechanical injuries can include globe perforation, injury of the lateral rectus muscle, scleral lacerations, and secondary ectropion. Most of these complications can be prevented by knowing and identifying the anatomic landmarks, reviewing the procedure before it is performed, and using extreme care in performing the canthotomy and cantholysis. Despite the use of aseptic technique, infections at the canthotomy and cantholysis sites can occur. They should be treated with parenteral antibiotics that cover typical skin flora.

SUMMARY

Emergency Physicians must be able to promptly recognize and be prepared to manage an acute orbital compartment syndrome, defined by an acute elevation of intraorbital and intraocular pressure with resultant ocular dysfunction. Patients will present with ocular pain, proptosis, an afferent pupillary defect, and diminished visual acuity. An acute orbital compartment syndrome requires emergent treatment to preserve vision. An immediate lateral canthotomy and cantholysis are indicated, preferably within 1 hour of injury and ocular dysfunction. Medical management should be considered an adjunctive therapy. Many patients will regain their visual function if the procedure is performed soon after the injury and before permanent ischemic changes occur.

163 Globe Luxation Reduction

Jeffrey S. Schlab

INTRODUCTION

Luxation of the globe is a rare event whereby the eyelids slip behind the midcoronal plane of the eye in an extremely proptosed eyeball (**Figure 163-1**). The orbicularis oculi muscle then goes into spasm, which maintains the luxation of the globe. Extraocular eye movements become severely limited. The optic nerve and retinal vasculature are subjected to an abnormal amount of traction, resulting in possible damage to these structures or the retina.[1] The end result is partial or full blindness in the affected eye if it is not reduced before irreversible ischemic changes occur.

ANATOMY AND PATHOPHYSIOLOGY

There are three major causes of globe luxation: spontaneous, voluntary, and traumatic. Spontaneous luxation tends to occur in individuals with shallow orbits.[2] Structural abnormalities—such as laxity of the supporting muscles and fascia as well as anomalous extraocular muscles—can predispose to spontaneous luxation.[2–4] Pathologic processes that cause proptosis can predispose to luxation. The literature documents cases of luxation associated with orbital tumors, Graves' disease, cerebral gummas, histiocytosis X, and craniofacial dysostosis.[1,5,6] Voluntary luxation occurs in individuals who learn to cause globe propulsion by using a digit or use of their extraocular muscles. Some patients use a Valsalva maneuver to luxate their globe(s) voluntarily. Traumatic luxation results from trauma to the globe or the surrounding bony orbit. It can occur from motor vehicle accidents or even relatively minor trauma to the face.[7,8] Traumatic luxation can also occur from intentional eye gouging or even during the forceps-assisted delivery of a neonate.[9,10]

The normal anatomic relationship of the globe to the surrounding structures is seen in **Figure 163-2**. The midcoronal plane of the eye is a transverse section through the eye in the coronal plane. It is through the widest portion of the eye and divides the eye into anterior and posterior halves. When the eyelids get behind the midcoronal plane, the orbicularis oculi muscle is pulled taut and begins to go into spasm. This spasm prevents spontaneous reduction of the globe.

INDICATIONS

Globe reduction is indicated to relieve traction on the optic nerve and retinal vessels. The patient's visual acuity has the potential of being compromised without prompt reduction. Sustained globe luxation is physically and psychologically uncomfortable for the patient, may result in permanent loss of vision, and is difficult to reduce without general anesthesia.

CONTRAINDICATIONS

Obvious rupture of the globe and extensive orbital fractures that require immediate surgical intervention are relative contraindications to globe reduction. Edema and retrobulbar hemorrhage can make reduction outside the Operating Room impossible.[1,6]

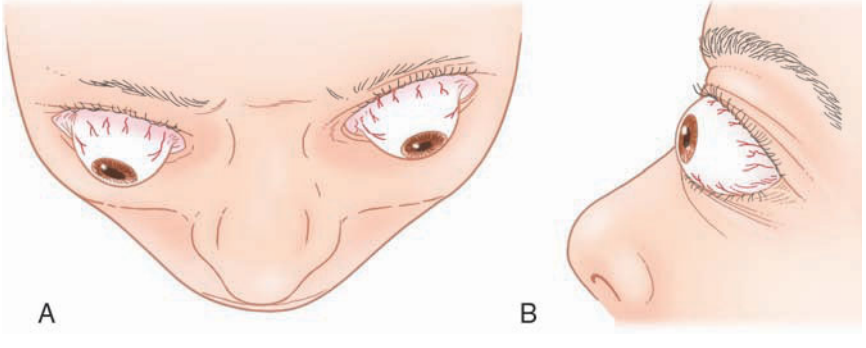

FIGURE 163-1. The luxated globe. **A.** Superior view. **B.** Lateral view.

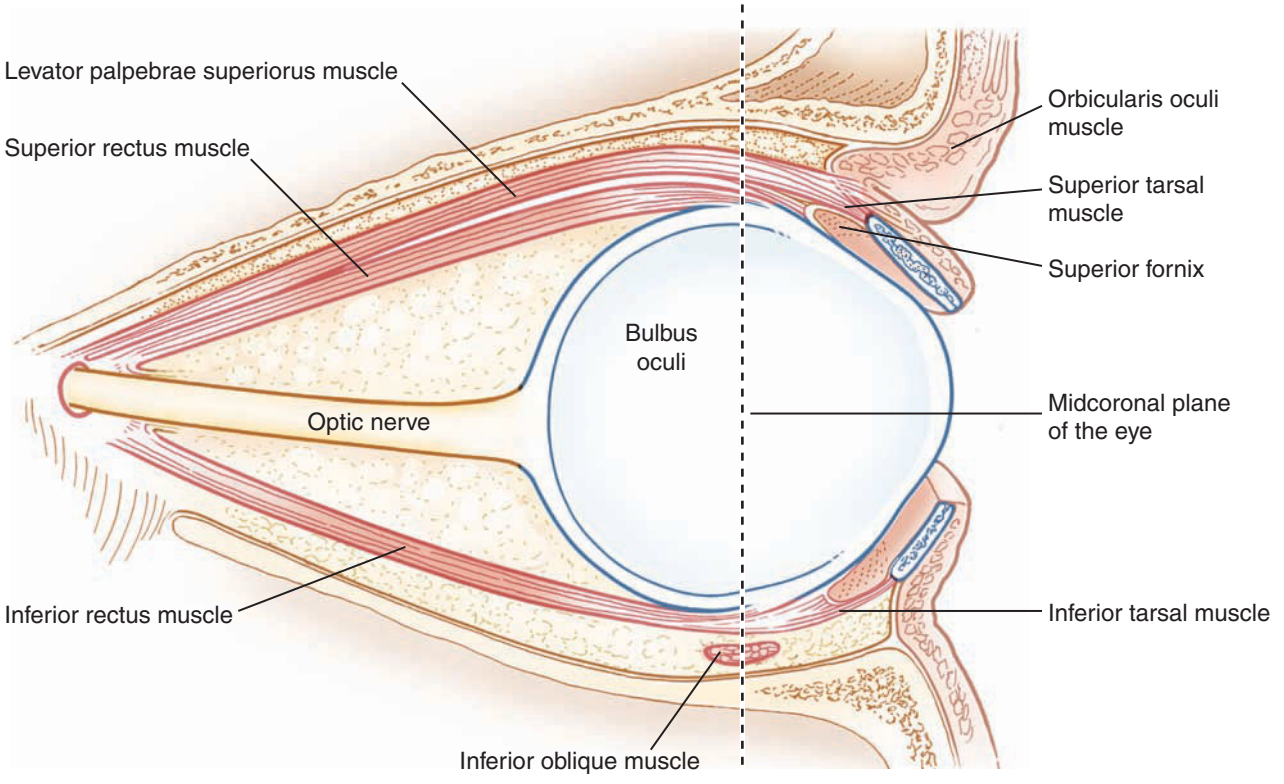

FIGURE 163-2. Anatomy of the eye and orbit.

EQUIPMENT

- Topical ocular anesthetic agent (e.g., 0.5% proparacaine or tetracaine)
- Sterile gauze and gloves
- Sutures or eyelid retractors
- Local anesthetic solution (1% lidocaine), if eyelid retaining sutures need to be placed
- 3 mL syringe
- 27 gauge needle

PATIENT PREPARATION

Prior to any attempt at reduction, a directed eye exam addressing the integrity of the globe, visual acuity, pupillary reactivity, and range of ocular motion should be performed. Describe the procedure to the patient and/or their representative. Answer any questions about the procedure and obtain an informed consent for the procedure. Relaxation of the patient and the orbicularis muscles are essential for procedural success. The use of a parenteral anxiolytic and analgesic or procedural sedation (Chapter 129) is recommended if not contraindicated.[11] Place the patient supine. Instill a topical ocular anesthetic agent onto the affected eye. Allow 1 to 2 minutes for the anesthetic to take full effect.

TECHNIQUE

Reduction of a globe luxation ideally requires two people (**Figure 163-3**).[11,12] Instruct an assistant to apply steady upward and outward traction on the upper eyelid and downward and outward traction on the lower eyelid by grasping and pulling on the eyelashes. Instruct the patient to maintain a constant downward gaze. The downward gaze posture negates the retracting action of the levator palpebrae superioris muscle and simultaneously relaxes the superior rectus muscle.[12] While traction is being applied to the eyelids, apply steady and gentle pressure with a gloved thumb to the exposed superior sclera of the globe in a simultaneously downward and posterior direction. Physical contact over the sclera minimizes discomfort and avoids possible

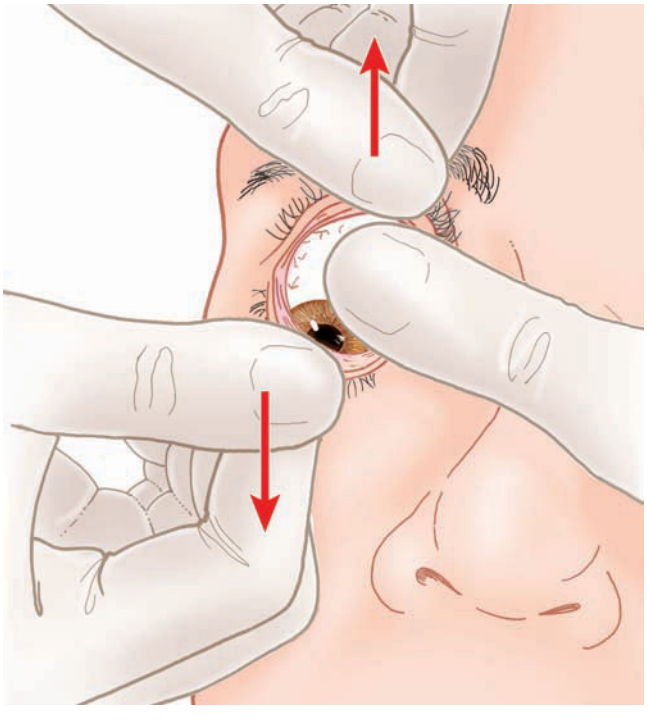

FIGURE 163-3. Reduction of a globe luxation.

corneal abrasions.[12] Continue to apply constant and gentle pressure until the globe is manipulated back into the orbit.[1,6]

ALTERNATIVE TECHNIQUE

Occasionally the patient's eyelashes are small or not accessible, or an assistant is not available. In these cases, an eyelid retractor may be placed behind the eyelids to provide countertraction. Other authorities have recommended the placement of a suture through the anesthetized skin of the eyelids to help retract them.[1,4,6] **Extreme care must be taken to prevent penetration of the globe by the anesthetic needle or the suture needle if retaining stitches are placed in the eyelids.** If either of these techniques are used, the globe is then reduced in the same manner as described previously.

ASSESSMENT

A repeat and complete eye examination must be performed after the procedure and documented in the medical record. Pay special attention to visual acuity, pupillary reflexes, and range of extraocular muscle movement.[1,6,10] Full visual acuity may not return to baseline for several days or longer.[4] A search for the possible causes of a nontraumatic luxation should be initiated in the Emergency Department.[1] This includes but is not limited to thyroid function testing and orbital imaging to rule out a tumor. This evaluation should be performed after consultation with an Ophthalmologist. Conduct a search for associated injuries such as a bony periorbital fracture, globe rupture, retroorbital hematoma, or intracranial injury in the cases of traumatic luxation.

AFTERCARE

Patients with spontaneous luxations that reduce without difficulty and who are without visual impairment may be discharged home after consultation with an Ophthalmologist. These patients require follow-up with the Ophthalmologist within 24 hours.[1,6] They should be instructed to avoid Valsalva maneuvers.[1] All patients with traumatic luxation require emergent Ophthalmologic consultation and imaging of the orbits.[1,6]

COMPLICATIONS

It is not uncommon for eyelashes to be retained in the conjunctival fornices after this procedure.[10] A thorough evaluation and removal of any free eyelashes is warranted to prevent corneal abrasions or injury.[1,6,10] If one or two attempts at reduction are not successful, instill saline drops to the eye and apply an eye shield to prevent further injury while an emergent Ophthalmologic consult is obtained.[1,6] Refer to Chapter 161 for the complete details regarding the application of an eye shield.

SUMMARY

Globe luxation is a rare entity that can be effectively dealt with in the Emergency Department. Prompt intervention by an Emergency Physician can result in the preservation of visual acuity. After a brief initial eye examination, uncomplicated cases can be reduced by the Emergency Physician. Complicating factors—such as the presence of trauma, an open globe injury, or the inability to reduce the globe—warrant emergent Ophthalmologic consultation. Predisposing factors for a spontaneous luxation should be investigated.

164 Hordeolum (Stye) Incision and Drainage

Sami H. Uwaydat and Jamil D. Bayram

INTRODUCTION

A hordeolum is a suppurative infection of one of the eyelid glands. The nomenclature that describes infectious and inflammatory conditions of the eyelid glands is at times confusing. A brief description of the eyelid margin anatomy may help resolve some of the confusion. The patient usually presents with an acutely painful, erythematous, localized, and tender mass on either the upper or lower eyelid. A hordeolum may be associated with a blepharitis.

ANATOMY AND PATHOPHYSIOLOGY

The eyelid is composed of numerous structures (**Figure 164-1**). The eyelid skin is thin and vascular. The orbicularis oculi muscle encircles the eyelids and controls their movements. The hair follicles which form the eyelashes are fine and delicate in comparison to hair on other body areas. Numerous glands are contained within the eyelids. The glands of Zeis are modified sebaceous glands associated with the hair follicles. The glands of Moll are modified sweat glands that open into the base of the hair follicles. The tarsus is a rigid fibrous plate containing the sebaceous Meibomian glands. The orifice of the elongated Meibomian glands can be seen posterior to the eyelashes at the eyelid margin. The inner aspect of the eyelids is lined by the thin and delicate conjunctiva.

A hordeolum can be located internally or externally in relation to the eyelid and tarsal plate. They are essentially an abscess of the eyelid. An internal hordeolum is a bacterial infection of the Meibomian gland and usually points to the inside or conjunctiva (**Figure 164-2**). An internal hordeolum is usually larger than an external hordeolum. If the infection blocks the neck of the Meibomian gland, the infection points toward the conjunctival surface of the eyelid. If the neck of the Meibomian gland is not blocked, the infection often points to the eyelid margin. An external hordeolum, also known as a stye, is a bacterial infection of the glands of Zeis or Moll. These tend to be small, superficial, and point to the eyelid skin or, more commonly, the eyelid margin. The most common causative agent in both internal and external hordeola is *Staphylococcus aureus*.[1]

Patients with a hordeolum almost always present with localized pain, redness, and swelling of the eyelid margin. It is usually a benign process but can progress to a preseptal or septal cellulitis. It may rarely result in a corneal epithelial defect,[2] periorbital necrotizing fasciitis,[3] and bacteremia.[4]

A chalazion is a chronic, more than 2 weeks, granulomatous inflammation of a sebaceous Meibomian gland. Acute chalazion lesions, those less than 2 weeks old, are often difficult to distinguish from an acute hordeolum. Clinically, the management of an acute chalazion and an acute hordeolum are the same and it is not necessary to differentiate the two processes. A chalazion may persist for many months and slowly enlarge over time. A chronic chalazion is characterized by a painless localized swelling of the eyelid margin with no inflammatory signs and feels rubbery upon palpation. A chronic chalazion does not require an urgent intervention and should be managed by an Ophthalmologist. A chalazion that is acute, large, or causes local irritation may require an incision and drainage. Recurrent chalazia require an evaluation by an Ophthalmologist to rule out a malignancy.

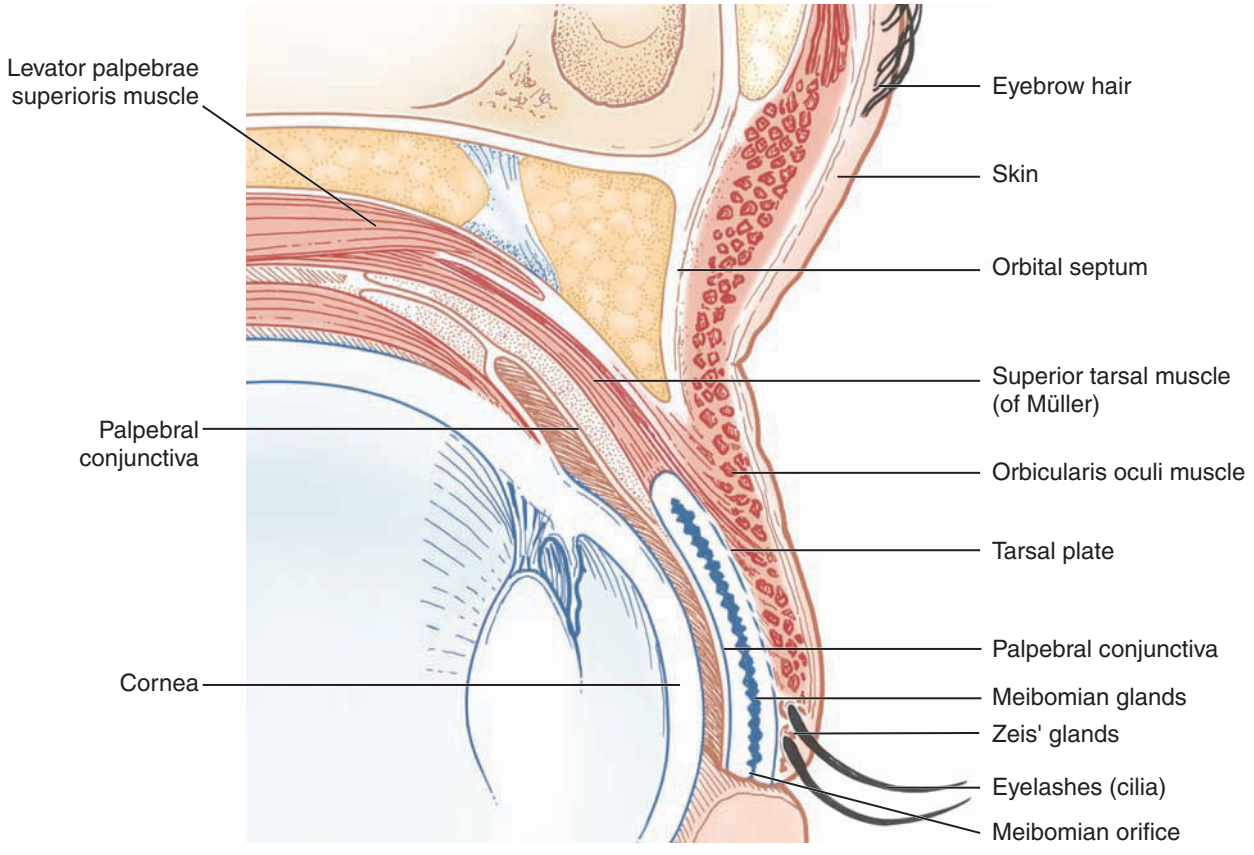

FIGURE 164-1. Eyelid margin anatomy. The type and location of the infected gland determine whether it is an internal hordeolum or an external hordeolum (stye).

MANAGEMENT

Hordeola are initially managed conservatively. Warm compresses should be applied over the eyelid for 10 to 15 minutes at a time, and three to six times per day. An alternative and portable solution to warm compresses would be to place 8 to 10 ounces of dry rice in a sock and heat it in a microwave (typically for 30 seconds). The rice tends to maintain the heat for a longer period compared to the warm compresses. Apply diluted baby shampoo to the eyelid margins with a washcloth or cotton-tipped applicator for daily eyelid scrubs. Topical antibiotic ointments (e.g., erythromycin) can be placed in the conjunctiva or on the eyelid margin three times per day. The purpose of topical antibiotics is to prevent the infection spreading to adjacent hair follicles. Oral antibiotics are indicated only if the signs and symptoms of a cellulitis develop. Most hordeola will spontaneously drain and resolve within 5 to 7 days with conservative management. Treat any accompanying blepharitis to prevent the formation of additional hordeola.

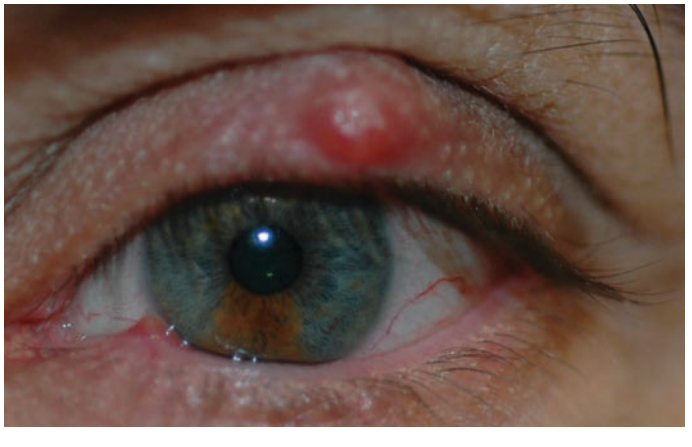

FIGURE 164-2. An internal hordeolum with redness and swelling.

INDICATION

Surgical excision is warranted if the hordeolum does not resolve with conservative management and the patient has significant discomfort. A hordeolum can be excised if it causes a cosmetic deformity, blocks the visual axis, or is of a significant size.

CONTRAINDICATIONS

Not all hordeola should be incised and drained in the Emergency Department. Hordeola close to the lacrimal puncti or the medial canthus are best managed conservatively until surgery can be coordinated with an Oculoplastic surgeon. Drainage in patients on blood thinners and in those who are unable to follow commands is contraindicated. Sedation is required for children, the confused patient, and the uncooperative patient. Consult an Ophthalmologist prior to sedating a patient to incise and drain a hordeolum. A recurrent hordeolum should be referred to an Ophthalmologist for biopsy and evaluation of the lesion for a malignancy. Consult an Ophthalmologist prior to the procedure if the hordeolum affects visual acuity or ocular movements.

EQUIPMENT

- Buffered local anesthetic solution (e.g., lidocaine with epinephrine and $NaHCO_3$)
- 30 gauge, 0.5 inch needle on a 3 mL syringe
- 0.5% proparacaine drops
- Povidone iodine or chlorhexidine swabs
- Small drape with central opening
- Sterile 4 × 4 gauze squares
- Sterile cotton-tipped applicators
- Sterile marking pen
- Corneal eye shield
- #11 or #15 scalpel blade on a handle
- Wescott scissors
- Desmarres chalazion clamps, multiple sizes
- Meyerhoefer chalazion curettes, multiple sizes
- Castro-Viejo forceps
- Topical ophthalmic antibiotic ointment without steroids, e.g., erythromycin
- Eye pad
- Culture swabs
- 1-inch tape

A chalazion clamp is a device specifically designed to aid in the incision and drainage of a chalazion or hordeolum (**Figure 164-3**). It is similar to a forceps, except the distal ends are expanded and has a clamp mechanism. One of the distal ends is an open circle used to surround the hordeolum. The other distal end is flat, solid, and acts to prevent injury to underlying structures. Just proximal to the distal expanded ends is a screw mechanism that allows the distal ends to be closed and clamped securely in place.

PATIENT PREPARATION

Perform a brief ophthalmic examination including visual acuity, motility, and an anterior segment assessment. Document the size and location of the hordeolum. Explain the procedure, its risks, and benefits to the patient and/or their representative. Place a signed informed consent in the medical record. Many patients are apprehensive when a surgical procedure is performed close to their eye. It is imperative that the patient remains still during this procedure, given that sharp instruments will be exchanged over the globe. A thorough explanation of the surgical steps should alleviate some of the patient's fears. Consider the use of parenteral sedation or procedural sedation (Chapter 129).

Place the patient supine. Support their head with a headrest or a foam doughnut. Place one drop of proparacaine in the cul-de-sac of the affected eye. Mark the circumference of the hordeolum with a sterile skin marker (**Figure 164-4A**). This is important as the injection of local anesthetic solution will obscure the margins of the hordeolum. Gently wipe the eyelid skin with an alcohol swab. **Do not allow the alcohol to get onto the eye.** Clean the skin of the eyelid with povidone iodine or chlorhexidine solution. **Do not allow these solutions to get onto the eye.** If they do get onto the eye, irrigate the eye copiously with normal saline. Arm a 30 gauge needle onto a 3 mL syringe. Draw up 1 mL of buffered local anesthetic solution with epinephrine. Inject the solution around and into the hordeolum (**Figures 164-4A & B**). **Direct the syringe tangential to the skin (for an external hordeolum) or conjunctive (for an internal hordeolum) so as to avoid inadvertent penetration of the globe.** Place a corneal shield, if available, over the cornea.

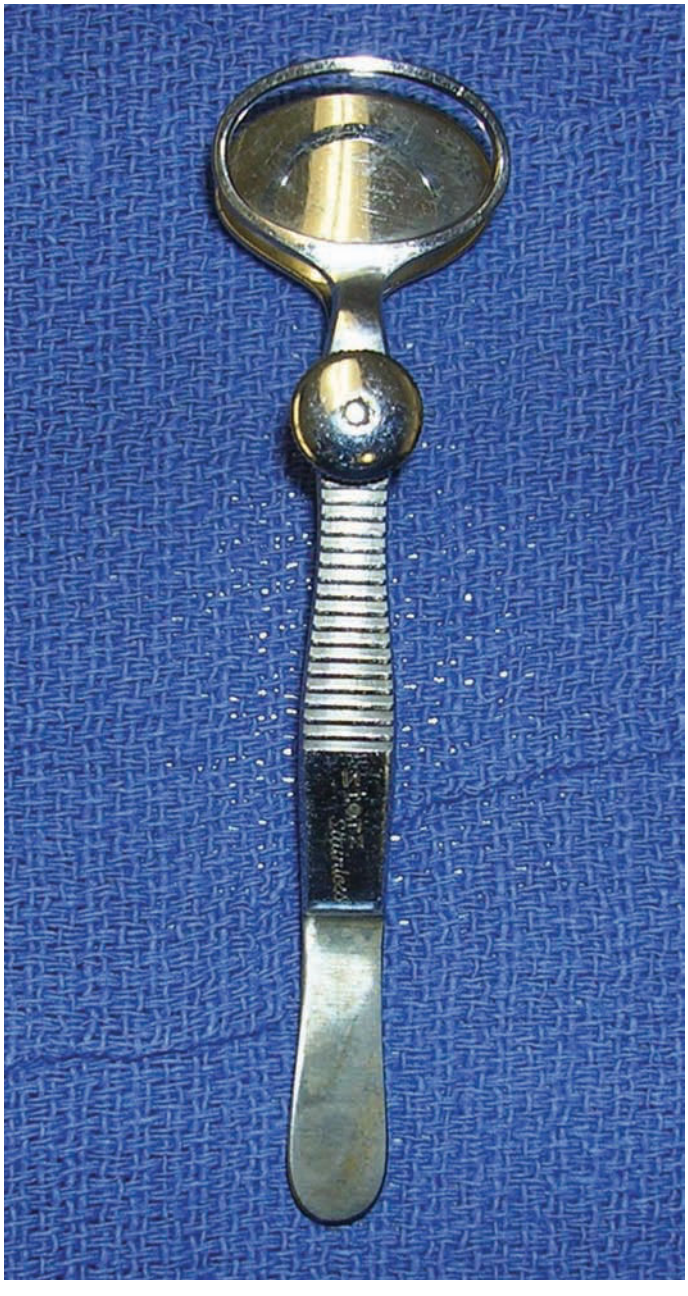

FIGURE 164-3. The chalazion clamp.

TECHNIQUES

INTERNAL HORDEOLUM

Cleanse and anesthetize the area as described above. Apply a chalazion clamp to the eyelid. Place the loop of the clamp on the conjunctival surface of the eyelid and encompassing the marked edges of the hordeolum (**Figure 164-4C**). Place the plate of the clamp on the skin surface of the eyelid. Gently close the clamp by turning the screw mechanism. Gently flip the clamp to expose the hordeolum. Make a superficial cruciate incision in the hordeolum with a #11 or #15 scalpel blade (**Figures 164-4C & D**). Gently insert the chalazion curette to scoop out the purulent material (**Figure 164-4D**). Alternatively, use a sterile cotton-tipped applicator. Grasp the edge of the inflammatory tissue with the Castro-Viejo forceps. Carefully use Wescott scissors to dissect the planes between the hordeolum and the tarsus (**Figure 164-4E**). Release the chalazion clamp gently

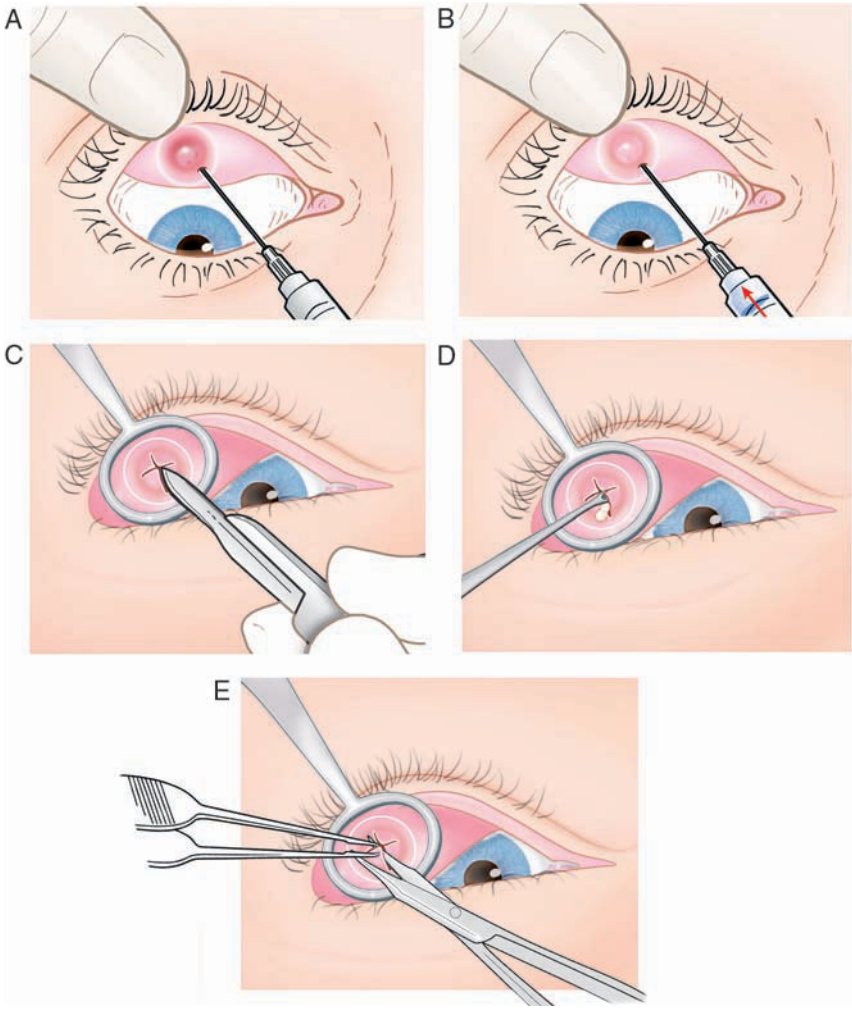

FIGURE 164-4. Incision and drainage of a hordeolum. **A.** The hordeolum is identified and a circle is drawn around its margins. A needle is inserted to inject local anesthetic solution. **B.** Local anesthetic solution is injected into and around the hordeolum. **C.** A chalazion clamp is applied and an incision is made over the hordeolum. **D.** Purulent material is expressed for the incision using a chalazion curette. **E.** Inflammatory tissue is removed.

and remove it from the eyelid. Apply gentle pressure with a gauze square to the incision to control any bleeding. **Be careful to not touch the eye with the gauze and cause a corneal abrasion.** Culture the expressed purulence. Place ophthalmic erythromycin ointment in the cul-de-sac. Apply a pressure patch over the eye (Chapter 161).

EXTERNAL HORDEOLUM

Cleanse and anesthetize the area as described above. Make an incision over the hordeolum with a #11 or #15 scalpel blade. **Do not cut the eyelid margin and the underlying tarsus.** Gently roll a sterile cotton-tipped applicator over the eyelid skin and toward the incision to express the purulent material. Apply gentle pressure with a gauze square to the incision to control any bleeding. **Be careful to not touch the eye with the gauze and cause a corneal abrasion.** Culture the expressed purulence. Place ophthalmic erythromycin ointment on the eyelid skin. Apply a pressure patch over the eye (Chapter 161).

ASSESSMENT

Palpate the eyelid at the end of the procedure. If a residual pus collection is detected, attempt to express the pus with a cotton-tipped applicator. If this fails, a second incision parallel to the first one is required to completely drain the hordeolum. **Do not undermine the delicate eyelid tissues to express the purulent material.** While not required, some physicians may perform a repeat fluorescein examination to ensure that they did not cause a corneal abrasion during the procedure.

AFTERCARE

The follow-up instructions are simple and straightforward. Instruct the patient to remove the pressure patch in 1 to 2 hours. It was placed to minimize any edema and bleeding from the procedure. If significant bleeding is noted when the patch is removed, the patient should immediately return to the Emergency Department. They should apply a warm compress (or warm rice in a sock) to the eyelid every 3 to 4 hours for the first 24 hours. An eyelid skin incision should remain clean and dry for 24 hours. Prescribe topical ophthalmic antibiotic ointment (e.g., erythromycin if no contraindications exist) to be applied on the skin incision or in the cul-de-sac three times a day for 3 to 4 days. Someone must follow up on the culture results in 12 to 24 hours. If MRSA is detected, the patient must be notified and they require follow-up with an Ophthalmologist within 24 hours or return to the Emergency Department for the consideration of oral antibiotics. Treat any associated blepharitis to prevent the formation of a new hordeolum.

The patient should follow up with an Ophthalmologist within 5 to 7 days for an evaluation of the eyelid. They need to be evaluated sooner if the cultures are positive for MRSA. They should immediately be seen by an Ophthalmologist or return to the Emergency Department if any of the following develop: uncontrollable bleeding, increase in eyelid pain and/or swelling, the appearance of yellow or green pus in the eye or on the eyelid, and fever.

Oculoplasty referral is warranted to evaluate a recurrent hordeolum or chalazion to rule out malignancy.[5] Recurrent bilateral hordeolum may indicate an underlying immunodeficiency (e.g., IgM).[6]

COMPLICATIONS

Numerous complications are possible both during and as a result of the incision and drainage procedure. Inadvertent injury to the globe (e.g., corneal abrasion or corneoscleral perforation) or eyelid structures (e.g., lacrimal duct or punctum) may occur.[7] Early complications include infections such as a cellulitis or conjunctivitis. Most bleeding can be controlled with gentle pressure or tying off of the offending vessel with fine absorbable sutures. **Never use a portable hot cautery unit on the eyelid to control bleeding.** Uncontrolled bleeding is rare but can occur and will require an Ophthalmologist to control. Late complications occur from excessive scarring at the incision site. If an external incision was made, the contracting scar can lead to an ectropion, eyelid retraction, uneven eyelid margins, and trichiasis. If an internal incision was made, conjunctival scarring can lead to an entropion and chronic conjunctivitis.

SUMMARY

Patients with an acute hordeolum often present to the Emergency Department with a painful, localized, red, and swollen eyelid margin. They should be initially managed conservatively. Subsequent incision and drainage may be required to alleviate patient's discomfort. The incision and drainage procedure is simple to perform and can be done by the Emergency Physician.

SECTION 13

Otolaryngologic Procedures

165 External Auditory Canal Foreign Body Removal

Rebecca R. Roberts

INTRODUCTION

Foreign bodies are commonly found in the external auditory canal (EAC) of children and sometimes in adults.[1] Children commonly place small objects such as food (e.g., beans, peas, corn, and seeds) or small round objects (e.g., beads, rocks, and toys) in the EAC.[2–5] Adults are more likely to suffer from items used to clean or scratch the ear (e.g., cotton swab, paper, paper clips, and pencil lead) and insects that crawl into the ear.[4] The EAC and tympanic membrane (TM) are exquisitely sensitive and delicate.[3,6] Foreign bodies in the EAC are extremely irritating to patients; especially live insects that will scratch the TM in an effort to escape. Injuries can occur unless proper care is taken in the removal of EAC foreign bodies.

ANATOMY

The EAC is S-shaped and 2.5 cm long in adults.[7] The lateral or distal third is cartilaginous, with thick skin. It has more hair follicles, glands, and subcutaneous tissue than the medial or proximal two-thirds of the EAC. The medial EAC is bony, with a thinner and more fragile layer of skin.[7,8] The narrowed isthmus is located between the cartilaginous and bony portions.[2,7] The canal ends medially at the TM, which is situated obliquely to increase the surface area for carrying sound energy to the middle ear.[8] The anteroinferior EAC is 0.6 mm longer than the posterosuperior portion.[7] Auriculotemporal branches of cranial nerves V, VII, IX, and X and the greater auricular nerve of the cervical plexus supply sensation to the EAC.[7]

INDICATIONS

All EAC foreign bodies must be removed. The only question is how quickly this must be done, who should do it, and which is the safest of available techniques. The method used is individualized to the patient, type of foreign body, Emergency Physician preference and experience, and the availability of an Otolaryngologist. Some foreign bodies are very easily and safely removed with the equipment available in any Emergency Department. Others—due to impaction, large size, sharp edges, location in the canal, involvement of the TM or middle ear structures, or patient age—will require removal under general anesthesia or even an approach to removal from outside the canal.[2,6,9]

The most urgent indication for immediate removal is an alkaline button battery because of the extensive and severe damage it may cause in a very short time.[1] These are most commonly found in the EAC of a young child. There are two mechanisms for the rapid destruction of surrounding tissues by the batteries. The moisture and cerumen in the EAC have a high conductivity, which causes conduction of electric current from the battery and results in localized electrical burns. Local inflammation from those burns will cause fluid exudation into the EAC. This increases the electrical conduction injury and causes the battery to begin leaking alkaline electrolyte solution, which can penetrate deeply into underlying tissues, with resultant liquefaction necrosis.[3,10] **Therefore, irrigation with water or saline is contraindicated in button battery removal and another technique must be used.[1]**

CONTRAINDICATIONS

Rather than contraindications to removal, these can also be thought of as indications for referral to an Otolaryngologist for removal of the foreign body. The major contraindication to removal in the Emergency Department is probable injury with direct removal. Examples are foreign bodies that have perforated or impaled the TM. Removal will cause further damage to the TM as well as potential disruption of the middle ear ossicles and loss of hearing. These foreign bodies require removal under general anesthesia with the aid of an operating microscope.[2,3,5,9] Another contraindication is a large object that has impaled itself in the wall of the EAC. Direct removal will require anesthesia and possibly an approach from outside the EAC to avoid denuding the skin of the EAC.[3] Finally, objects that are difficult to remove and a patient (usually a young child) who cannot hold still or be held still for the procedure should be referred to an Otolaryngologist.[2,5,9] These cases are likely to result in injury if the foreign body is removed in the Emergency Department.

Irrigation is almost always safe to attempt.[11] The most important contraindication for irrigating the EAC is an acute or chronically ruptured TM.[9,11–14] Water forced into the middle ear can lead to otitis media, labyrinthitis, mastoiditis, disruption of the ossicles, and loss of balance or hearing. Some authors recommend alternate methods for any patient who has never had an ear exam to document the integrity of the TM.[9,11,12] Completely impacted foreign bodies that leave no space for the irrigant fluid to flow behind it will only be driven deeper into the EAC, making subsequent removal even more difficult.[1,15] A relative contraindication for irrigation with water is an organic object, such as a dry bean, seed, or rice.[15] Organic foreign bodies will absorb water and swell, making removal more difficult. Irrigation can be attempted if the object is very small and irrigation is expected to rapidly succeed in removal before swelling occurs. Otherwise, irrigate the object with alcohol, remove it with instruments, or extract it with suction.

Directly grasping the foreign body with forceps is contraindicated for large or spherical objects that will not allow clear passage of the forceps jaws along its sides. Attempts to grab this type of object will only drive it deeper into the EAC.[15]

EQUIPMENT

Anesthesia

- 1%, 2%, or 4% lidocaine solution or gel
- 1 mL syringe
- 5 mL syringe
- 27 or 30 gauge needle
- EAC speculum

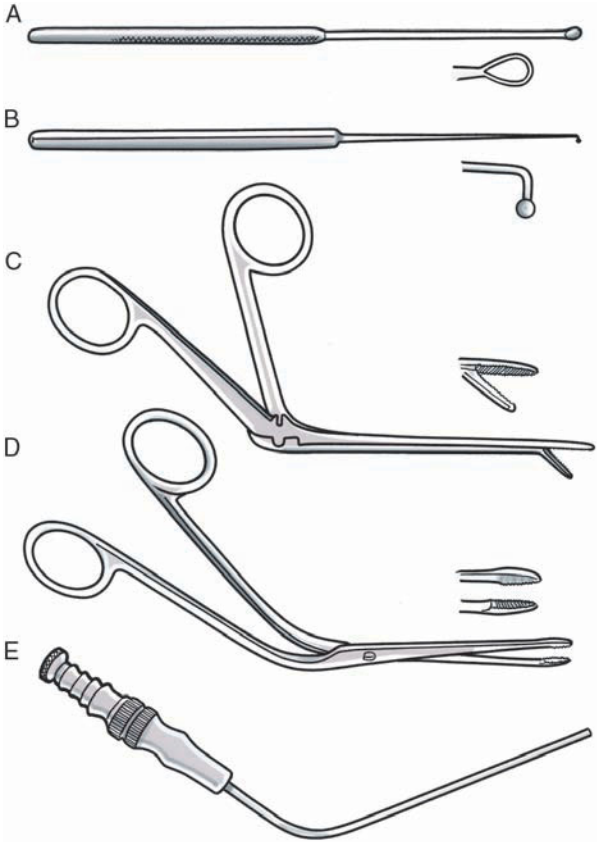

FIGURE 165-1. Instruments used for removal of foreign bodies from the external auditory canal. **A.** Cerumen loop. **B.** Right-angle ball hook. **C.** Alligator forceps. **D.** Hartman forceps. **E.** Frazier suction catheter.

Irrigation

- 10 or 20 mL syringe
- Butterfly catheter with any size needle (after needle and most of tubing is cut off)
- Kidney basin
- One Chux or other water barrier
- Tap water or saline at or slightly above body temperature[6,8,11,13,14]

Alternate Irrigation Equipment[8]

- Plastic portion of 18 gauge angiocatheter
- Dental jet-irrigation device (e.g., Water-Pik)
- DeVilbiss irrigator and a compressed air source
- Metal ear syringe

Instruments to Pass Behind Object and Pull It Out (Figures 165-1 to 165-4)

- Ear curettes or cerumen spoon, metal or disposable plastic
- Wire loop
- Blunt or ball right-angle hook

Instruments Used to Grasp Object Directly (Figures 165-1 & 165-3)

- Alligator forceps
- Hartman forceps
- Lighted forceps (Bionix Medical Technologies, Toledo, OH)

FIGURE 165-2. Examples of plastic disposable curettes. Note the variety of head shapes. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

FIGURE 165-3. Lighted, disposable, and single patient use devices to aid in cerumen removal. From left to right: articulating curette, open loop curette, and grasping forceps. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

FIGURE 165-4. The EasiEar metal curette (Splash Medical Devices LLC, Atlanta, GA).

Suction

- Frazier suction tips
- Intravenous tubing with flange created at tip using a heat source
- Vacuum or suction source
- Connection tubing
- Hemostat

Cyanoacrylate Glue[16]

- Ear speculum
- Cyanoacrylate wound/tissue glue or Superglue
- Paper clip or cotton-tipped applicator
- Superglue removal equipment

Cyanoacrylate Glue Removal[17]

- Acetone to debond glue from skin
- Cotton balls
- Cotton-tipped applicators
- Irrigation or instruments for final removal

Commercially Available Devices

- Hognose otoscope tip
- Katz extractor

Pediatric Immobilization

- Sheets
- Commercial immobilization device (e.g., Papoose board)

PATIENT PREPARATION

Explain the procedure and potential complications to the patient and/or their representative. The discussion should include discomfort, dizziness, minor bleeding, postprocedural otitis externa, and TM perforation. Discuss the importance of remaining still during the procedure. Warn the patient that they may experience an occasional loud noise, especially if suction is used. The most convenient position for adult patients is to remain seated with the affected ear facing the Emergency Physician. Children can sit on the lap of a parent or attendant with the affected ear facing the Emergency Physician. The parent or attendant should wrap one arm around the child's arms and body while stabilizing the head with their other arm.[3] Smaller children can be swaddled in a papoose made from a sheet and tape or a commercial immobilization device.[3] Place the patient supine with their face toward the ceiling. **Do not place the patient with the affected ear facing up, as this may cause the foreign body to move farther into the EAC.**

All removal techniques require the EAC to be straightened before inserting any device. In the adult, this is accomplished by pulling the pinna up and back while simultaneously pulling it straight out from the head.[8] In the small child, pull the pinna down, back, and slightly out from the head.[6,8]

The patient may require anesthesia of the EAC. Fill the EAC with 5 to 10 mL of 1% lidocaine using the syringe tip, an angiocatheter without the needle, or a butterfly catheter with the needle cut off. This will result in substantial but short-lived topical anesthesia for the procedure.[15] If the effect wears off before the procedure is complete, the topical application of lidocaine can be repeated as needed or longer-acting agents may be used. Although usually not necessary, local anesthetic solution may be injected to provide analgesia. Fill a 1 mL syringe with local anesthetic solution and apply a 2-inch long, 27 or 30 gauge needle. Position a plastic or metal ear speculum into the EAC. Insert the needle through the speculum. Inject 0.25 mL subcutaneously in the superior and inferior quadrants of the EAC distal to the isthmus. If needed, all four quadrants can be injected.[15] Refer to Chapter 168 for a complete discussion of EAC anesthesia. A final option is to use procedural sedation and analgesia (Chapter 129) to control the patient and remove the foreign body.[24]

TECHNIQUES

PRECAUTIONS FOR USING INSTRUMENTS IN THE EAC

There are two major precautions the Emergency Physician must take to avoid pushing the foreign body further into the EAC or causing damage to the EAC and TM. First, the procedures must be performed under direct vision. Second, the hand holding the instruments must remain firmly in contact with the patient's head at all times to stabilize the hand and avoid abrading or lacerating the EAC wall or damaging the TM should the patient abruptly move.[2,8] Even a very cooperative patient may move due to an involuntary reflex cough.[6]

IRRIGATION

Irrigation is the safest method of foreign body removal.[2,8,9,18] It is most successful for nonimpacted and smaller foreign bodies. Tuck a water barrier into the patient's gown or collar. Place a kidney basin under the ear and against the cheek to catch the irrigation solution and the foreign body. Instruct the patient or an assistant to hold the basin in place. Attach a butterfly needle to a 10 or 20 mL syringe. Cut the needle and most of the tubing, leaving only 1 to 2 cm of the tubing (**Figure 165-5**). This remaining tubing will usually be curved, which is optimal for precisely directing the irrigation stream. Others use a 14 or 16 gauge plastic angiocatheter.[19] It is important to remember that wider diameter instruments deliver fewer pounds per square inch of pressure with a reduced chance of injury.[19]

Draw up body temperature or slightly warmer tap water or saline into the syringe. **Be sure to use only body temperature or slightly warmer fluid to avoid complications from caloric stimulation.**[8,11] Straighten the EAC by manipulating the pinna. Insert the butterfly tubing or angiocatheter 1 cm into the EAC with the tip aimed upward and away from the foreign body (**Figure 165-5**).[13] Rapidly inject the irrigating solution. This will cause the fluid to shoot past the foreign body, bounce off the TM, and carry the foreign body out of the EAC along with the irrigating solution.[2,9]

Care must be taken to make sure that the irrigation stream and foreign body can easily exit the EAC, to prevent an increase in hydrostatic pressure, which could damage the TM.[12] Sometimes irrigation will not completely remove the foreign body but move it more laterally, where an instrument can be safely used to grasp and remove it. All water or saline should be removed from the EAC to prevent an otitis externa.[8,11]

Many physicians have used mechanical dental irrigation devices (e.g., Water-Pik) to irrigate the EAC and remove either cerumen or a foreign body. These devices shoot a stream of fluid from its tip. While they will often remove the cerumen or foreign body, the direct fluid stream can rupture a TM.[11,19,22]

The OtoClear Ear Irrigation Tip (Bionix Medical Technologies, Toledo, OH) is an improvement for EAC irrigation (**Figure 166-6**). This device is designed as disposable and single patient use. It attaches to the Luer hub of a syringe. The OtoClear tip can also be attached to a spray bottle or dental irrigating device, allowing these devices to be safely used. When inserted into the EAC, its flared base fits snugly and prevents it from being inserted too far. Holes in the base allow for the egress of irrigation fluid into the kidney basin

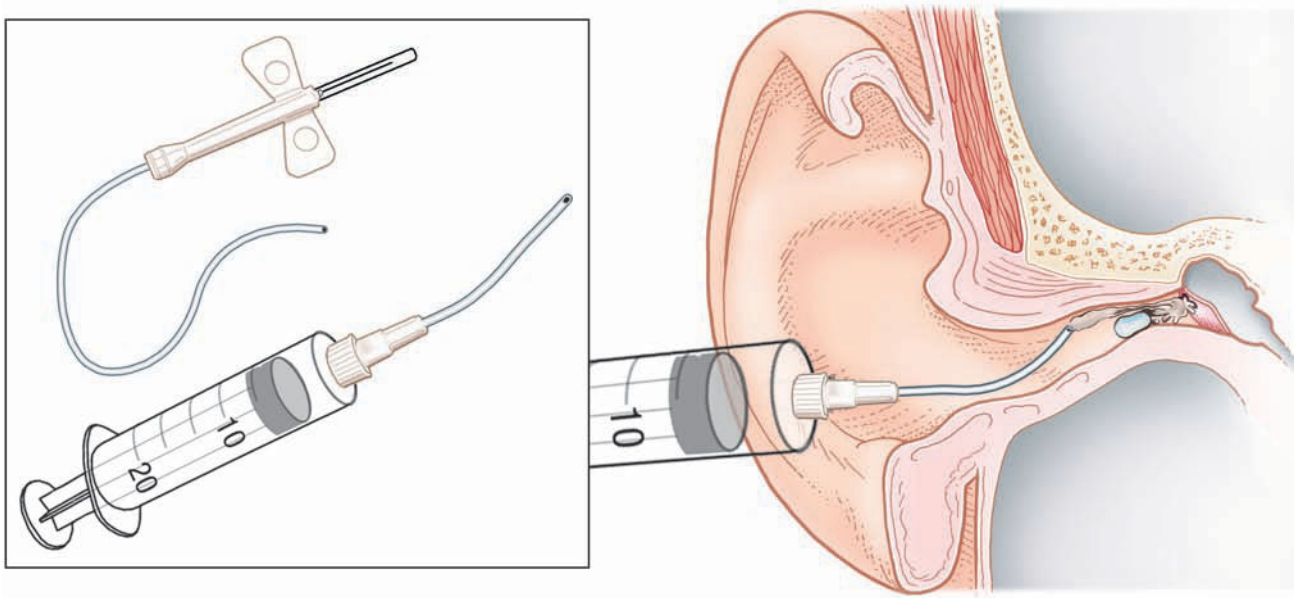

FIGURE 165-5. Irrigation with butterfly catheter tubing attached to a syringe. The stream of fluid is aimed toward the top of the external auditory canal and above the foreign body.

held against the skin. The OtoClear tip directs fluid toward the walls of the EAC (**Figure 166-6**). While this prevents damage to the TM, in some cases it may not provide enough flow or pressure to remove a foreign body.

SLIDING A FOREIGN BODY OUT WITH AN INSTRUMENT FROM BEHIND

This technique requires either a cerumen spoon or wire loop for small objects or a right-angle hook for larger ones (**Figures 165-1A, B, & 165-4**). Straighten the EAC by manipulating the pinna. Pass the tip of the instrument over and behind the foreign body with the spoon, loop, or hook in the same plane as the EAC wall. Rotate the instrument 90° to bring the loop or hook behind and directly in contact with the back (medial) side of the foreign body. Gently pull the instrument out of the EAC, pulling the foreign body out with it.[2,8] Take extra care so that the EAC and TM are not injured during the instrument insertion or removal.

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 165-4**). It is a stainless steel, single patient use, and disposable curette. The rounded wire head is smooth. It lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the EAC. This design may prevent EAC abrasions and lacerations, and procedure-related bleeding. The spring wire shaft provides some flexibility and enhanced maneuverability when compared to molded plastic curettes, making the foreign body removal process easier. The angled head and flexible shaft allow it to be manipulated within the EAC to remove a foreign body.

GRASPING FOREIGN BODIES WITH FORCEPS

If this maneuver is to be successful, there must be sufficient space between the EAC wall and the foreign body, or a projecting edge that can be grasped, so as to avoid pushing it further into the EAC.[2,4,9] This technique is contraindicated if the object is spherical and located against the TM, which can be injured during the procedure.[4] The most commonly used instruments include the alligator forceps (**Figure 165-1C**) and the Hartman forceps (**Figure 165-1D**). A lighted forceps (Bionix Medical Technologies, Toledo, OH) may also be used (**Figure 165-3**). Straighten the EAC by manipulating the pinna. Insert the forceps into the EAC and grasp the foreign body (**Figure 165-6**). Gently withdraw the instrument and the foreign body, taking care not to abrade the EAC wall. If the foreign body is located too far medially or instrumentation would cause pain or damage to the TM, irrigation may be able to move the foreign body laterally for subsequent grasping.

SUCTION REMOVAL

Frazier suction catheters (**Figure 165-1E**) are most useful with small foreign bodies. Otherwise, this technique will be unsuccessful or will push the object farther into the EAC. Attach the Frazier suction catheter to the suction tubing. Turn on the suction source. Straighten the EAC by manipulating the pinna. Gently insert the catheter into the EAC. Place a thumb over the hole in the catheter handle to direct the suction through the tip of the catheter. Gently advance the suction catheter until the tip is in contact with the foreign body. Withdraw the Frazier suction catheter and foreign body from the EAC.

For impacted smooth, spherical objects, suction with plastic intravenous tubing can be used.[1,20] Cut a short length of plastic intravenous tubing and attach one end to the suction source. Fashion the other end into a small flange shape using a heat source and any metal object with a rounded end, such as the tip of a hemostat or larger clamp. Heat the jaws of the hemostat and insert them into the plastic tubing just enough to create a flange. Turn on the suction source. Place a hemostat onto the tubing to temporarily clamp the suction tubing. Straighten the EAC by manipulating the pinna. Gently advance the flange tip into the EAC until it contacts the foreign body, taking care not to push it inward (**Figure 165-7**). Remove the hemostat from the tubing to activate the suction. Gently but quickly remove the tubing and attached foreign body from the EAC.

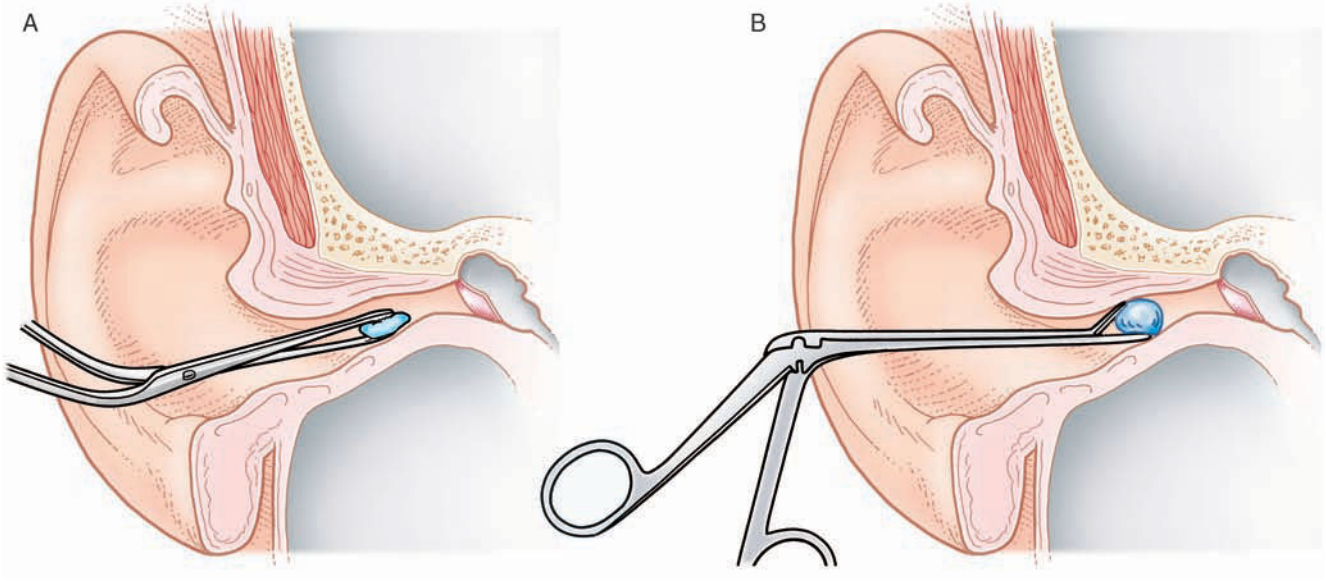

FIGURE 165-6. Forceps removal of a foreign body. **A.** Hartman forceps. **B.** Alligator forceps.

CYANOACRYLATE GLUE–ASSISTED REMOVAL

Cyanoacrylate glue can be used to extract impacted spherical objects that allow no space for irrigation or instrument removal and are located laterally or distally in the EAC.[1,16] However, this technique can be fraught with complication.[17] **Always use an ear speculum to decrease the chance of gluing the foreign body to the EAC or TM and to prevent creating a glue foreign body.** Insert an ear speculum into the EAC with the tip near the foreign body. **Do not touch the foreign body with the speculum so as to prevent it from being impacted.** The ear speculum will prevent the Emergency Physician from touching the EAC with glue.

Obtain a long, thin object (e.g., straightened paper clip or the stick end of a cotton-tipped applicator). Moisten the tip of the paper clip or applicator stick with a very tiny amount of cyanoacrylate glue. A larger amount can drop off into the EAC. Insert the ear speculum. Straighten the EAC by manipulating the pinna.

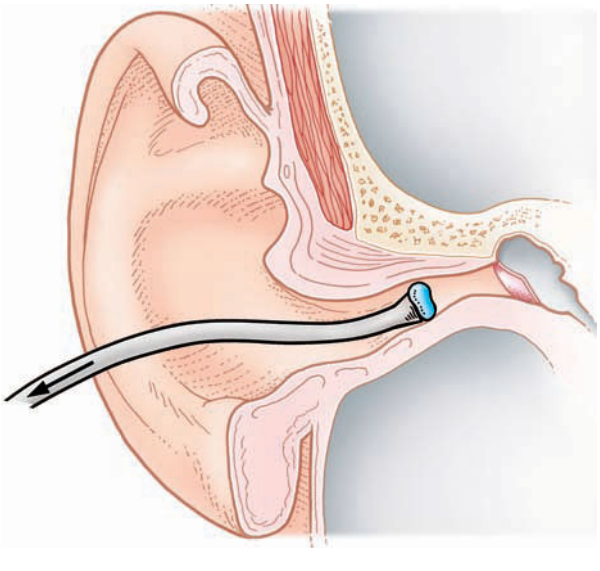

FIGURE 165-7. Suction removal of a foreign body.

Quickly insert the paper clip or applicator stick through the ear speculum, before the glue dries, until it just touches the foreign body. Maintain this position for 30 to 60 seconds to allow bonding of the glue to the foreign body. Remove the paper clip or applicator stick with the foreign body attached and the speculum all together.

REMOVAL OF CYANOACRYLATE GLUE

For either iatrogenic or patient-introduced cyanoacrylate glue, debonding from the patient's tissues by acetone must precede the removal.[1,17] Failure to do this will result in tearing of the skin or TM. **Do not apply acetone if the TM cannot be visualized or is not intact.**[11] Infuse acetone into the EAC using cotton balls or swabs. Allow it to remain in the EAC for 5 minutes. Since acetone evaporates rapidly, several applications may be necessary. Once the glue mass is free, it can be removed by irrigation, instruments, or suction.

HOGNOSE OTOSCOPE TIP

The Hognose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, and single-use device that attaches to a standard otoscope (**Figure 165-8**). It comes in three sizes (3, 4, and 5 mm), each with a color-coded tip. The size represents the cup size at the tip of the device. The tip is soft, self-molding, and looks like the nose of a hog. It has an insufflation port and suction tubing attached to its side. The adapter on the suction tubing attaches to standard wall suction tubing.

Attach the Hognose to the otoscope similar to attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Attach the hognose tubing to suction tubing and a suction source. Turn the suction source on to low or medium. Grasp the otoscope with your dominant hand. Straighten the EAC by manipulating the pinna. Insert the Hognose into the EAC while visualizing the foreign body through the otoscope head. When the tip of the Hognose is just next to the foreign body, place an index finger over the insufflation port to engage the suction at the device tip. Gently advance the otoscope until the tip of the Hognose is against and attached to the foreign body. If you suddenly see black through the otoscope, the soft tip has collapsed on itself. Remove the finger over

FIGURE 165-8. The Hognose otoscope tip attached to an otoscope. (Photo courtesy of IQDr. Incorporated, Manitou Springs, Co.)

the insufflation port and re-approach the object. While maintaining suction, withdraw the Hognose with the foreign body attached.

GATORNOSE OTOSCOPE TIP

The Gatornose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, and single-use device that attaches to a standard otoscope (**Figure 165-9**). It twists onto an otoscope like a speculum. It comes with three different jaw types that attach to the body of the device. These jaws are small flat jaws, large flat jaws, and open loop jaws. A trigger on the body of the device controls jaw opening and closing.

FIGURE 165-9. The Gatornose otoscope tip attached to an otoscope. Note the three types of jaws that are available to snap onto the base of the device. (Photo courtesy of IQDr. Incorporated, Manitou Springs, Co.)

FIGURE 165-10. The Katz Extractor. The balloon at the tip inflates and deflates by pushing and releasing the plunger, respectively. (Photo courtesy of InHealth Technologies, Carpinteria, CA.)

Attach the Gatornose to the otoscope similar to attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Grasp the otoscope with your dominant hand. Insert the ring finger into the trigger. Pull the trigger to close the Gatornose jaws. Straighten the EAC by manipulating the pinna. Gently insert the Gatornose jaws just into the EAC. Push the trigger to open the Gatornose jaws and be able to view through the otoscope. Gently advance the otoscope while visualizing the foreign body through the otoscope head. Position the jaws above and below or anterior and posterior to the foreign body. Pull the trigger to close the jaws onto the foreign body. Withdraw the otoscope with the foreign body in the jaws of the Gatornose.

KATZ EXTRACTOR

The Katz Extractor Oto-Rhino Foreign Body Remover (InHealth Technologies, Carpinteria, CA) is a device designed to extract foreign bodies from the nasal and auditory passages (**Figure 165-10**). It is a disposable single-use device consisting of a balloon-tipped catheter attached to a syringe. Always test the device before using it. Push the plunger to inflate the balloon and inspect it for any air leaks. Release the plunger to deflate the balloon.

Grasp the device with the dominant hand (**Figure 165-11**). Gently insert the catheter along the wall of the EAC until the balloon is just past the foreign body (**Figure 165-11A**). Inflate the balloon by depressing the plunger on the syringe (**Figure 165-11B**). Withdraw the catheter and foreign body from the EAC while maintaining the balloon in the inflated state (**Figure 165-11C**). If the foreign body has a central hole (e.g., candy or bead), insert the catheter through the hole rather than behind it.

LIVE INSECT REMOVAL

A live insect in the EAC is one of the most painful and upsetting foreign bodies. The patient suffers as the insect moves, vibrates, tries to flap its wings, or pushes against the sensitive TM in an effort to escape.[3] In the past, mineral oil was infused to smother and kill the insect prior to removal.[4,15,21] However, this method has several disadvantages. A significant time passes while the patient is still suffering and the insect dies. Due to being stuck in the viscous oil, the insect is more difficult to remove and frequently breaks into multiple pieces. The EAC is also now impossible to anesthetize with a local infusion of lidocaine, which is repelled by the oil.

A preferred technique is to immobilize the insect with an infusion of 1% lidocaine into the EAC.[21] A topical anesthetic composed of benzocaine and antipyrine (e.g., Auralgan) may also be used. The

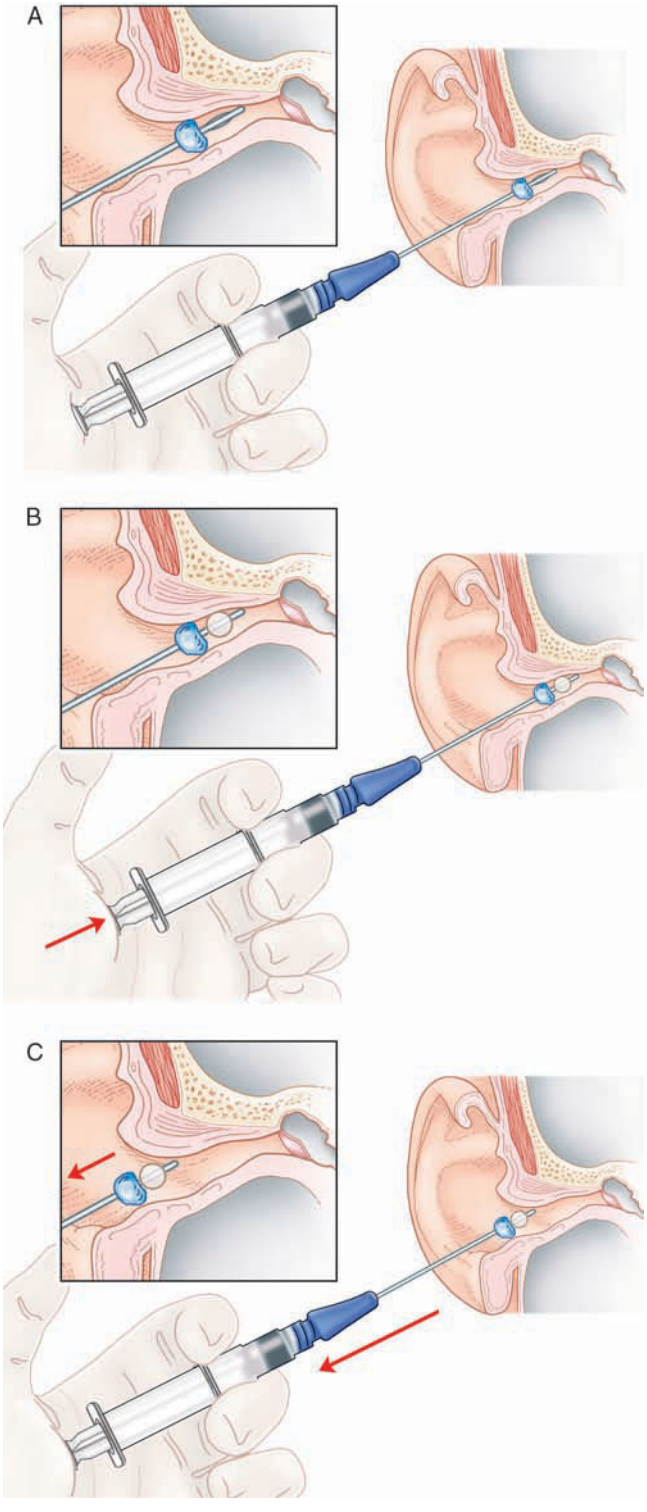

FIGURE 165-11. The Katz Extractor removing an EAC foreign body. **A.** The device is inserted until the balloon is just past the foreign body. **B.** The balloon is inflated. **C.** The Katz extractor is removed with the balloon inflated and the foreign body is removed.

local anesthetic results in the insect becoming inert much more quickly than with oil. The EAC and TM are thus anesthetized for patient comfort and the immobilized insect is more likely to be removed in a single piece than with mineral oil.

The insect can now be easily removed by irrigation or instrument removal. Sometimes both techniques are used. Irrigation can be used to move the dead insect more distally in the EAC, followed by instrument removal. It is recommended that the EAC be inspected and irrigated after the insect is removed to make sure that no tiny parts of the insect remain in the EAC, as they can cause an otitis externa.[3]

ASSESSMENT

After the foreign body has been removed, it is crucial to reexamine the patient to confirm that the EAC, TM, and hearing are all normal and have not been damaged.[3,4,18] In children, but also adults with mental or psychiatric problems, it is prudent to examine the other ear, the nostrils, and any other orifice that may be harboring an unsuspected foreign body.[3–5] Any remaining irrigation fluid in the EAC should be removed to prevent an otitis externa.[8]

AFTERCARE

Most authors recommend prescribing several days of topical otic drops to prevent or treat subclinical otitis externa, which is often precipitated by abrasion of the EAC or inflammation due to foreign body impaction.[3] Often recommended are topical combinations of antibiotics and steroids in solution or suspensions. Commonly prescribed agents include otic quinolones, Corticosporin Otic, Otic Domeboro, Otobiotic, Pediotic suspension, and VoSol to name a few. Consult an Otolaryngologist for patients with injuries, hearing deficits, severe otitis externa, or in whom removal was unsuccessful. Otherwise, the patient can receive follow-up with their Primary Care Physician in 48 to 72 hours. Instruct the patient in the proper application of ear drops. They should return to the Emergency Department if they develop ear pain, ear discharge, fever, decreased hearing, vertigo, headache, or a stiff neck.

COMPLICATIONS

Numerous complications can result from the removal of a foreign body from the EAC.[3–5,8,11,12,14,15,18] The complication rate for irrigation is reported as 1 per 1000 cases.[14,18] It is higher for all other techniques.[8,11] Irrigation can push a foreign body further into the EAC. If the irrigating solution is cold, caloric stimulation can result in vomiting, vertigo, bradycardia, and syncope.[1,11] Middle ear debris can be forced through a preexisting or iatrogenic TM defect, resulting in an otitis media, damage to the ossicles, labyrinthitis, mastoiditis, loss of hearing and balance, or a central nervous system infection.[9,11–14] Otitis externa can result from abrasions to the EAC or water left behind after irrigating. Butterfly tubing is less likely than an angiocatheter to damage the EAC or TM because of its more pliable nature, larger diameter, and curved tip.

It is known that mechanical dental irrigation devices, even at low pressures, can rupture the TM.[11,19,22] For this reason, they are not recommended for the removal of foreign bodies from the EAC.

Instrumentation and suction should be used with caution to prevent secondary injury. This includes EAC lacerations or abrasions, TM rupture, pushing of foreign bodies further into the EAC, and disruption or removal of the ossicles. Abrasions or lacerations to the EAC can result in an otitis externa.

Cyanoacrylate glue can cause complications and is the least favorite technique of this author. The Emergency Physician may glue their fingers together or to the instruments. The foreign body may be glued to the pinna, EAC, or the TM. Removal of the glue can abrade and irritate the skin and/or TM.

SUMMARY

Foreign bodies in the EAC are common. With adequate anesthesia, careful planning, and gentle handling, most foreign bodies can be successfully removed in the Emergency Department from the EAC.[23] The removal techniques require equipment that is readily available in the Emergency Department. The removal techniques are easy to perform, quick, and simple to learn. An impacted button battery is a true emergency and requires immediate removal. An emergent consultation with an Otolaryngologist is required if the button battery cannot be removed or if any evidence of injury is present after the button battery has been removed.

166 Cerumen Impaction Removal

Rebecca R. Roberts

INTRODUCTION

Removal of impacted cerumen is one of the most common otolaryngologic procedures performed by nonotolaryngologists.[1] This procedure is also believed to be the most common cause of iatrogenic otolaryngologic complications referred to specialists.[2] Approximately 8 million ears are irrigated annually in the United States to remove cerumen.[3,4]

ANATOMY AND PATHOPHYSIOLOGY

The S-shaped external auditory canal (EAC) is 2.5 cm long in adults.[5] The lateral or distal third is cartilaginous, with thicker skin, more hair follicles, glands, and subcutaneous tissue than the medial or proximal two-thirds, which is bony and has a thinner, more fragile layer of skin.[5,6] The narrowed isthmus is located between the cartilaginous and bony portions.[5] The canal ends medially at the tympanic membrane (TM), which is situated obliquely to increase the surface area for carrying sound energy to the middle ear.[6] The anteroinferior EAC is 0.6 mm longer than the posterosuperior portion.[5] Auriculotemporal branches of cranial nerves V, VII, IX, and X and the greater auricular nerve of the cervical plexus supply sensation to the EAC.[5]

Cerumen is a mixture comprising secretions of the ceruminous glands of the lateral two-thirds of the EAC, the pilosebaceous glands located at the roots of EAC hairs, and sloughed squamous epithelial cells.[5,7] Cerumen forms a barrier against infection, has antimicrobial activity, and protects the skin of the EAC as it is water repellant. It is expelled naturally by migration assisted by chewing movements.[7,8]

There are many reasons for cerumen to become impacted.[4,6,7] The most common is self-cleaning with cotton-tipped applicator swabs that can push cerumen further into the EAC. The abundant hairs in the EAC, more common in males than females, can obstruct cerumen migration. A small (especially in children), tortuous, or scarred EAC will obstruct cerumen migration. Some people produce large quantities of cerumen. Diseases such as Parkinson's can alter the consistency of the cerumen and inhibit its migration. Hearing aids, stethoscope earpieces, or any other object in the EAC may compact the cerumen. Deficits in the substances that cause sloughed squamous epithelial cells to separate will inhibit the movement of cerumen. Nonimpacted cerumen exposed to water can swell and obstruct the EAC.

INDICATIONS

Recently, the term "impaction" has been defined more clearly as cerumen that causes patient symptoms or prevents a necessary examination of the EAC or TM.[4] The primary indication for removal of cerumen is symptomology of impaction.[2,4] The most common complaint is hearing loss, which is often abrupt and expressed as a "blocked ear." Hearing remains normal or nearly so as long as there is a small space in the EAC through which sound can pass and cause vibration of the TM. The hearing loss becomes subjectively significant when the canal is completely obstructed or when the TM is compressed by cerumen and cannot freely move.[4,6,8] Other typical symptoms of cerumen impaction include fullness, itching, odor, pain, tinnitus, vertigo, unsteady gait, or reflex cough due to vagus nerve stimulation.[4,6,7] Other indications for removing cerumen include the need to examine the ear canal and TM or to test hearing.[4,8,9] Cerumen can cause feedback sound loops in those with hearing aids or damage the appliance.[4]

CONTRAINDICATIONS

There are several general contraindications to cerumen removal. An uncooperative patient or young patient that cannot follow instructions or be safely restrained can suffer an iatrogenic injury. Previous ear surgery with scarring of the EAC or TM risks iatrogenic injury. A known or suspected cholesteatoma is a contraindication to cerumen removal. Do not attempt removal if the anatomy of the EAC or TM cannot be clearly defined or is distorted.

The remaining contraindications to cerumen removal are specific to each removal technique. Nearly all cerumen can be safely removed by using one of the techniques listed. Often, two or more techniques can be used together with increased success.[6,9]

The most important contraindication for EAC irrigation is an acute or chronically ruptured TM.[4,7–12] Fluid forced into the middle ear can lead to otitis media, labyrinthitis, mastoiditis, disruption of the ossicles, and loss of balance or hearing.[4,10,12] Some authors recommend alternate methods for any patient who has never had an ear exam to document the integrity of the TM.[9,10] Most patients can provide the information of having a history of a ruptured TM. A relative contraindication is moderate to severe otitis externa.[4,7,8]

The major contraindication to instrument removal is a patient, usually pediatric, who is so uncooperative that injury to the EAC or TM is likely to occur with movement.[6,12,13] The second contraindication is cerumen pushed directly against the TM. In these circumstances, the TM can be abraded or perforated during cerumen removal with instruments.

The major contraindication to suction removal is a single, hard, irregular, and impacted cerumen plug. Suction will be unsuccessful. Suction works best if there are multiple tiny cerumen fragments or very soft cerumen.[9]

Cerumen softening or cerumenolytic agents should not be used if the patient has a ruptured TM. Other contraindications to softening agents are an allergy to the agent or an otitis externa.[4,7,14,15]

EQUIPMENT

Anesthesia

- Local anesthetic solution or suspension (e.g., viscous lidocaine, lidocaine solution, or Auralgan)
- 3 mL syringe

Irrigation

- 10 to 20 mL syringe
- Butterfly catheter with any size needle

- Kidney basins
- Chux or other water barrier
- Tap water or saline at or slightly above body temperature[5,6]

Alternate Irrigation Equipment[4]

- Plastic portion of 18 gauge angiocatheter
- Oral jet irrigation (Water-Pik); no longer recommended (see "Complications," below)
- DeVilbiss irrigator and a compressed air source
- Metal ear syringe

Instruments to Separate and Loosen Cerumen (Figures 166-1 to 166-4)

- Ear curettes or cerumen spoon, metal or disposable plastic
- Wire loop
- Blunt or ball right-angle hook

Instruments to Grasp Cerumen Directly (Figures 166-1 & 166-3)

- Alligator forceps
- Hartman forceps
- Lighted forceps (Bionix Medical Technologies, Toledo, OH)

Suction

- Frazier suction catheters
- Suction source
- Connection tubing
- Hemostat

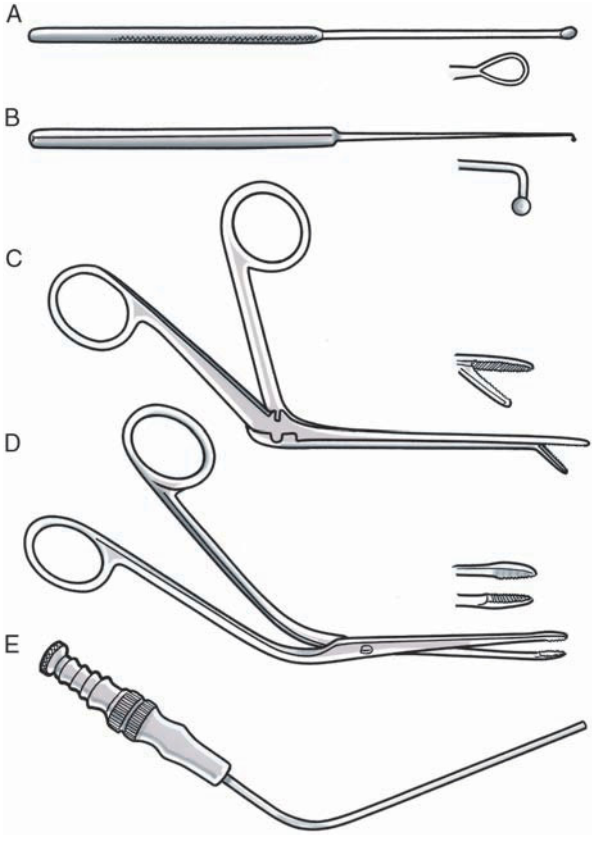

FIGURE 166-1. Instruments used for removal of cerumen from the external auditory canal. **A.** Cerumen loop. **B.** Right-angle ball hook. **C.** Alligator forceps. **D.** Hartman forceps. **E.** Frazier suction catheter.

FIGURE 166-2. Examples of plastic disposable curettes. Note the variety of head shapes. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

FIGURE 166-3. Lighted, disposable, and single patient use devices to aid in cerumen removal. From left to right: articulating curette, open loop curette, and grasping forceps. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

FIGURE 166-4. The EasiEar metal curette (Splash Medical Devices LLC, Atlanta, GA).

Cerumen Softening Agents

- Warm tap water
- Hydrogen peroxide
- Olive, mineral, vegetable, or almond oil
- 5%, 10%, or 15% sodium bicarbonate solution
- Commercial agents (e.g., Cerumenex, Cerumol, Auralgan, and Waxsol)
- Colace
- Glycerine
- Alcohol
- Propylene glycol

Pediatric Immobilization

- Sheets
- Commercial immobilization device (e.g., Papoose board)

PATIENT PREPARATION

Explain the procedure and potential complications to the patient and/or their representative. The discussion should include discomfort, dizziness, minor bleeding, postprocedural otitis externa, and TM perforation. Discuss the importance of remaining still during the procedure. Warn the patient that they may experience an occasional loud noise, especially if suction is used. The most convenient position for adult patients is to remain seated with the ear facing the Emergency Physician. Children can sit on the lap of a parent or attendant with the affected ear facing the Emergency Physician. The parent or attendant should wrap one arm around the child's arms and body while the stabilizing the head with their other arm.[16] Smaller children can be swaddled in a papoose made from sheets and tape or a commercial immobilization device.[16]

Turn the affected ear toward the ceiling and fill the EAC with 5 to 10 mL of local anesthetic solution or suspension using the syringe tip, an angiocatheter, or a butterfly catheter with the needle cut off. This will result in substantial but short-lived topical anesthesia for the procedure.[17] If the effect wears off before the procedure is complete, the topical application of local anesthetic can be repeated as needed or longer-acting agents may be used. All cerumen removal techniques require the EAC to be straightened. In the adult, this is accomplished by pulling the pinna slightly up and back while simultaneously pulling it straight out from the head.[6] In the small child, pull the pinna down, back, and slightly out from the head.[6,18]

TECHNIQUES

PRECAUTIONS FOR USING INSTRUMENTS IN THE EAC

There are two major precautions the Emergency Physician must take to avoid pushing cerumen further into the EAC or causing damage to the EAC and TM. **First, the procedures must be performed under direct vision.[6] Second, the hand holding the instrument must remain firmly in contact with the patient's head at all times to stabilize the hand and avoid scrapping the canal wall or puncturing the TM should the patient move.[6,15]** Even a very cooperative patient may move due to an involuntary reflex cough.[18]

IRRIGATION

Irrigation is the safest and easiest method of removing cerumen, and is usually successful.[2,4,6,10,15] It is less likely to lacerate or damage the EAC or TM than other techniques. It is also the technique most commonly used by nonotolaryngologists.

Place a kidney basin under the affected ear and against the patient's cheek to catch the exiting irrigation solution and cerumen. Instruct the patient or an assistant to hold the basin in place. This author's favorite device for irrigating is to cut the needle and most of the tubing off a butterfly needle, leaving only 1 to 2 cm of tubing (**Figure 166-5**).[13] This remaining tubing will usually be curved, which is optimal for precisely directing the irrigation stream. Others use a 14 or 16 gauge plastic angiocatheter.[12] It is important to remember that wider diameter instruments deliver fewer pounds per square inch of pressure with reduced chance of injury.[12] Attach the irrigation tubing or angiocatheter onto a 10 or 20 mL syringe. Draw up body temperature normal saline or tap water into the

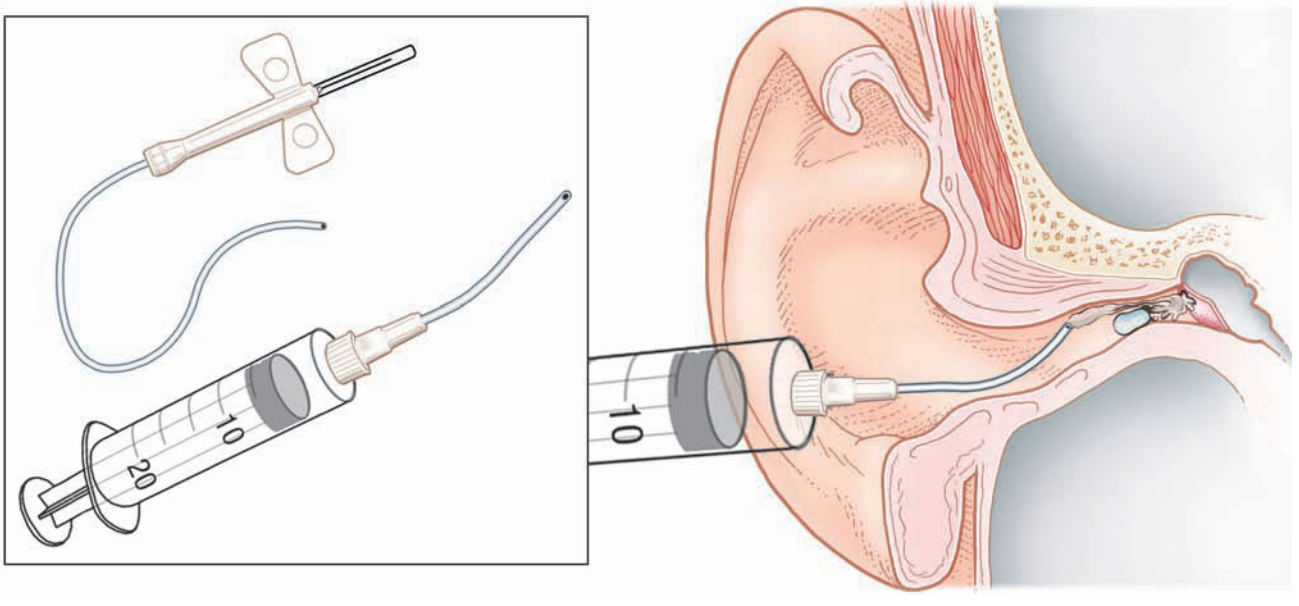

FIGURE 166-5. Irrigation with butterfly catheter tubing attached to a syringe. The stream of fluid is aimed toward the top of the external auditory canal and above the cerumen.

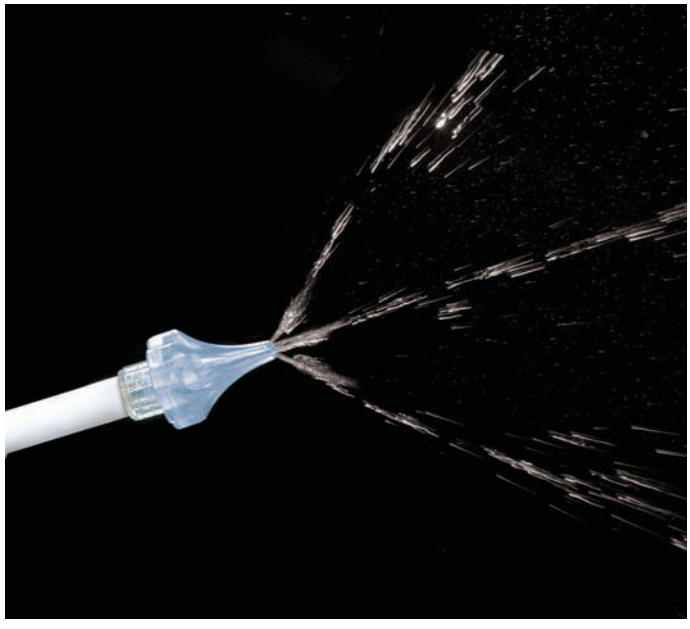

FIGURE 166-6. The OtoClear Ear Irrigation Tip. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

syringe. Insert the butterfly tubing or angiocatheter 1 cm into the EAC with the tip aimed in a direction opposite to the location of the cerumen[8] (**Figure 166-5**). This will cause the water to shoot past the cerumen, bounce off the TM, and force the cerumen out of the EAC along with the irrigating solution.[10] If there is no obvious break in the cerumen, direct the stream superiorly or slightly anterior and superiorly.[4,10]

Care must be taken to make sure that the irrigation stream can easily exit the EAC, to prevent an increase in hydrostatic pressure, which could damage the TM.[9] **Use only body temperature, or slightly warmer, fluid to avoid caloric stimulation symptoms.**[4] Irrigation will often have to be repeated numerous times, but persistence is usually rewarded with success.[6] Irrigation will sometimes have to be combined with either cerumen softening agents, manual separation of cerumen from the EAC wall, or direct grasping of a partially dislodged cerumen plug.[4,6]

Many physicians have used mechanical dental irrigation devices (e.g., Water-Pik) to irrigate the EAC and remove cerumen. These devices shoot a stream of fluid from its tip. While they will often remove the cerumen, the direct fluid stream can rupture a TM.[3,4,12,20]

The OtoClear Ear Irrigation Tip (Bionix Medical Technologies, Toledo, OH) is an improvement for EAC irrigation (**Figure 166-6**). This device is designed as disposable and single patient use. It attaches to the Luer hub of a syringe. The OtoClear tip can also be attached to a spray bottle or dental irrigating device, allowing these devices to be safely used. When inserted into the EAC, its flared base fits snugly and prevents it from being inserted too far. Holes in the base allow for the egress of irrigation fluid and cerumen into the kidney basin held against the skin. The OtoClear tip directs fluid toward the walls of the EAC (**Figure 166-6**). This prevents damage to the TM.

INSTRUMENT REMOVAL: SEPARATION OF CERUMEN FROM THE EAC WALL

This technique is a useful adjunct to irrigation and/or instrument removal.[15] Sometimes the cerumen is firmly pressed against the EAC wall in all visible directions. Irrigation will not work or may even worsen the situation by pushing the cerumen further into the EAC. Use either cerumen curettes (**Figures 166-2 to 4**), loops (**Figure 166-1A**), right-angle hooks (**Figure 166-1B**), or wires to gently separate the cerumen from the EAC wall and compress it into the center of the lumen.[9]

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 166-4**). It is a stainless steel, single patient use, and disposable curette. The rounded wire head is smooth. It lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the EAC. This design may prevent painful cerumen removal, EAC abrasions and lacerations, and procedure-related bleeding. The spring wire shaft provides some flexibility and enhanced maneuverability when compared to molded plastic curettes, making the cerumen removal process easier.

The best place to start is superiorly. **The cerumen should not be pulled out with the same movement, as this can abrade the EAC.**[15] Once there is a visible passage to the TM, irrigation as described above is highly successful and safe. Alternatively, separation of the cerumen from the EAC wall can be performed circumferentially, all the way around the cerumen plug. This results in a cerumen plug freely suspended in the EAC, which can easily be removed by irrigation, pulled out with a right-angle hook, or grasped with forceps.[15]

INSTRUMENT REMOVAL: SLIDING CERUMEN OUT WITH INSTRUMENTS FROM BEHIND

This technique requires either a cerumen spoon (**Figure 166-1A**), a wire loop for small cerumen particles, a right-angle hook (**Figure 166-1B**) for larger quantities, or an EasiEar curette (**Figure 166-4**). Separate the cerumen from the EAC wall as described above. Position the instrument with the loop or hook in the same plane as the EAC wall. Insert the tip of the instrument into the EAC above and just beyond the cerumen to be removed. Rotate the instrument 90° to bring the loop or hook behind and directly in contact with the back (medial) side of the cerumen. Gently pull the instrument out of the EAC, pulling the cerumen out with it.[6] **Take care not to abrade the EAC wall with the instrument.**

INSTRUMENT REMOVAL: GRASPING CERUMEN WITH FORCEPS FOR REMOVAL

To be successful, there must be sufficient space for the jaws of the forceps on both sides between the EAC wall and the cerumen, or a lateral leading edge that can be grasped. Separate the cerumen from the EAC wall as described above. Insert the forceps into the EAC. Grasp the cerumen with the jaws of the Hartman (**Figure 166-7A**) or alligator forceps (**Figure 166-7B**). Gently withdraw the forceps, taking care not to abrade the EAC wall. If the cerumen is located too far medially or instrumentation would cause pain or damage to the TM, irrigation can move the cerumen plug laterally for subsequent grasping with a forceps.

For an optimal outcome, one may need to alternate irrigation and instrument removal to remove all of the cerumen plug safely and completely.[4,6] For example, irrigation may gently soften or loosen the plug. A cerumen loop or curette can then be used to separate it from the EAC wall. Irrigation can be used again to move it more laterally. Finally, a forceps or hook can be used to remove the cerumen plug from the EAC.

SUCTION REMOVAL

This technique requires soft cerumen or multiple small flakes.[9] Use the same preparations and precautions described above. Attach the

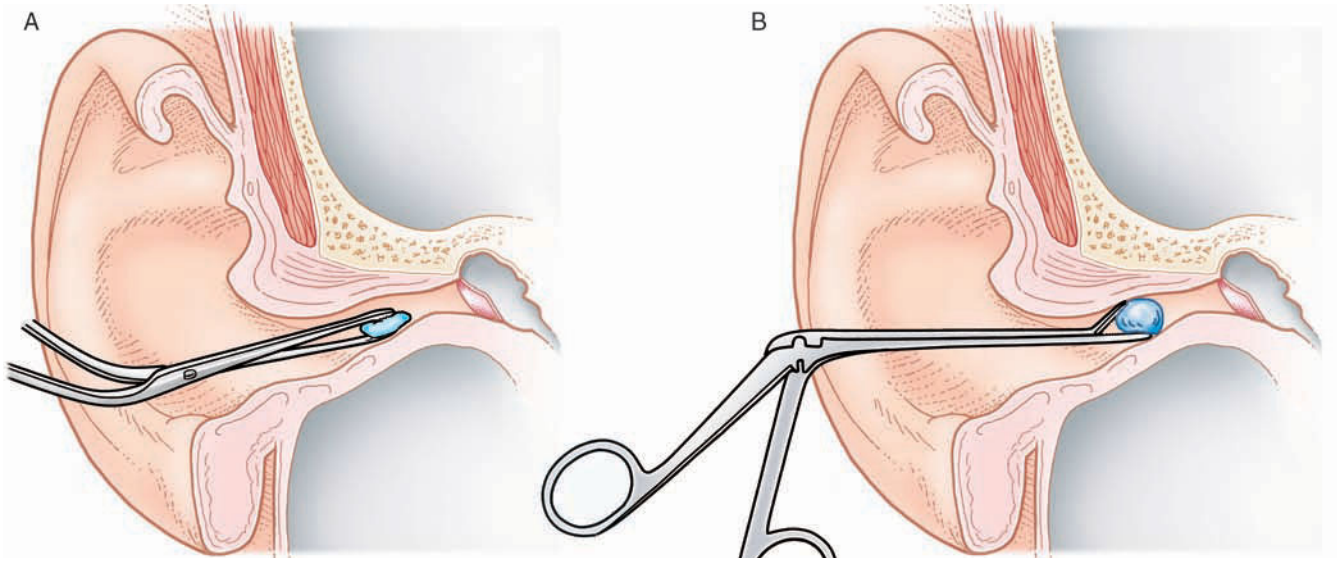

FIGURE 166-7. Forceps removal of cerumen. **A.** Hartman forceps. **B.** Alligator forceps.

Frazier suction catheter or suction tubing to the suction source. Turn on the suction source. Insert the suction catheter into the EAC. Gently advance the suction catheter until the tip is in contact with the cerumen (**Figure 166-8**). If using a Frazier suction catheter, place the thumb over the hole on the catheter shaft to direct the suction through the tip of the Frazier catheter. Gently advance the Frazier catheter until its tip is in contact with the cerumen. Withdraw the suction catheter or Frazier catheter and cerumen from the EAC. Usually the tip must be withdrawn and cleaned continuously, because most cerumen will plug the suction tip. For additional safety, insert the suction catheter through a plastic otoscope speculum and withdraw both together.

CERUMEN SOFTENING AGENTS

If the cerumen is so impacted and hard that the above techniques are likely to cause pain and/or injury or if the cerumen cannot be removed, apply a "cerumenolytic" or cerumen softening agent. After the cerumen has softened, it can be removed using the techniques described above. Many studies have compared different agents and most are surprisingly comparable in their effectiveness.[1,4,7,14] In fact, even water or saline is effective for cerumen softening and disintegration.[1,4,7,14] This may explain why persistent irrigation is so frequently successful. The more commonly available agents in the Emergency Department are listed in the "Equipment" section.

Fill the EAC with one of the cerumen softening agents. Insert a cotton ball into the opening of the EAC to prevent the agent from leaking out. Apply the agent to the contralateral EAC if indicated. An alternative is to place the patient lying on their side with the affected ear facing upward. Insert the agent into the EAC. The agent will not leak out if the patient remains in this position. The disadvantage of placing the patient on their side is that only one ear can be worked on at a time.

Most authors recommend waiting 15 to 30 minutes after the application of the cerumen softening agent before attempting to remove the cerumen.[8] Some recommend using the agents at home for up to a week before further removal attempts.[8,9] Prolonged exposure to these agents can precipitate an otitis externa, allergic reactions, or a contact dermatitis in the EAC. These agents must be removed and the canal thoroughly dried after their use.[4,6]

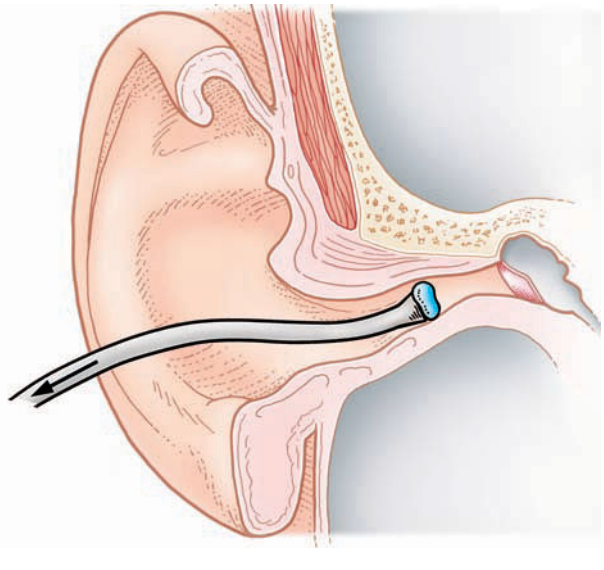

FIGURE 166-8. Suction removal of cerumen.

ASSESSMENT

After cerumen has been removed, it is critical to reexamine the ear to confirm that the EAC, TM, and hearing are all normal.[2,4] Remove all remaining water and softening agents to prevent an otitis externa.[4,6]

AFTERCARE

Many authors recommend prescribing several days of topical otic drops to prevent or treat subclinical otitis externa, which is frequently present in these patients. Often recommended are topical combinations of antibiotics and steroids in solution or suspensions. Commonly prescribed agents include otic quinolones, Corticosporin Otic, Otic Domeboro, Otobiotic, Pediotic suspension, and VoSol to name a few. Consult an Otolaryngologist for patients with injuries, hearing deficits, severe otitis externa, or in whom cerumen removal was unsuccessful. Otherwise, the patient

can receive follow-up with their Primary Care Physician in 48 to 72 hours. Instruct the patient in the proper application of ear drops. They should return to the Emergency Department if they develop ear pain, ear discharge, fever, decreased hearing, vertigo, headache, or a stiff neck. They should also be cautioned against future use of cotton swabs or other instruments in the EAC.

COMPLICATIONS

Numerous complications can result from the removal of cerumen from the EAC.[2,3,4,7,9,12,13,19,20] The complication rate for irrigation is 1 per 1000 cases.[2,4,7] It is higher for all other techniques. Irrigation can push cerumen further into the EAC. Irrigation fluid must be body temperature or slightly warmer. Cold fluid can cause caloric stimulation resulting in vertigo, vomiting, bradycardia, or syncope. Middle ear debris can be forced through a preexisting or iatrogenic TM defect, resulting in an otitis media, ossicle damage, labyrinthitis, mastoiditis, loss of hearing and balance, or a central nervous system infection. Otitis externa can result from abrasions to the EAC or retained fluids. Butterfly tubing is less likely than an angiocatheter to damage the EAC or TM because of its more pliable nature, larger diameter, and curved tip.

It is known that mechanical dental irrigation devices, even at low pressures, can rupture the TM. For this reason, they are not recommended for cerumen removal.[3,4,12,20]

Instrumentation and suction should be used with caution to prevent secondary injury. This includes lacerations or abrasions of the EAC, rupture of the TM, pushing foreign bodies further into the EAC, and disruption or removal of the ossicles. Abrasions or lacerations to the EAC can result in an otitis externa.

Cerumen softening agents can cause a contact dermatitis in the EAC, which may lead to an otitis externa. If the TM is not intact, these agents may cause permanent middle ear damage. Do not use these agents if the TM is ruptured acutely or the history suggests a potential defect.

SUMMARY

Successful cerumen removal will often require using multiple techniques in sequence, adapted to the individual patient's situation. With adequate anesthesia, careful planning of the procedural sequence, and gentle handling, those who have been relieved of cerumen impaction will be among your most grateful patients.

167 Tympanocentesis

Paul J. Jones

INTRODUCTION

Tympanocentesis, first described in 1768, is a diagnostic and therapeutic procedure in which a needle is inserted through the tympanic membrane to aspirate fluid from the middle ear space (**Figure 167-1**). The procedure is considered diagnostic when the material obtained is sent for laboratory and/or microbiological analysis. It is considered therapeutic in most instances because it relieves pressure, thereby reducing pain and many times shortens the course of an acute otitis media (AOM).

The procedure is quick, simple, and not as frequently performed as it should be. In the preantibiotic era, general practitioners and pediatricians would frequently perform the procedure for the relief of pain. Tympanocentesis is making a resurgence. It should be considered when a patient presents to the Emergency Department seeking treatment for a painful AOM. The American Academy of Family Physicians, American Academy of Pediatrics, and the Centers for Disease Control all include tympanocentesis in their practice guidelines for AOM. Many authors are calling for culture-directed antibiotic therapy for otitis media to reduce the need for broad-spectrum antibiotics and prevent, as much as possible, the emergence of multiresistant organisms.[1–6]

ANATOMY AND PATHOPHYSIOLOGY

The ear is divided into the external, middle, and inner parts. The external ear is comprised of the auricle, the external auditory canal, and the external auditory meatus. The middle ear contains an air space and mastoid cells ventilated by the eustachian tube, the tympanic membrane, and the three ossicles. The inner ear is comprised of the cochlea, semicircular canals, fluids, and cranial verve VIII. The facial nerve courses through the middle ear space and mastoid process. It can be affected by a severe infection in these areas. Facial asymmetry during an acute ear infection is an indication of an unusually severe infection.

Inspection of the tympanic membrane will usually show it to be bulging during an acute infection with loss of mobility on

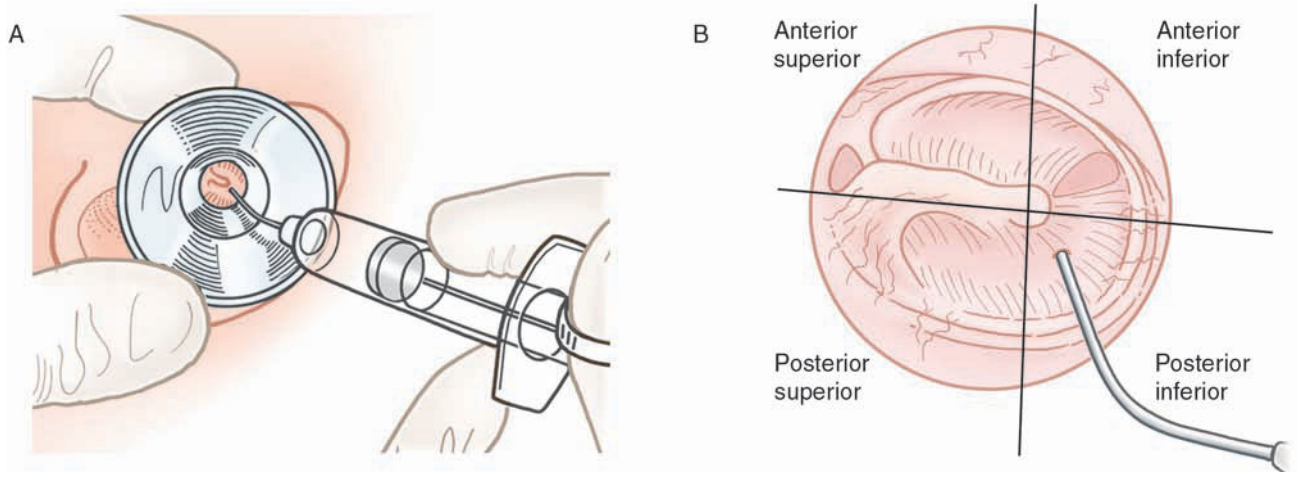

FIGURE 167-1. Tympanocentesis of the right ear. The patient is lying supine with their head directed to the left. **A.** An ear speculum is inserted into the external auditory canal. A needle is inserted through the posterior inferior quadrant of the tympanic membrane to aspirate middle ear fluid. **B.** Magnified view of the tympanic membrane.

pneumatic otoscopy. Conditions that are more chronic may show color changes of the tympanic membrane, with or without associated scarring and distortion.

INDICATIONS

Tympanocentesis is performed to obtain fluid for microbiological culture and antibiotic sensitivity testing to determine the infectious cause of a middle ear effusion. Tympanocentesis is warranted for patients with AOM that is severe, unresponsive to 48 to 72 hours of conventional antimicrobial therapy, or in a child less than 8 weeks of age to rule out gram-negative organisms. Tympanocentesis is warranted for patients with an AOM and either an acquired or congenital immunodeficiency as they will often require directed therapy. Patients who develop AOM while taking appropriate antimicrobial therapy should undergo tympanocentesis to be evaluated for the organism responsible and its sensitivity to antibiotics. Tympanocentesis is also performed when the patient has an AOM associated with unusually severe pain, signs of toxicity, or bullous myringitis. Tympanocentesis will provide immediate relief of pain, pressure, and/or hearing loss associated with AOM or a middle ear effusion. It may be performed in a patient with AOM and multiple antibiotic allergies to determine appropriate antibiotic selection and sensitivity. Finally, it can be performed in the patient with AOM prior to the 48 hour "watchful waiting" period to allow accurate antibiotic selection if the patient is still symptomatic after 48 hours.

CONTRAINDICATIONS

There are no absolute contraindications to tympanocentesis. It should not be performed in a patient who is uncooperative and cannot be restrained and/or sedated, as secondary injury may result. Uncooperative patients will require sedation to perform this procedure. Tympanocentesis should be performed by an Otolaryngologist if the landmarks on the tympanic membrane are unable to be absolutely identified or are obscured. Consult an Otolaryngologist prior to performing a tympanocentesis if an AOM is associated with a facial nerve palsy, mastoiditis, meningitis, encephalitis, brain abscess, or dural sinus thrombosis. Do not perform a tympanocentesis if the patient has an otitis externa.

EQUIPMENT

- Topical otic anesthetic solution
- 21 gauge spinal needle, 2.5 or 3 inches long
- 3 mL aspirating syringe
- Ear speculum
- Ear wax curette
- Culture swabs and media
- Laboratory tubes for fluid cell count and differential
- Intravenous extension tubing
- Otoscope
- Headlamp or overhead surgical light source
- Frazier suction catheters
- Suction tubing
- Suction source
- CDT Speculum, optional

The Channel Directed Tympanocentesis or CDT Speculum (Walls Precision Instruments LLC, Baker City, OR) is a single patient use, disposable, easy to use, and sterile device with built-in safety features. It was designed for use by Primary Care Physicians in the outpatient setting. The CDT Speculum attaches to most commonly available otoscopes (**Figure 167-2**). The device allows tympanocentesis and the aspiration of middle ear effusions.

FIGURE 167-2. The CDT Speculum attached to an otoscope. (Photo courtesy of Walls Precision Instruments LLC.)

There are several advantages to this device over the traditional spinal needle on a syringe. The ensheathed needle protects the Emergency Physician as well as the patient from accidental needle sticks. The needle is incorporated into a speculum to prevent it from contacting the external auditory canal. The needle is automatically retracted by a spring into a protected position when not being used. A safety latch prevents accidental needle extension. Needle extension is limited and prevents it from being inserted too far into the middle ear cavity.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. Obtain a signed consent for the procedure.

Place the patient supine on a locked gurney. View the tympanic membrane with an otoscope. Remove any cerumen from the external auditory canal using a curette. The cerumen may also be flushed from the external auditory canal. Refer to Chapter 166 for the complete details regarding cerumen removal. Again, view the tympanic membrane with an otoscope.

Administer analgesic medicine in advance of the procedure. Topical anesthetic solutions include benzocaine–antipyrine (e.g., Auralgan), viscous 4% lidocaine, 8% tetracaine, and cocaine. The administration of topical or local anesthesia is often not helpful in the presence of an acute infection. Topical anesthetics can potentially affect culture results due to their antimicrobial activity. If culture results are not a concern, apply a topical anesthetic solution into the external auditory canal followed by a cotton ball. Allow the solution to remain for 5 to 10 minutes. Use a wick to absorb the topical anesthetic solution and dry the external auditory canal. Refer to Chapters 126 and 168 for the details regarding regional anesthesia of the ear.

Children and uncooperative patients must be restrained and/or sedated so that the head is immobile. A papoose is effective for young children. Some practitioners use intravenous sedation. Only rarely is procedural sedation or general anesthesia required.

TECHNIQUES

TRADITIONAL NEEDLE-BASED TECHNIQUE

Bend a 21 gauge spinal needle at the hub to approximately 60°. Attach the spinal needle to a 3 mL aspirating syringe. Insert the ear speculum into the external auditory canal (**Figure 167-1A**). View the tympanic membrane through the ear speculum using a headlight or overhead surgical light source for illumination or an operating otoscope.

Insert the spinal needle through the speculum. Advance the needle and penetrate just into the inferior half of the tympanic membrane (**Figures 167-1A & B**). **Avoid inserting the needle through the posterior superior quadrant of the tympanic membrane. This location is near the ossicles. Any movement of the needle near the ossicles could result in disarticulation of the ossicles requiring surgical repair.** Aspirate the middle ear fluid into the syringe (**Figure 167-1A**). Simultaneously withdraw the syringe and ear speculum.

CHANNEL DIRECTED TYMPANOCENTESIS (CDT) SPECULUM

Remove the sterile CDT Speculum from the package. Attach the aspirator bulb and tubing to the CDT Speculum. Attach the CDT Speculum to the otoscope. Align the arm of the CDT Speculum with the insufflator port of the side of the otoscope head. Firmly attach the CDT Speculum onto the otoscope. Rotate the CDT Speculum 90° clockwise so that the arm is aligned with the seam on the top of the otoscope head. Disengage the safety latch.

Grasp the CDT Speculum with the dominant hand while simultaneously holding the otoscope and aspiration bulb with the nondominant hand (**Figure 167-3**). Compress the aspirator bulb. Insert the CDT Speculum into the external auditory canal. Visualize the tympanic membrane through the CDT Speculum. While looking through the CDT Speculum, press the actuator with the dominant thumb to extend the needle toward the inferior portion of the tympanic membrane (**Figure 167-3**). Continue to press the actuator to keep advancing the needle through the tympanic membrane and no more than 1 to 2 mm into the middle ear cavity. Release the compression on the aspirator bulb to aspirate the middle ear fluid. Release the pressure on the actuator to retract the needle. Withdraw the CDT Speculum from the external auditory canal.

FIGURE 167-3. Proper grasping of the CDT Speculum attached to an otoscope. Note that the dominant thumb is placed on the actuator. (Photo courtesy of Walls Precision Instruments LLC.)

Place the tip of the CDT Speculum over the culture swab or medium. Compress the aspirator bulb to expel the middle ear fluid sample. Discard the CDT Speculum.

ALTERNATIVE TECHNIQUE

An alternative method involves attaching intravenous extension tubing between the spinal needle and the syringe. The Emergency Physician can observe the tympanic membrane, insert the spinal needle, leaving a hand available for manipulation of the ear speculum or a suction catheter. An assistant is required to hold the syringe and aspirate the middle ear fluid. The remainder of the technique is as described previously.

ASSESSMENT

Tympanocentesis will decompress the middle ear pressure and provide the patient significant symptom relief. Transfer the fluid into appropriate laboratory medium and containers as quickly as possible. Label the containers and have them transported to the laboratory for a Gram's stain, culture and sensitivities, cell count, and differential of the cells present.

AFTERCARE

Since most of the distress associated with the procedure in small children is due to immobilization, immediately release the child from the papoose or restraining device. Most patients will have immediate improvement in their pain and, in many cases, their hearing. Some Otolaryngologists will rinse the external auditory canal after a tympanocentesis with a 3% peroxide solution then absorb the solution with a wick. This is optional and at the discretion of the treating Emergency Physician. Because there is a small opening in the tympanic membrane, further drainage including bleeding may occur and should be expected for 48 to 72 hours. Instruct the patient and/or their caregivers to keep the ear dry for 2 to 3 days. This is especially true during bathing or hair washing. A cotton earplug coated with a thin film of petrolatum jelly (e.g., Vaseline) works well. The tympanic membrane usually spontaneously heals within 48 to 72 hours, but can take up to 10 days. Follow-up for laboratory results and documentation of antimicrobial change or appropriateness is necessary in 48 to 72 hours.

COMPLICATIONS

Complications are uncommon. The most frequently cited complications include laceration of the ear canal, persistent perforation with or without otorrhea, development of a scar on the tympanic membrane, and an otitis externa. Pain and bleeding are usually minimal and self-limited. One of the most significant (but rare) complications is the disruption of the ossicles of the middle ear. **Disruption of the ossicles can be avoided by inserting the needles into the inferior half of the tympanic membrane and preventing patient movement during the procedure.** Injury to the chorda tympani, facial nerve, or internal carotid artery is theoretically possible, but virtually unheard of with this procedure.

SUMMARY

Acute otitis media is a common infection of childhood, but is also seen in adults. Most episodes respond quickly, with or without antimicrobial therapy. Tympanocentesis can be used to direct antimicrobial therapy in patients when a clinical response is delayed, host immunosuppression exists, or unusual organisms are suspected. Tympanocentesis can be used to provide immediate

pain relief from a severe middle earache. The procedure is quick and simple to perform in the Emergency Department.

168 Auricular Hematoma Evacuation

Eric F. Reichman

INTRODUCTION

Blunt trauma to the auricle can cause abrasions, ecchymosis, hematoma formation, and lacerations. Abrasions and ecchymosis of the auricle require no therapy other than oral analgesics and observation for infection.[1] Some authors recommend the application of topical antibiotics to all abrasions as prophylaxis for infection.[2] Lacerations to the auricle are addressed in Chapter 96. This chapter addresses the management of an auricular hematoma.

Injuries to the auricle are common due to its exposed position and lack of protection from surrounding structures.[3] The most common cause for an auricular hematoma formation is blunt trauma while participating in the contact sports of wrestling or boxing.[1,2,4–6] Such trauma may occur in other situations, including assaults, falls, fights, and motor vehicle crashes. Auricular trauma and hematomas are common in children due to the high incidence of head injuries during playtime.[2,4] Blood dyscrasias may also cause an auricular hematoma.

An auricular hematoma presents as a firm and painful swelling that obscures the normal convolutions on the lateral aspect of the auricle. It can develop within minutes to hours of the blunt trauma. **An auricular hematoma must be evacuated to prevent the cosmetic disfigurement known as cauliflower ear. The sooner it is evacuated, the less chance of permanent disfigurement.**[4,5] After evacuation, the patient requires a pressure dressing to the auricle, oral antibiotics, and close follow-up to prevent complications.[2,5,7,8]

ANATOMY AND PATHOPHYSIOLOGY

The auricle is that portion of the external ear that projects from the side of the head. It functions to augment sound delivery to the tympanic membrane and assist in sound localization. It is fixed in position by both ligaments and muscles.[9] It has an underlying cartilaginous framework that is 0.5 to 1.0 mm thick and provides the auricle with its unique shape. The cartilage is a single, thin sheet of flexible yellow elastic cartilage with many convolutions on the lateral surface.[10] The only portion of the auricle without cartilage is the lobule in which fibrofatty tissue replaces the cartilage.[9] **The cartilage is avascular and derives its blood supply and nutrients from the adjacent perichondrium.**[11]

The skin covering the auricle is similar to that elsewhere on the body.[12] It contains sebaceous glands and a varying number of hair follicles. The skin on the lateral surface of the auricle is tightly adherent to the perichondrium and lacks a subcutaneous layer (**Figure 168-1**). The skin on the medial surface of the auricle is loosely attached and has a layer of subcuticular tissue between the skin and perichondrium.

Trauma may cause the perichondrium to be torn off the underlying cartilage due to the tight attachment of the skin to the perichondrium on the lateral surface of the auricle. This traumatic avulsion of the perichondrium causes hemorrhage into the space between it and the cartilage, allowing a hematoma to form (**Figure 168-2**). Bleeding into this potential subperichondral space causes dissection

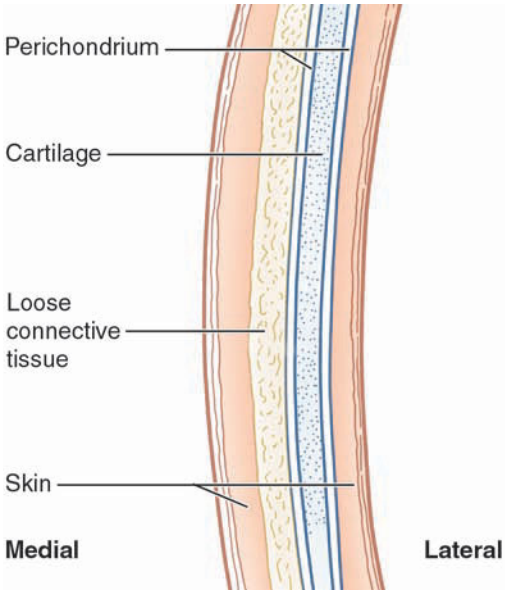

FIGURE 168-1. Cross section of the auricle. The skin on the medial surface has a layer of loose connective tissue that is lacking on the lateral surface.

of the perichondrium from the underlying cartilage. Auricular hematomas can be painful due to the rich sensory innervation to the area and the accumulation of blood in this relatively closed space.[11] **Failure to adequately evacuate a hematoma may lead to cartilage necrosis and a deformed ear.** The necrosis is due to a combination of separating the cartilage from its blood supply and direct pressure effects from the hematoma.

The cauliflower ear is a purely cosmetic deformity that results from an auricular hematoma not being evacuated and allowing the auricle to spontaneously heal. The hematoma is invaded by fibroblasts and slowly replaced by fibrous tissue. This organization of the hematoma causes irregular thickening of the auricle. The perichondrium, elevated from the cartilage by the hematoma, senses the

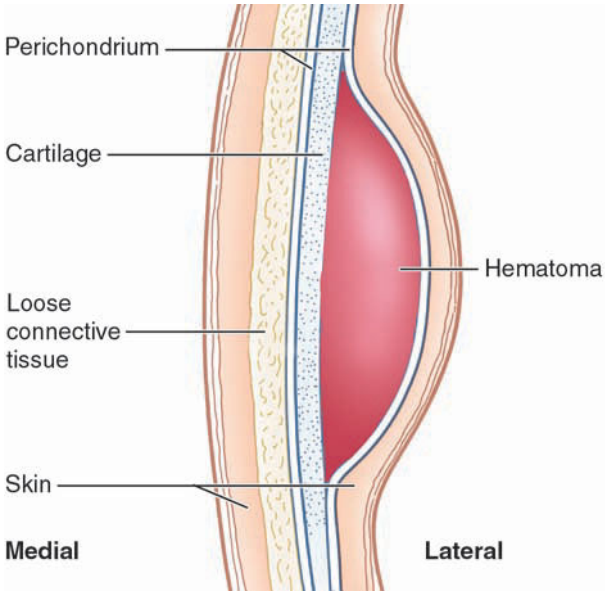

FIGURE 168-2. An auricular hematoma. The blood collects between the perichondrium and the cartilage.

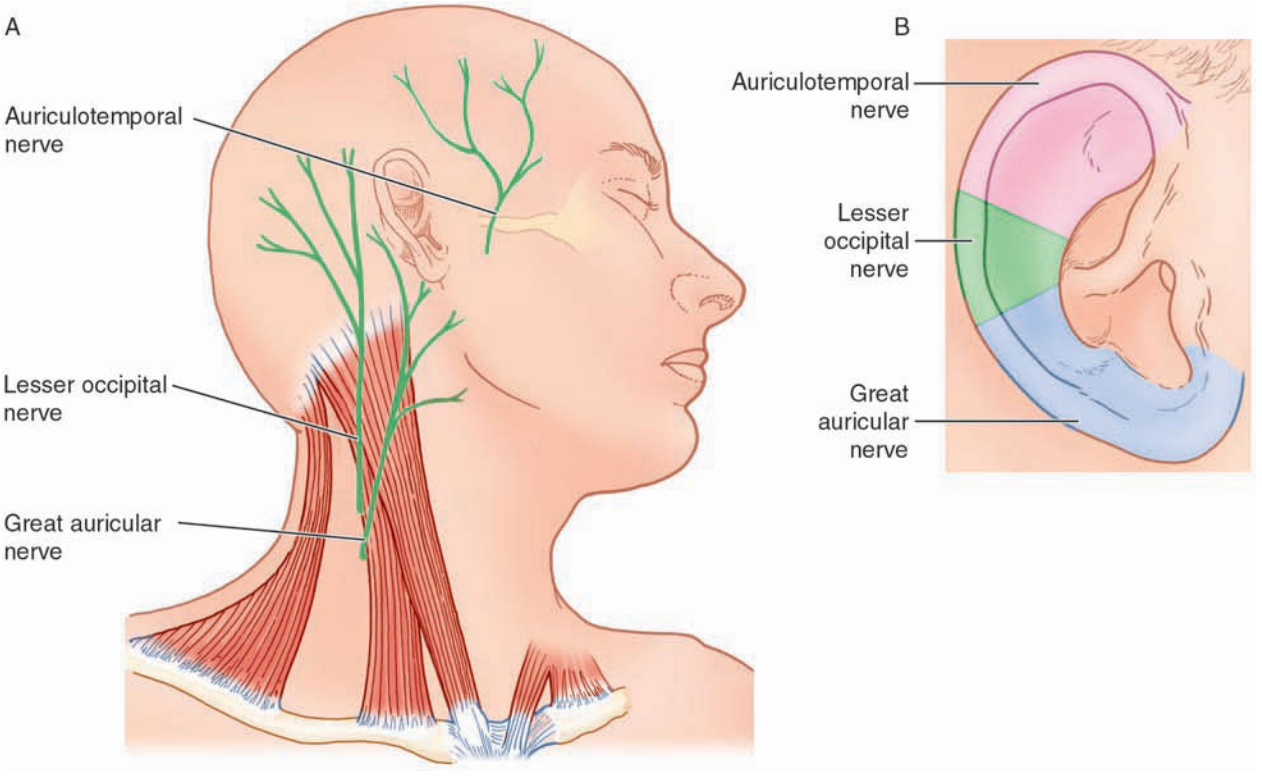

FIGURE 168-3. The sensory innervation of the auricle. **A.** The distribution of cutaneous nerves surrounding the auricle. **B.** An enlarged view of the auricle demonstrating the cutaneous innervation.

lack of adjacent cartilage and activates chondroblasts. New cartilage is deposited on the surface of the hematoma causing further thickening and deformity of the auricle.

INNERVATION OF THE AURICLE

A brief review of the innervation of the auricle will later aid in understanding the technique of regional anesthesia. Three nerves contribute to the sensory enervation of the auricle (**Figure 168-3**).[8,11–15] The auriculotemporal branch of the mandibular division of the trigeminal nerve supplies sensation to the upper, lateral surface of the auricle. This nerve emerges subcutaneously just anterior to the auricle at the level of the external auditory canal. Two branches of the cervical plexus become subcutaneous at the posterior border of the midportion of the sternocleidomastoid muscle and ascend to the auricle. The lesser occipital nerve provides sensory innervation to the upper medial surface of the auricle. The great auricular nerve provides sensory innervation to most of the medial surface and the lower half of the lateral auricular surface.

INDICATIONS

An auricular hematoma must be evacuated. The indication for evacuation is to prevent the cosmetic deformity known as the cauliflower ear.[7] It is preferable to evacuate the hematoma within 12 to 24 hours after its occurrence. Although there is no urgency to immediately evacuate the hematoma, the longer it remains the higher the chance of clot organization and new cartilage deposition.[7,16]

CONTRAINDICATIONS

There are no absolute contraindications to the evacuation of an auricular hematoma. If the skin overlying the hematoma is cellulitic, or if purulent material is drained from the hematoma, the patient will require hospital admission and intravenous antibiotics.[1,8] An Otolaryngologist or Plastic Surgeon should be immediately consulted on these patients. The auricular hematoma should be evacuated by a consultant if it has been present for more than 5 to 7 days. These hematomas have already begun organization and new cartilage has developed requiring curettage associated with the evacuation.[7,16,21,23] An uncooperative patient (e.g., young child or due to altered mental status) may require evacuation under procedural sedation or in the operating room.

EQUIPMENT

Auricular Anesthesia

- Povidone iodine or chlorhexidine solution
- 1 mL syringe
- 10 mL syringe
- 25 to 30 gauge needles, 2 inches long
- 10 to 20 mL of local anesthetic solution without epinephrine

Auricular Hematoma Aspiration

- Povidone iodine or chlorhexidine solution
- Tuberculin or insulin syringe
- 0.25 mL of local anesthetic solution without epinephrine
- 10 mL syringe
- 18 gauge needle
- Topical antibiotic ointment

Auricular Hematoma Incision and Drainage

- Auricular anesthesia as above
- #15 surgical scalpel blade on a handle
- Curved hemostat
- Sterile drain (optional)

- 10 mL syringe
- 18 gauge angiocatheter without the needle
- Sterile saline
- Topical antibiotic ointment
- Forceps

Mastoid Pressure Dressing

- Petrolatum gauze
- Cotton balls soaked in sterile saline
- Dry cotton balls
- 4 × 4 gauze squares
- 4 inch elastic bandage
- Scissors

Surgical Pressure Dressing

- Cotton bolsters or dental rolls
- Needle driver
- 4-0 monofilament nylon suture

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedural care should also be discussed. Obtain a signed consent for the procedure. Some Emergency Physicians omit the signed consent and place the following statement in the procedure note: "The risks, benefits, and complications were described and discussed with the patient. They understood this and gave verbal consent for the procedure." This decision must be based on physician preference, hospital guidelines, and state guidelines for documentation requirements.

Remove any dirt and debris from the auricle and surrounding skin. Apply povidone iodine or chlorhexidine solution to the same areas. Follow aseptic technique for the remainder of the procedure.[4] In patients who are anxious and without other associated injuries, the administration of intramuscular, intravenous, or oral benzodiazepines may be beneficial.[15]

AURICULAR ANESTHESIA

The local anesthetic solution used for auricular anesthesia should contain no epinephrine.[2,13,14,17] Epinephrine is not used for fear of intense vasoconstriction of end arterioles resulting in decreased perfusion with possible ischemia and necrosis of the auricle. Some authors recommend the use of 1/100,000 epinephrine mixed with the local anesthetic solution.[1,15,16] The epinephrine may decrease bleeding by its vasoconstrictive action. It may also prevent reaccumulation of the hematoma after it has been evacuated. Authors who advocate using epinephrine state that the auricle has a rich blood supply and that, based on anecdotal evidence, there is no danger of ischemia or necrosis from the use of epinephrine in healthy patients without evidence of traumatized vascularity. **Although many physicians will use epinephrine, it has not been proven safe to use or proven to prevent reaccumulation of the hematoma.** It may be wiser to be conservative and not use epinephrine than to use it and have to deal with the complications to the patient and potential litigation.

The choice of which local anesthetic to use is physician-dependent. Lidocaine (1%) is the most commonly used local anesthetic. Long-acting local anesthetic solutions, such as bupivacaine (Marcaine) or etidocaine (Duranest), may be used to provide analgesia for several hours after the procedure is completed.[14]

The methods of anesthesia for evacuation of an auricular hematoma range from none to a superficial skin wheal to a regional block. Some authors advocate using no anesthesia if needle aspiration of a small and fresh hematoma is performed.[2] This is not generally recommended as the pain from an 18 gauge needle aspiration is more uncomfortable than local anesthesia infiltration.

If using the aspiration technique to evacuate the hematoma, local anesthetic solution can be infiltrated directly over the hematoma. Apply a 25 to 30 gauge needle on a 1 mL syringe. Place a skin wheal, using 0.25 mL of local anesthetic solution without epinephrine, over the hematoma in the area of maximum fluctuance. **When placing the skin wheal, be careful not to inject the local anesthetic solution into the hematoma.** This will cause expansion of the hematoma and increase the separation of the perichondrium from the underlying cartilage.[17] It may also cause new bleeding, which can increase the possibility of hematoma reaccumulation.

A regional auricular block is the preferred method to obtain anesthesia.[13] It prevents distortion of the auricle from direct injection and further separation of the perichondrium from the underlying auricular cartilage.[17] Subcutaneous infiltration of the surrounding skin is less painful than injection directly into the sensitive auricular skin.[15] The landmarks for regional anesthesia are simple to locate, consistent, and predictable. The greatest reason for failure of an auricular block is incorrect needle placement.[14] A regional auricular block can be done prior to using the aspiration technique or the incision and drainage technique to evacuate the hematoma. If the aspiration technique fails (i.e., hematoma reaccumulates), then there is no need to reprep and perform an auricular block prior to performing the incision and drainage.

There are three methods to perform a regional auricular block (**Figures 168-4 & 168-5**). Each method blocks the lesser occipital, great auricular, and auriculotemporal nerves. Some Emergency Physicians prefer to subcutaneously inject local anesthetic solution circumferentially around the attachment of the auricle to the head (**Figure 168-4**).[2,11,13,17] An alternative method is based on blocking the sensory supply to the ear in a more anatomic distribution (**Figure 168-5**).[8,14] This latter method uses half the anesthetic

FIGURE 168-4. Regional anesthesia of the auricle. The technique of circumferential application of local anesthetic solution. Shaded areas represent subcutaneous infiltration of local anesthetic solution.

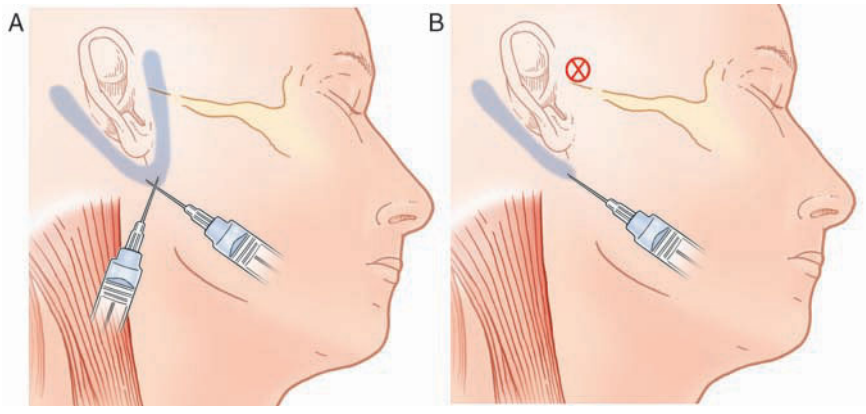

FIGURE 168-5. Regional anesthesia of the auricle. **A.** A more anatomical auricular block. **B.** An alternative regional block that anesthetizes the auriculotemporal nerve at its origin. Local anesthetic solution is injected at the ⊗ symbol. Shaded areas represent subcutaneous infiltration of local anesthetic solution.

and half the number of subcutaneous injections than the former method. For these reasons, this author prefers the second method, which is described in the following paragraph.

To perform a regional auricular block, first cleanse the auricle and surrounding skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution. Place a skin wheal of local anesthetic solution 0.5 cm below the pinna of the auricle (**Figure 168-5A**). Insert a 2 inch, 25 or 27 gauge needle through the skin wheal, aimed just posterior to the attachment of the auricle to the head. Infiltrate subcutaneously, in a superior direction, always remaining 0.5 to 1.0 cm posterior to the auricular attachment to the head. Stop infiltrating at the level of the superior attachment of the auricle to the head. This infiltration requires 4 to 7 mL of local anesthetic solution. Withdraw the needle almost completely. Redirect the needle through the skin wheal and aimed just anterior to the attachment of the auricle to the head. Infiltrate subcutaneously, in a superior direction, always remaining 0.5 to 1.0 cm anterior to the auricular attachment to the head. Stop infiltrating at the level of the superior attachment of the auricle to the head. This infiltration also requires 4 to 7 mL of local anesthetic solution. Care must be taken not to inject too deeply anterior to the auricle as it can cause temporary paralysis of the facial nerve. An alternative to the anterior infiltration is the injection of 3 to 4 mL of local anesthetic solution just superior and anterior to the tragus (**Figure 168-5B**).[1,18] This injection blocks the auriculotemporal nerve at its origin. **Allow 10 to 15 minutes for the full anesthetic effect prior to beginning the procedure.**[17]

TECHNIQUES

The methods for treating and managing an auricular hematoma require the evacuation of the hematoma and replacing the perichondrium onto the underlying cartilage. The techniques include aspiration, incision and drainage, and closed suction drainage. The first two techniques will be described in detail. The closed suction technique requires inpatient admission and is not a procedure to be performed in the Emergency Department. It will therefore not be described here.

ASPIRATION

Some consider the aspiration technique to be the primary method to evacuate an auricular hematoma.[2,3,5,6] They reserve the incision and drainage technique for incomplete aspiration or recurrence of the hematoma. Unfortunately, the hematoma frequently recurs after using the aspiration technique and the patient requires a second procedure to evacuate the hematoma.[1,3,6,19] Because of the high rate of recurrence, this author and others prefer to use the incision and drainage technique as the primary procedure.[16]

Clean and prep the skin. Anesthesia is achieved by performing a regional auricular block or by placing a skin wheal of local anesthetic over the hematoma. Attach an 18 gauge needle onto a 10 mL syringe. Insert the needle into the area of maximum fluctuance (**Figure 168-6**). Apply negative pressure to the syringe, by withdrawing the plunger, to evacuate the hematoma. Express or "milk" the hematoma between the thumb and index finger of the nondominant hand while applying negative pressure with the syringe to ensure complete evacuation of the hematoma (**Figure 168-6**).

Remove the needle and apply manual pressure to the area of the former hematoma for 3 to 5 minutes. If the hematoma recurs or if complete aspiration is not possible, perform the incision and drainage technique. If the hematoma is completely evacuated and does not recur, apply topical antibiotic ointment and a pressure dressing.

There are several disadvantages to this technique. First, the hematoma frequently recurs.[1,3,6,19] This means that the patient often needs a second drainage procedure. Even if the hematoma is adequately evacuated, the elimination of the dead space is problematic.[19] The dead space may fill with blood or serous fluid requiring a second procedure. A surgically applied pressure dressing may alleviate the dead space and make the aspiration technique more successful. Finally, the aspiration technique may not remove all of the hematoma.[1] Again, the patient will need a second procedure.

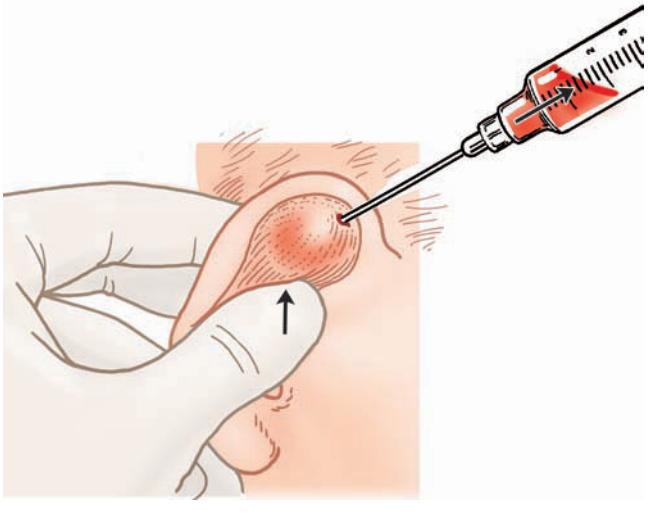

FIGURE 168-6. The aspiration of an auricular hematoma. The hematoma is expressed with the thumb and index finger as negative pressure is applied to the syringe.

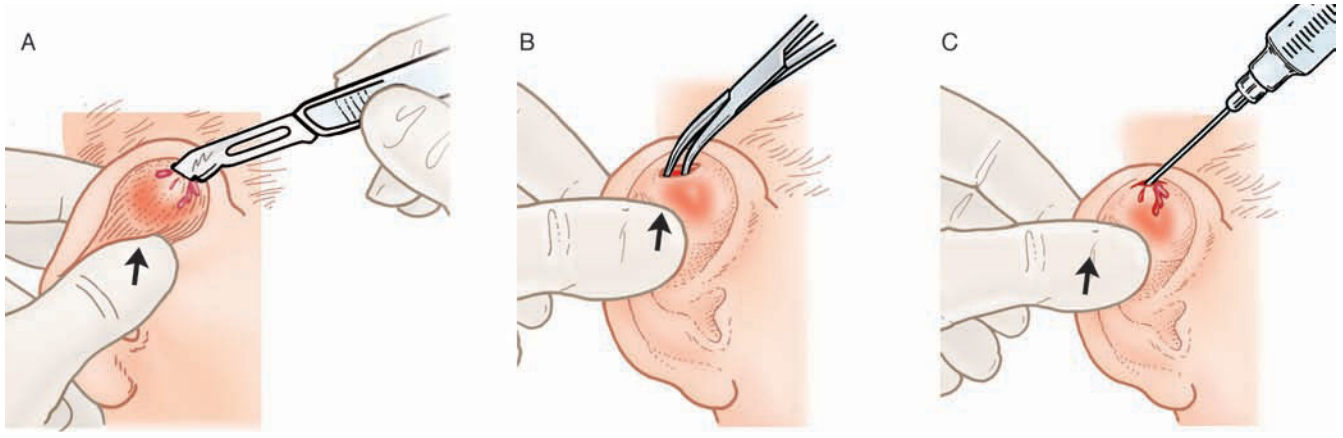

FIGURE 168-7. Incision and drainage of an auricular hematoma. **A.** An incision is made along the helical rim. **B.** The hematoma is evacuated with the aid of a hemostat. The thumb and index finger express the hematoma from the subperichondral space. **C.** The subperichondral pocket is flushed with normal saline to remove any residual blood and clot.

For these above stated reasons, the aspiration technique is not the preferred method to drain an auricular hematoma.

INCISION AND DRAINAGE

This is the preferred technique to evacuate an auricular hematoma.[16] It requires a regional auricular block for anesthesia. This technique takes more time to perform than the aspiration technique.

As noted previously, the skin should be cleaned and prepped in the usual manner. Perform a regional auricular block to provide adequate analgesia. Allow the block 10 to 15 minutes to achieve maximal effect.[17] Incise the auricular skin with a #15 surgical scalpel blade at the edge of the hematoma (**Figure 168-7A**). **When making the incision, it should follow the curvature of the pinna and be no longer than 1 cm.** Gently peel this skin and attached perichondrium off the hematoma using forceps. Express or "milk" the hematoma with the thumb and index finger of the nondominant hand. Insert a curved hemostat and gently loosen any remaining blood clot (**Figure 168-7B**). Fill a 10 mL syringe with sterile saline and attach a plastic 18 gauge angiocatheter. Gently flush out the area of the hematoma (**Figure 168-7C**).

Reapproximate the skin and perichondrium on the cartilage. Compress the tissue to eliminate any fluid and dead space. Some authors apply a small rubber drain through the incision to prevent accumulation of blood or serous fluid.[4,8] The use of a drain is optional. A drain can be made by cutting a small strip from a sterile Penrose drain.

Apply manual pressure to the area of the former hematoma for 3 to 5 minutes. If the hematoma or serous fluid does not reaccumulate, apply topical antibiotic ointment and a pressure dressing as described below. If the hematoma or serous fluid does reaccumulate, consider inserting a rubber drain or applying a surgical pressure dressing.

PRESSURE DRESSINGS

A pressure dressing must be applied to the auricle after the successful drainage of an auricular hematoma. It prevents reaccumulation of the hematoma or serous fluid, and supports the auricle while the perichondrium reattaches to the cartilage.[3,6,10] The pressure dressing must be applied for at least 48 hours.[4] The pressure dressing can be the traditional mastoid dressing or a surgically applied dressing.[16,17,19,20] These pressure dressings apply even pressure over the entire auricle without compromising the blood flow while simultaneously eliminating the dead space within the wound.[17]

MASTOID PRESSURE DRESSING

The most commonly applied dressing is the mastoid pressure dressing (**Figure 168-8**). Although simple to place, it has many

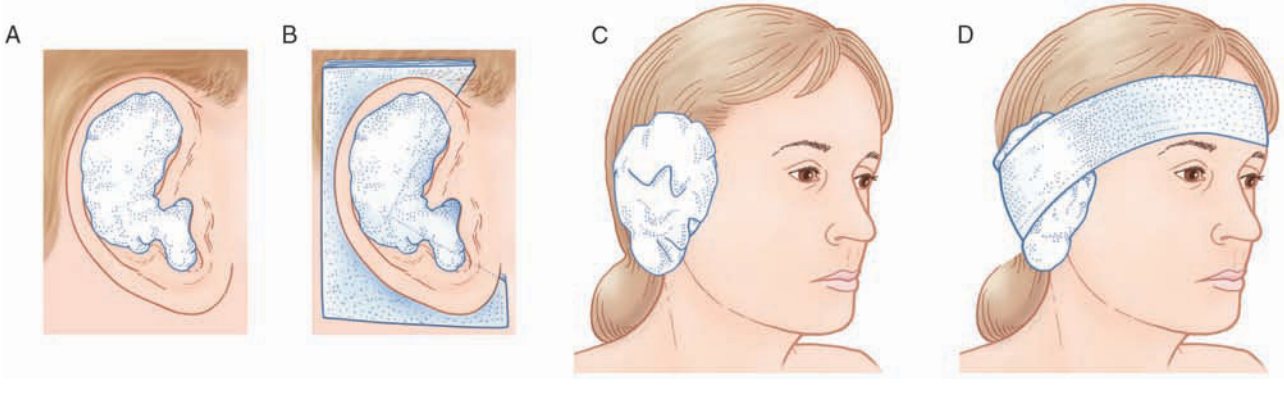

FIGURE 168-8. The traditional mastoid dressing. The convolutions are covered with a layer of petrolatum gauze. **A.** Saline-soaked cotton balls are packed over the convolutions, level with the helical rim. **B.** Trimmed gauze squares are placed between the auricle and the head. **C.** Fluffed gauze is placed over the auricle. **D.** The circumferential application of an elastic gauze bandage to the head. The bandage should cover the injured auricle and not the contralateral auricle.

disadvantages when compared to the surgically applied pressure dressing. It is bulky and hard to keep in place. It is very conspicuous. Patients must keep it dry and remain relatively inactive to prevent it from coming off.

Place a piece of sterile dry cotton in the external auditory canal and level with the base of the auricular cartilage. Mold a sterile material that conforms easily onto all the convolutions of the auricle until it is level with the lateral helical rim (**Figure 168-8A**). The choices of material include cotton balls soaked in mineral oil, cotton balls soaked in saline, or petrolatum gauze. The material chosen is left to Emergency Physician preference and what is available in the Emergency Department. This author prefers to use petrolatum gauze. The petrolatum gauze allows the dressing to be removed with minimal trauma to the ear. Pack the auricle with saline-soaked cotton balls. **All the convolutions of the auricle must be thoroughly packed. The packing of the auricular convolutions assures even application of pressure to all portions of the auricle.**

Cut out and discard a semicircle or a V-shaped section from a pile of gauze squares. Place the remaining C-shaped gauze pads behind the auricle (**Figure 168-8B**). The gauze pads should be built up until they completely fill the area between the auricle and the head. This padding is used to support the auricle as well as prevent undue contortion or uneven pressure from the compression dressing.[2]

Unfold and fluff several gauze squares or open a roll of gauze. Place the fluffed gauze over the lateral surface of the auricle (**Figure 168-8C**). Wrap an elastic bandage snugly over the auricle and around the head to hold the dressing in place (**Figure 168-8D**). The circumferential head dressing should not encompass the opposite auricle. The elastic bandage is used to compress the auricle between the two layers of gauze padding.

SURGICAL PRESSURE DRESSING

A surgically applied pressure dressing may be used instead of the traditional mastoid dressing (**Figure 168-9**).[1,7,16,19] This dressing applies even pressure over the former hematoma site to prevent reaccumulation. It takes more skill to apply than the traditional mastoid dressing. Aseptic technique is mandatory to prevent infection and perichondritis. This dressing requires a skin prep of a much wider area to include the entire medial and lateral surface of the ear, and the surrounding skin.

The surgically applied pressure dressing has many advantages over the traditional mastoid dressing. It produces pressure exactly where it is needed. The wound is not obscured with a bulky dressing. This allows the patient to easily observe and monitor the site for reaccumulation of fluid and possible infection. This dressing is comfortable and well tolerated by the patient. It is unlike the bulky and conspicuous mastoid dressing that is difficult to keep in place, especially when sleeping. The dressing can remain in place while monitoring the auricle, unlike the mastoid dressing that must be removed and replaced daily. The patient can remain active, including taking a shower, without fear of the dressing coming undone. The surgical pressure dressing is adaptable to any location or a variety of hematomas.

Trim a cotton dental bolster or cotton roll to fit the convolution of the auricle over the site of the drained hematoma. Place the cotton roll over the site of the former hematoma (**Figure 168-9A**). Place a second dental roll on the medial surface of the auricle opposite the first dental roll (**Figures 168-9A & B**). Place the needle of a 4-0 monofilament nylon suture immediately adjacent to the first cotton bolster. Pass the suture through the entire thickness of the auricle and out the medial surface. Pass the needle over the second cotton bolster and back through the auricle. Snugly tie the suture over the anterior cotton bolster (**Figure 168-9B**). The suture should be snug enough to allow the cotton bolsters to firmly hold the perichondrium to the cartilage without causing vascular compromise. Apply additional sutures using the same technique until the cotton bolsters are firmly attached and any dead space is eliminated. Depending upon the location of the hematoma, it may require a minimum of two to a maximum of four bolsters to reapproximate the skin and perichondrium and to eliminate all of the dead space.

Monofilament nylon is the preferred suture material for this procedure.[7] It causes less tissue reaction than silk, cotton, gut, or absorbable sutures. It has less of a tendency to cut the ear tissues when tied over the cotton bolsters. Monofilament nylon is less likely to wick bacteria into the auricle and cause an infection than multifilament nylon. The suture may be safely left in place for up to 3 weeks without any complications.

ALTERNATIVE TECHNIQUES

An alternative to packing the pinna with petrolatum gauze is to use either ENT silicone putty or dental impression material.[22,25]

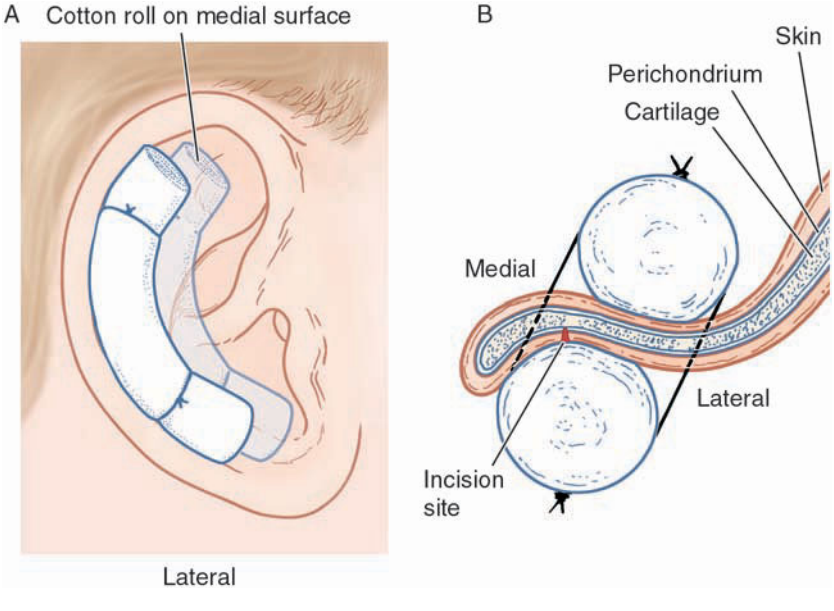

FIGURE 168-9. A surgically applied pressure bandage. **A.** A cotton roll is applied to the lateral surface of the auricle, over the site of the evacuated hematoma. A second cotton roll is applied on the medial surface of the auricle directly beneath the first cotton roll. The cotton rolls are secured with 4-0 monofilament nylon suture. **B.** Cross-sectional illustration of the surgical pressure dressing. The position of the cotton rolls and suture is seen in relation to the incision site. Note that the perichondrium is apposed to the cartilage and the dead space is eliminated.

Evacuate the hematoma as described previously. Mix the chosen material to form a uniform composite and activate it. Mold it to fill the pinna, wrapping over the pinna and filling the space between the medial surface of the ear and the head. The putty or impression material will solidify in a few minutes after mixing it and the application. Apply an elastic bandage as described previously. Unfortunately, ENT silicone putty and dental impression material is not often available in the Emergency Department.

The placement of cotton bolsters is often cumbersome and difficult if the Emergency Physician has little experience with this technique. An alternative is to use thermoplastic splinting material.[24] Trim a sheet of thermoplastic splinting material to form a lateral and medial splint of an appropriate size to conform to the lateral and medial surfaces of the ear, respectively. Place the splints in warm water to soften them. Apply the splints to the surfaces of the ear, mold them to the contours of the ear, and apply pressure until they cool and become rigid again. Suture the rigid splints through the ear as described previously.

A second surgical alternative to the use of bolsters is to apply running mattress sutures through the ear to reapproximate the skin and perichondrium.[26–28] Begin posteriorly and weave 4-0 Vicryl or chromic gut suture through-and-through the ear in a running pattern to reapproximate the soft tissues and repair the ear contours. The main advantages of this technique include eliminating bolsters, eliminating the bulky dressing, and the comparable success rates while minimizing the reaccumulation of blood or fluid.

AFTERCARE

The postprocedural care of the auricle is as important as the initial hematoma evacuation. Proper follow-up and care can minimize or prevent any cosmetic deformities. All patients should be seen within 12 to 24 hours to reevaluate the auricle for infection or reaccumulation of the hematoma or serous fluid. Analgesia can be provided by the use of nonsteroidal anti-inflammatory agents. Determine the patient's tetanus immune status and provide prophylaxis as required.

Provide all patients with oral and written instructions regarding the signs and symptoms of cellulitis and perichondritis. This includes the immediate return to the Emergency Department for increasing pain, progressive swelling, redness, tenderness, and warmth. Prophylaxis with oral antibiotics is indicated with any laceration, incision, or puncture of the auricular skin.[4] Prescribe antibiotics for 5 days.[4,5,16] Recommendations include a range of first-generation cephalosporins, antistaphylococcal antibiotics, or antipseudomonal antibiotics.[4,5,16]

Apply the pressure dressing for a minimum of 48 hours.[4] A pressure dressing is recommended for a total of 4 to 5 days. A mastoid dressing must be removed daily to evaluate the auricle, then reapplied. A surgically applied dressing will avoid daily visits to the physician.

Drain any residual clot or serous fluid at the follow-up visit. This can easily be accomplished by needle aspiration and replacement of the pressure dressing.[6,20] If necessary, a sterile drain can be inserted.[8] All drains must be removed within 48 hours of placement to decrease the risk of infection.

COMPLICATIONS

The complications are primarily related to incomplete evacuation of the hematoma or reaccumulation of the hematoma. Incomplete evacuation of the hematoma, if by the aspiration technique, requires an incision and drainage of the hematoma. If necessary, gentle curettage of the cartilage with a hemostat should dislodge the clot. Reaccumulation of the hematoma, or serous fluid, must be evacuated. Consider placing a sterile drain into the incision.[8] Another option is to place a surgical pressure dressing.[7] A hematoma located within the cartilage will result in a treatment failure and require operative management.[29]

Infection may complicate any surgical procedure. This may be due to reaccumulation or incomplete evacuation of the hematoma, which then becomes infected. Strict adherence to aseptic technique will usually prevent infection. Since patients are prophylactically placed on antibiotics, any cellulitis of the auricle at the follow-up visits requires hospital admission and intravenous antibiotics.

Perichondritis is the most feared complication. It is an aggressive and rapidly progressive infection. The auricle will become red, hot, and exquisitely tender if perichondritis develops. This is followed by diffuse swelling and abscess formation. This infection can lead to significant cartilage necrosis and a deformed ear if not promptly treated. *Pseudomonas aeruginosa* is isolated in 95% of patients with perichondritis.[1] Over 50% of cases are polymicrobial with *Staphylococcus aureus* associated with *P. aeruginosa*. These patients require Otolaryngology or Plastic Surgery consults for surgical debridement, broad spectrum intravenous antibiotics, and hospital admission.[1,8]

SUMMARY

An auricular hematoma forms in minutes to hours after blunt trauma to the ear. It presents as a firm and painful swelling that obscures the normal convolutions on the lateral aspect of the auricle. It requires drainage to restore the normal convolutions of the auricle and prevent future deformity. Complete evacuation can be accomplished by needle aspiration or by incision and drainage. After the procedure, prescribe oral antibiotics prophylactically to prevent infection. Follow-up is required within 12 to 24 hours of the procedure to evaluate the patient for reaccumulation of the hematoma and infection. Patients should be educated about the signs and symptoms of perichondritis. Frequent wound evaluation is required until the auricle is healed.

169 Nasal Foreign Body Removal

Raemma Paredes Luck

INTRODUCTION

Nasal foreign bodies are commonly seen in children, particularly those between 1 and 4 years of age. Adult patients with mental retardation or psychiatric illness can also present to the Emergency Department with a nasal foreign body. Young children are naturally curious and spend a great deal of time investigating themselves and the world around them. This involves handling, tasting, and smelling whatever they get their hands on. When these investigations go too far, the Emergency Physician is faced with a foreign body in a youngster's nose. The most common foreign bodies found are beads, food (e.g., corn, nuts, peas, and popcorn), paper, rocks, and toy parts.[1,2] Nasal foreign bodies also result from attempts to clean the nose and to control bleeding. In these cases, most of the foreign bodies retrieved consist of cotton swabs, paper, or sponge material.

Children may present with a known nasal foreign body. However, other presentations are common and may be subtle. This includes body odor, halitosis, persistent unilateral nasal discharge, or recurrent epistaxis. Foreign bodies can be found during a routine examination or as an incidental finding on radiographs in the asymptomatic child.[1,3,4]

The task of the Emergency Physician in these cases is fourfold. First is to suspect the presence of a nasal foreign body. Second is to perform a thorough physical examination, including a search for the foreign body. Next is to visualize the foreign body. Finally, remove the foreign body efficiently and with minimal trauma.

ANATOMY AND PATHOPHYSIOLOGY

The nasal cavity consists of two passages on either side of the nasal septum. The superior, middle, and inferior bony turbinates project medially into each passage and are covered by a mucous membrane overlying a venous plexus. Although foreign bodies can be located anywhere in the nose, most foreign bodies are found on the floor of the inferior turbinate or anterior to the middle turbinate.[5] The cartilaginous septum is covered by a thin mucosa and receives its blood supply from the mucoperichondrium. Sensory nerves of the nasal cavity are branches of the greater palatine nerve and sphenopalatine ganglion.[6] These nerves are easily anesthetized with topical anesthetics. The nasal cavity is separated from the orbit by the thin lamina papyracea and from the anterior cranial fossa by the cribriform plate of the ethmoid bone.

A foreign body in the nasal cavity sets off an inflammatory response and the venous plexus becomes congested. This swelling may eventually obscure the foreign body from view. The longer the foreign body remains in the nasal cavity, the more likely the patient is to develop pressure necrosis, granulation tissue, infection, and a purulent discharge. The foreign body can erode into the surrounding areas over time if it is not removed. A unilateral malodorous discharge and/or epistaxis from a child's nose is the hallmark of a foreign body.

The presence of a disk or button battery in the nasal cavity requires urgent removal. These batteries contain a strong alkali, usually potassium hydroxide or sodium hydroxide. The moisture in the nasal cavity may cause corrosion of the battery, leakage of the battery contents, and a low-voltage direct current between the anode and cathode. This may cause liquefaction necrosis, tissue electrolysis, and tissue destruction (mucosa, cartilage, and bone) within hours.[6] These patients need to be seen and followed by an Otolaryngologist after the battery is removed. An electrical thermal burn may cause damage to the nasal tissues that is more extensive than is visible initially in the Emergency Department.[7,8] Patients may develop a delayed septal perforation and alar collapse from extensive tissue damage.[9]

Small magnets can produce pressure necrosis in the tissues, particularly when they span either side of the cartilaginous septum or a turbinate. These magnets are commonly used as beads, clasps for necklaces and bracelets, and in faux piercings.[10,11]

INDICATIONS

All nasal foreign bodies must be removed to prevent complications. The direct observation of a foreign body in one or both nostrils is an indication for its removal. The presence of signs or symptoms such as unilateral persistent nasal discharge, recurrent unilateral epistaxis, halitosis, or an unusual body odor should prompt a search for a nasal foreign body. More than 90% of nasal foreign bodies can be removed by the Emergency Physician with readily available equipment.[1,3]

CONTRAINDICATIONS

There are a few contraindications to the removal of a nasal foreign body in the Emergency Department. One contraindication is if the airway is in danger. **Do not attempt to retrieve a nasal foreign body if the patient is in distress or unstable.** This might be due to a posteriorly placed foreign body or an uncooperative patient. **Management of the airway in the Emergency Department or in the Operating Room must take priority to foreign body removal.**

An Otolaryngologist should be consulted in patients with nasal foreign bodies that are impacted, cause excessive bleeding, or have resulted in nasal perforation or penetration. Foreign bodies located posterior and superior to the middle turbinate pose a risk of being pushed back during retrieval and may perforate the cribriform plate. If a larger foreign body has entered the nose traumatically, it should be removed by an Otolaryngologist as it may have penetrated the cranial cavity, the orbit, or a sinus cavity.[12,13] Other indications to consult an Otolaryngologist include failure of the Emergency Physician to remove the foreign body after repeated attempts, failure to properly sedate the patient, or the inability to sedate the patient. All of these contraindications may require foreign body removal in the Operating Room under more controlled circumstances and with equipment not available in the Emergency Department.

EQUIPMENT

Nasal Anesthesia and Vasoconstriction

- 1% or 2% lidocaine solution
- 4% lidocaine solution with 0.25% phenylephrine
- 4% cocaine
- 0.25% phenylephrine (Neosynephrine)
- 5 mL syringe or cotton pledgets
- Atomizer device if available

Manual Removal of Foreign Body (Figure 169-1)

- Head light or head mirror, surgical lamp, or overhead light
- Nasal speculum
- Alligator forceps

FIGURE 169-1. Instruments used for the manual extraction of a nasal foreign body. Top row (from left to right): disposable medicine cup, pledgets, nasal decongestant spray. Bottom row (from left to right): zero-degree telescope, bayonet forceps, nasal speculum, 90° blunt-tipped ear pick or mastoid probe, small alligator (ear) forceps, and large alligator or Blakesley forceps.

- Hartman forceps
- Bayonet forceps
- Frazier suction catheter
- Ear curette
- Blunt mastoid hook
- Wire loop

Catheter Removal of a Foreign Body

- Fogarty vascular catheter, size #4 or #5
- Foley catheter, 5 to 6 French
- 5 mL syringe
- Katz Oto-Rhino Extractor (InHealth Technologies, Carpinteria, CA)

Positive Pressure

- Cooperative parent
- Bag-valve device
- Face mask, various sizes
- Male-male tube adapter

Cyanoacrylate Glue

- Cyanoacrylate tissue/wound glue or "superglue"
- Paper clip or cotton-tipped applicator
- Superglue removal equipment (Chapter 165)

Nasal Wash

- Bulb syringe
- Normal saline

Pediatric Immobilization

- Sheets
- Commercial immobilization device (e.g., Papoose board)

PATIENT PREPARATION

Discuss the risks, benefits, complications, and different techniques available with the patient and/or their representative. Include the possibility of using procedural sedation initially or if initial attempts at removal are unsuccessful. Obtain consent for the removal procedure and the procedural sedation. The type, shape, size, and location of the foreign body are important factors to consider in choosing the most appropriate technique. The patient's age, ability to cooperate during the examination and removal, and the experience and skill of the Emergency Physician can influence the choice of techniques.

The Emergency Physician should observe universal precautions, especially eye protection, while working in close proximity to the mucous secretions in the airway. It is recommended to wear a gown, gloves, and a face mask with an eye shield or goggles. Both nasal cavities should be carefully inspected for foreign bodies before and after the mucosa is decongested. A child will sometimes insert foreign bodies up both nostrils. A good light source is indispensable for examining the nasal cavity and removing the foreign body.

Preparation is important to ensure that the first attempt at retrieval is successful. A variety of equipment should be readily available at the bedside in the event that additional attempts and techniques are required. A Frasier suction catheter should be available to clear the nasal passages of blood and/or mucous. **A good light source, particularly a hands-free device (i.e., overhead light source or a head lamp) is important in directly visualizing the foreign body and facilitating its removal.**

Anesthesia of the nasal mucosa is obtained by the topical application of lidocaine (maximum 4 mg/kg) or cocaine (maximum 3 mg/kg). Cocaine has the added benefit of vasoconstriction and decongestion of the nasal mucosa. If lidocaine is used, a vasoconstrictive agent such as epinephrine or phenylephrine should be added. A syringe can be used as a dropper to apply the medication intranasally. This is best done by administering several drops at a time and then reassessing visibility before adding more. If the entire dose is added at one time, the child is more apt to blow the medication out their nose before it can take effect. An atomizer device may also be used. Commonly available are devices that attach to a syringe (e.g., Mucosal Atomizer Device, Wolfe-Tory Medical Inc., Salt Lake City, UT) or a nasal decongestant container. Allow 5 to 10 minutes for the medication to take effect.

If the patient is cooperative, it would be appropriate to have them attempt to blow the foreign body out of their nostril. Have the patient sit up and lean forward. Have the patient blow forcefully through their nose while covering the uninvolved nostril with a finger. Even if this has failed at home, it may work with the nasal mucosa swelling alleviated by the decongestants.[9]

Most children will need to be restrained while the foreign body is being removed. Even the child who appears cooperative and is adequately anesthetized may move suddenly while instruments are in the nasal cavity. One method is for the child to sit on their parent's lap (**Figure 169-2**). The adult should cross their legs over the child's

FIGURE 169-2. Method to properly restrain a child.

legs, using one arm to restrain the child's arms and trunk and the other arm to hold the child's forehead (**Figure 169-2**). Alternatively, instruct an assistant to hold the patient's head while the parent controls the body and limbs. Another alternative is to wrap the child in a sheet or use a commercial restrain device (e.g., papoose board).[9]

Severely uncooperative patients may require sedation, procedural sedation, or general anesthesia prior to removal of the foreign body. Procedural sedation may be used to facilitate removal, especially in the uncooperative or fearful patient. In one study, approximately 21% of pediatric patients with nasal foreign bodies required procedural sedation.[4] The nasal foreign body was successfully removed in 95% of these cases. Ketamine was the most commonly used agent.

TECHNIQUES

DIRECT INSTRUMENTATION OR MANUAL REMOVAL

The most straightforward and common method is to remove the anteriorly located nasal foreign body under direct vision. Instrument removal should not be attempted if the foreign body is located posteriorly. The instruments most often used include alligator forceps, bayonet forceps, straight forceps, or mosquito forceps. Hooked probes, such as right angles or curved hooks, ear curettes, wire loops, or mastoid hooks can also be utilized. In the absence of these, a paper clip can be fashioned into a hook. A novel device is the Lighted Forceps for Foreign Body Removal (Bionix Medical Technologies, Toledo, OH). It is a single patient use and disposable device that contains a light source and acts like a forceps (**Figure 169-3**).

FIGURE 169-3. The Lighted Forceps for foreign body removal. (Photo courtesy of Bionix Medical Technologies, Toledo, OH.)

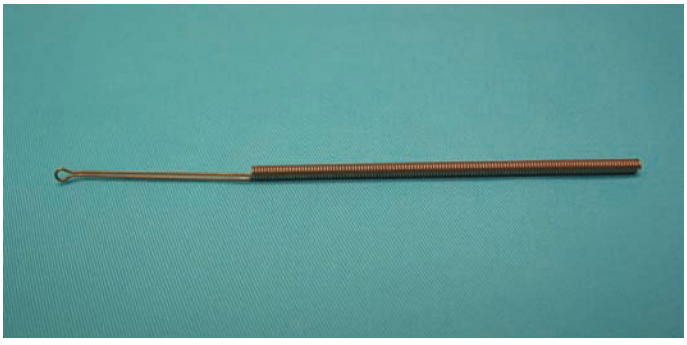

FIGURE 169-4. The EasiEar Metal Curette (Splash Medical Devices LLC, Atlanta, GA).

The EasiEar Disposable Comfort Curette (Splash Medical Devices LLC, Atlanta, GA) is an improvement to the standard disposable plastic curette (**Figure 169-4**). It is a stainless steel, single patient use, and disposable curette. The rounded wire head is smooth. It lacks the jagged and sharp plastic edges that are often found on molded plastic curettes. The EasiEar has no abrasive edges, seams, or surfaces to potentially abrade the nasal mucosa. This design may prevent abrasions, lacerations, and procedure-related bleeding. The spring wire shaft provides some flexibility and enhanced maneuverability when compared to molded plastic curettes, making the foreign body removal process easier. The angled head and flexible shaft allow it to be manipulated within the nasal cavity to remove a foreign body.

These instruments enable the Emergency Physician to grasp the foreign body directly or pull it out from behind. Anterior located foreign bodies are often easily removed with instrumentation. Forceps are better suited for soft and irregularly shaped foreign bodies (**Figure 169-5**).[5,14] Curettes and hooks are more effective

FIGURE 169-5. Using forceps to remove a thumb tack lodged in the nostril.

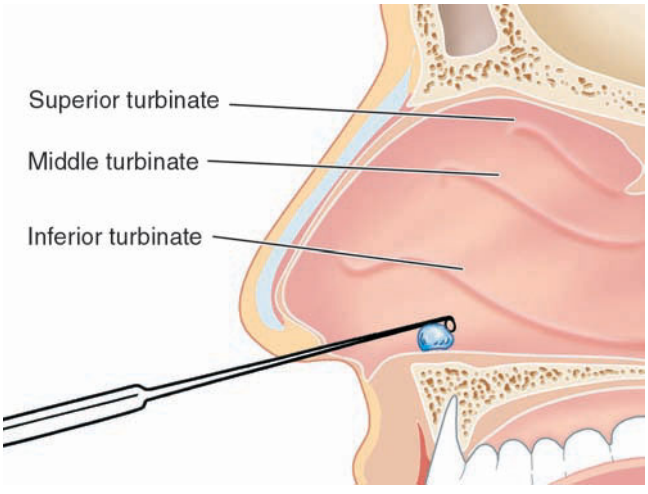

FIGURE 169-6. Removing a round, smooth foreign body from the nasal cavity. The curette, mastoid hook, or wire loop is passed through the nares and behind the foreign body. The hook is used to pull the foreign body out.

for hard and spherical foreign bodies.[5,14] Relative contraindications to instrumentation include posterior located foreign bodies, friable foreign bodies, and smooth or round foreign bodies. Potential complications include posterior displacement of the foreign body leading to nasal obstruction or even aspiration, mucosal abrasions and lacerations, and epistaxis.

Insert the nasal speculum to hold the nostril open. Adjust the headlight or head mirror to illuminate the nasal cavity. **It cannot be overemphasized how crucial adequate light and visibility are to successfully remove the foreign body.** Remove any mucus or blood with the Frazier suction catheter. Grasp an irregularly shaped foreign body with a type of forceps. Forceps may cause a round or smooth foreign body to slip farther posteriorly when the jaws close. In these cases, pass a curette, wire loop, or mastoid hook behind the foreign body and pull it out (**Figure 169-6**).[9] If the foreign body is a bead and the opening is facing outward, the jaws of a small alligator forceps can be passed through the opening (**Figure 169-7**). Open the jaws when they are beyond the lumen of the bead and pull the bead from the nasal cavity.

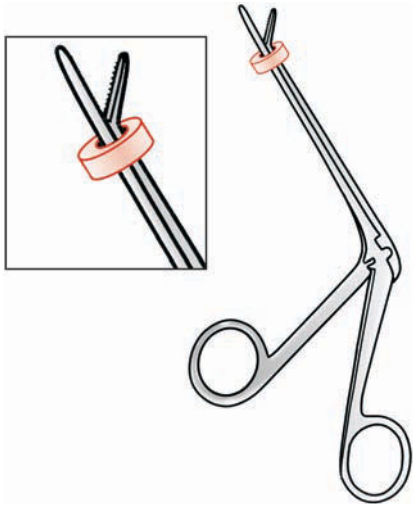

FIGURE 169-7. An alligator forceps is used to remove a bead or other foreign body with a hollow center.

BALLOON CATHETER EXTRACTION

Some Emergency Physicians prefer to use a catheter with a balloon to pull foreign bodies from the nasal cavity. This technique has a reported success rate of 90%, and is used most successfully for foreign bodies that are round, smooth, and cannot be grasped readily.[15] A balloon catheter does not work if the foreign body fully obstructs the nasal passage. Authors describe using a variety of catheters. This includes a #4 to 8 Fogarty vascular catheter, a #6 Fogarty biliary catheter, and a 5 to 6 French Foley balloon catheter.[3,9,16] Suction is relatively contraindicated if the foreign body is shaped so that the suction device cannot form a seal or if the foreign body is friable.

Inflate the balloon to ensure it has no leaks. Deflate the balloon. Lubricate the catheter. Insert the catheter until the balloon is beyond the foreign body. The catheter may be placed either above or below the foreign body.[9] Inflate the balloon with 2 to 3 mL of air. Gently pull the catheter. The balloon will push the foreign body out of the nostril. A balloon catheter can also be used to stabilize a foreign body from behind while it is removed with a forceps.

The disadvantage to this method is that it is more traumatic and epistaxis is more common.[2] If the catheter is not passed under direct vision or if it is too large to pass around the foreign body, the Emergency Physician risks pushing the foreign body posteriorly and impacting it, obstructing the nasal passage, or dislodging it into the airway.

KATZ EXTRACTOR

The Katz Extractor Oto-Rhino Foreign Body Remover (InHealth Technologies, Carpinteria, CA) is a device designed to extract foreign bodies from the nasal and auditory passages (**Figure 169-8**). It is a disposable single-use device consisting of a balloon-tipped catheter attached to a syringe. Always test the device before using it. Push the plunger to inflate the balloon and inspect it for any air leaks. Release the plunger to deflate the balloon.

Grasp the device with the dominant hand (**Figure 169-9**). Gently insert the catheter along the wall of the nasal activity until the balloon is just past the foreign body (**Figure 169-9A**). Inflate the balloon by depressing the plunger on the syringe (**Figure 169-9B**). Withdraw the catheter and foreign body from the nasal cavity while maintaining the balloon in the inflated state (**Figure 169-9C**). If the foreign body has a central hole (e.g., candy or bead), insert the catheter through the hole, rather than behind it, and inflate the balloon.

HOGNOSE OTOSCOPE TIP

The Hognose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, and single-use device that attaches to a standard otoscope (**Figure 169-10**). It comes in three sizes (3, 4, and 5 mm), each with a color-coded tip. The size represents the cup size at the

FIGURE 169-8. The Katz Extractor. The balloon at the tip inflates and deflates by pushing and releasing the plunger, respectively. (Photo courtesy of InHealth Technologies, Carpinteria, CA.)

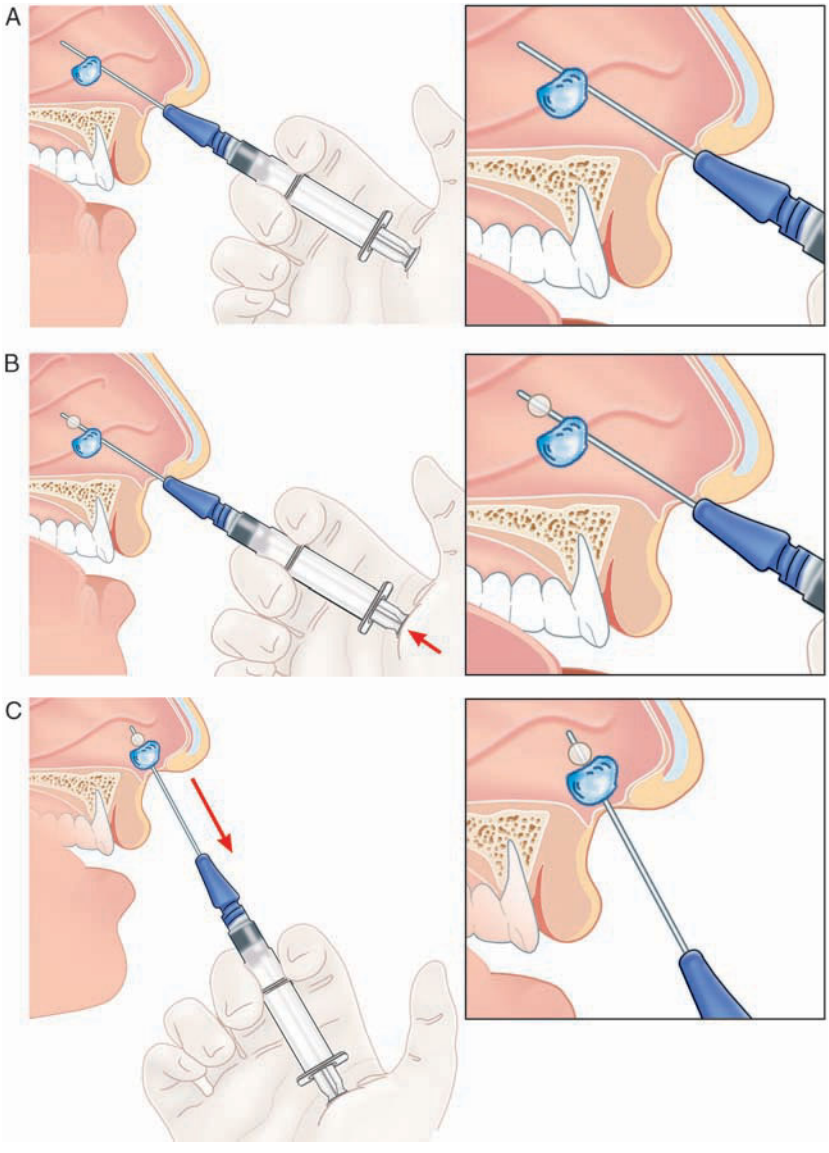

FIGURE 169-9. The Katz Extractor removing a nasal foreign body. **A.** The device is inserted until the balloon is just past the foreign body. **B.** The balloon is inflated. **C.** The Katz Extractor is removed with the balloon inflated and the foreign body is removed.

FIGURE 169-10. The Hognose otoscope tip attached to an otoscope. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

tip of the device. The tip is soft, self-molding, and looks like the nose of a hog. It has an insufflation port and suction tubing attached to its side. The adapter on the suction tubing attaches to standard wall suction tubing.

Attach the Hognose to the otoscope similar to attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Attach the hognose tubing to suction tubing and a suction source. Turn the suction source on to low or medium. Grasp the otoscope with the dominant hand. Insert the Hognose into the nasal cavity while visualizing the foreign body through the otoscope head. When the tip of the Hognose is just next to the foreign body, place an index finger over the insufflation port to engage the suction at the device tip. Gently advance the otoscope until the tip of the Hognose is against and attached to the foreign body. If you suddenly see black through the otoscope, the soft tip has collapsed on itself. Remove the finger over the insufflation port and reapproach the object. While maintaining suction, withdraw the Hognose with the foreign body attached.

GATORNOSE OTOSCOPE TIP

The Gatornose (IQDr. Incorporated, Manitou Springs, CO) is a disposable, latex free, and single-use device that attaches to a standard

FIGURE 169-11. The Gatornose otoscope tip attached to an otoscope. Note the three types of jaws that are available to snap onto the base of the device. (Photo courtesy of IQDr. Incorporated, Manitou Springs, CO.)

otoscope (**Figure 169-11**). It twists onto an otoscope like a speculum. It comes with three different jaw types that attach to the body of the device. These jaws are small flat jaws, large flat jaws, and open loop jaws. A trigger on the body of the device controls jaw opening and closing.

Attach the Gatornose to the otoscope similar to attaching a disposable speculum to an otoscope. Turn on the otoscope light source. Grasp the otoscope with your dominant hand. Insert the ring finger into the trigger. Pull the trigger to close the Gatornose jaws. Gently insert the Gatornose jaws just into the nasal cavity. Push the trigger to open the Gatornose jaws and be able to view through the otoscope. Gently advance the otoscope while visualizing the foreign body through the otoscope head. Position the jaws above and below or anterior and posterior to the foreign body. Pull the trigger to close the jaws onto the foreign body. Withdraw the otoscope with the foreign body in the jaws of the Gatornose.

SUCTION TECHNIQUE

Frazier suction catheters are most useful with small or round foreign bodies. Otherwise, this technique will be unsuccessful or will push the object farther into the nasal cavity. This technique is best reserved for large, round foreign bodies where suction can be maintained between the device and the foreign body. Complications include trauma to the surrounding tissues and epistaxis.[17]

Attach the Frazier suction catheter to the suction tubing. Turn on the suction source to at least 100 mmHg. Gently insert the catheter into the nasal cavity. Place a thumb over the hole in the catheter handle to direct the suction through the tip of the catheter. Gently advance the suction catheter until the tip is in contact with the foreign body. Withdraw the Frazier suction catheter and foreign body from the nasal cavity.

For impacted smooth, spherical objects, suction with plastic intravenous tubing can be used.[18,19] Cut a short length of plastic intravenous tubing and attach one end to the suction source. Fashion the other end into a small flange shape using a heat source and any metal object with a rounded end, such as the tip of a hemostat or larger clamp. Heat the jaws of the hemostat and insert them into the plastic tubing just enough to create a flange. Turn on the suction source. Place a hemostat onto the tubing to temporarily clamp the suction tubing. Gently advance the flange tip into the nasal cavity until it contacts the foreign body, taking care not to push it inward. Remove the hemostat from the tubing to activate the suction. Gently but quickly remove the tubing and attached foreign body from the nasal cavity.

POSITIVE PRESSURE

This technique is best utilized for foreign bodies that are large, posteriorly located, or occlude the nasal passage. It involves the generation of positive pressure in the nasopharynx behind the foreign body to force it out of the nostril. There are several ways to generate positive pressure within the nasal cavity. One is to simply ask the patient to occlude the unaffected nostril, take a deep breath through their mouth, close their mouth, and then forcefully exhale the air out through the nostril with the foreign body while keeping their mouth closed. This technique is most successful in older children and adults who are cooperative and can coordinate the movements. **The advantage to this technique, if it is successful, is that no instruments are placed into the nose. The disadvantage is that the foreign body becomes a flying body. Eye protection is advised.**

Other variants of this technique have been developed. The "big kiss," also known as the "parent's kiss" or "mouth-to-mouth" technique, involves asking the parent to blow into the child's mouth.[20] This is similar to rescue breaths during cardiopulmonary resuscitation (CPR). Explain the procedure to the child and the parent. Instruct the parent to open the child's mouth with one hand and stabilize the chin while occluding the unaffected nostril with a finger from their other hand. Instruct the parent to open their mouth, take a big breath, and then place their mouth over the child's open mouth. The child's mouth must be completely covered by their parents and a good seal formed. Instruct the parent to deliver a sudden and forceful breath into the child's mouth. This entire sequence of events should only take 3 to 4 seconds to complete.

This maneuver causes the child's glottis to close. If enough pressure is generated, the foreign body will be expelled from the affected nostril. This technique may be less traumatic to the child and involves no instrumentation or restraint.[20] High success rates have been reported.[21] However, this technique may be difficult for some parents to perform. A modified version of this technique involves using a drinking straw or small tube between the child's mouth and parent's mouths. The parent then gives a big puff of air through the straw while the child tries to make a tight seal between their mouth and the straw. This technique can also be performed by the Emergency Physician without placing their mouth on the child's mouth.

A bag-valve-mask device (i.e., the Ambu-bag) can also be used to blow the foreign body out the nostril.[22] Choose a face mask that is small enough so that it only covers the patient's open mouth. Cover the patient's mouth tightly with the mask. Close the unobstructed nostril with a finger (**Figure 169-12**). Squeeze the bag to force air into the mouth, lungs, and out the nose.[22] A variant of this method uses an anesthesia bag connected to high-flow oxygen (10 to 15 L/min). Cover the mouth with the mask, close the thumb hole, and allow the bag to expand and gradually increase the airway pressure. If this does not expel the foreign body, compress the bag.[3]

The "Beamsley Blaster" technique makes use of the positive pressure generated from the application of high flow (10 to 15 L/min) oxygen from tubing attached to an oxygen wall outlet.[23] The other end of the tubing is attached to a male-male

FIGURE 169-12. Bag-valve-mask method of removal. The child is restrained and the contralateral nostril is occluded. Bag-valve-mask is applied on the mouth to create a seal and a few breaths are delivered until foreign body is expelled.

adapter, which is then inserted into the unaffected nostril. The set-up generates enough pressure in the posterior nasopharynx to dislodge the foreign body from the nostril. The patient's mouth must be closed during the procedure to create a seal. Although there were no complications noted in the initial study, a subsequent case of barotrauma (subcutaneous orbital emphysema) was recently reported.[24]

If an SMR cabinet or other blower with a nasal tip is available, place the nasal tip in the unobstructed nasal cavity. This method is contraindicated if there are foreign bodies in both nasal passages. **It is important to be sure that the nasal tip is placed in the open nasal cavity or the foreign body could be blown into the trachea or esophagus.** Blow short puffs of air during the child's cries. The soft palate will close when the child is vocalizing and direct both the air and the foreign body out the other nostril.[2]

CYANOACRYLATE GLUE–ASSISTED REMOVAL

Cyanoacrylate glue can be used to extract spherical and other solid foreign bodies that are visible.[25] However, this technique can be fraught with complication. **There is a chance of gluing the foreign body to the nasal mucosa as well as creating a glue foreign body. The foreign body can be further impacted if pushed posteriorly or fall into the oropharynx and aspirated.**

Obtain a long, thin object (e.g., straightened paper clip or the stick end of a cotton-tipped applicator). Moisten the tip of the paper clip or applicator stick with a very tiny amount of cyanoacrylate glue. A larger amount can drop off into the nasal cavity. Insert the paper clip or applicator stick before the glue dries and until it just touches the foreign body. Maintain this position for 30 to 60 seconds to allow bonding of the glue to the foreign body. **Do not allow the drop of glue to fall from the stick, as it will bond to the nasal mucosa. Do not touch the tip of the wooden applicator stick to the nasal mucosa, as it will bond to the mucosa.** Remove the paper clip or applicator stick with the foreign body attached. The main disadvantages of this technique are potential bonding of the nasal mucosa and the time it takes for the glue to bond to the foreign body.

ALTERNATIVE TECHNIQUES

NASAL WASH

The nasal wash technique involves the introduction at high pressure normal saline through a bulb syringe into the unaffected nasal cavity. Place approximately 7 mL of normal saline into a bulb syringe. Insert the bulb syringe into the unaffected nostril. Advance it into the nostril until a seal is created. Forcefully squeeze the bulb syringe. The pressure generated is believed to expel the saline and the foreign body from the other nostril. The use of this technique carries a high risk of aspiration of saline and the foreign body, as well as concerns about reflux of the saline into the sinuses or eustachian tubes.[26] This technique should not be used in patients with a button battery or organic matter in their nasal passages. The increased moisture will hasten corrosion of the battery and cause swelling of the organic matter, making additional attempts at removal more difficult. This technique should also not be used in young infants and those with airway or neurologic abnormalities.

MAGNET REMOVAL

An occasional patient will present with a mini-magnet adhered to the nasal mucosa. The source of the magnets can be from their insertion in young children or nasal jewelry in older children, adolescents, and adults.[10] Adherence of magnets across the nasal septum creates the potential for septal necrosis and perforation.[11,27,28] They may be difficult to remove because of the attractive force they create across the nasal septum.

Numerous methods can be used to facilitate magnet removal. They may be grasped with a variety of forceps or hemostats. A hook can be made from nonferromagnetic blunt probe.[10] A magnet can be used to facilitate nasal magnet removal.[11,29,30] A pacemaker magnet is readily available in most Emergency Departments. A small and strong pocket magnet may also be available from the hospital maintenance department.

ASSESSMENT

Inspect the nasal cavity for any remaining fragments of the foreign body, ulcerations, bleeding, or a second foreign body. A gray precipitate may be noted if a disk battery has been removed. After a battery is removed, the nasal cavity should be irrigated with saline to remove any electrolyte solution or precipitate to prevent further damage.[12] Bleeding can be controlled with topical phenylephrine or epinephrine, pressure, or any of the methods described to control epistaxis (Chapter 172).

AFTERCARE

The patient can be discharged home with nasal saline spray to the affected nostril until secretions are clear of blood or pus. Oral antibiotics may be prescribed if the patient has developed sinusitis from a retained foreign body. Patients with ulcerations on opposing sides of the nasal cavity must be followed up to prevent obstructive synechiae or adhesions from forming. Patients with button batteries, mini-magnets in their nasal passages, or other injuries or complications should follow up with an Otolaryngologist. The caretakers should be educated to remove any small objects from the child's reach, supervise children when they have access to small objects, and childproof the house.

COMPLICATIONS

Complications can arise from the nasal foreign body itself or the removal technique. Foreign bodies can cause nasal obstruction, epistaxis, pressure on surrounding tissues, infection, ulceration, perforation, or aspiration.[5] The risk of complications increases the longer the foreign body is present. Otitis media, sinusitis, facial and orbital cellulitis, epiglottitis, and meningitis have been associated with retained nasal foreign bodies.[5,8]

The most significant complication would be to dislodge the foreign body into the airway. This is most likely to occur in an uncontrolled situation. Placing the patient supine and in the Trendelenburg position may prevent accidental aspiration of the foreign body.[31] Consider the use of sedation, procedural sedation, or general anesthesia if the patient is uncooperative.

Potential complications associated with each technique were described with each specific technique. Aspiration from posterior dislodgment of a nasal foreign body remains a serious potential complication for all the techniques described. Positive pressure techniques can result in barotrauma. Periorbital emphysema has been described in the "Beamsley Blaster" method.[24] Secondary infection may also result from the procedure. In most cases, once the foreign body has been removed antibiotics are generally not indicated. Complications related to manipulation within the nasal cavity include bleeding or subsequent infection. In rare instances, an anterior nasal pack may be required to tamponade bleeding. Toxic doses of cocaine and/or lidocaine may result in cardiac arrhythmias and seizures.

SUMMARY

The vast majority of nasal foreign bodies can be safely removed by the Emergency Physician with instruments that are readily available in the Emergency Department. There are multiple techniques for removing foreign bodies from the nasal cavity. Each has its own advantages and disadvantages. These methods include the use of forceps, balloon catheters, and positive pressure. The Emergency Physician should choose a method according to the shape and location of the foreign body, the tools available, the cooperativeness of the patient, and their experience with the different removal techniques.

170 Nasal Fracture Reduction

Eric F. Reichman

INTRODUCTION

Nasal fractures due to blunt trauma are a common occurrence. Fights, auto accidents, and sports accidents account for most fractures in an urban setting. Work, farm, sports, or leisure activity accidents account for most of these injuries in rural areas.[1] The majority of nasal fractures occur in males aged 15 to 25 years old, with fights being the major etiology.[2–5] Nasal fractures are often missed on initial evaluation, especially when there are many more urgent trauma concerns. It is best to perform closed or open reduction of a nasal fracture within the first 2 weeks, when it is easiest to avoid more elaborate operations later to correct the disfigurement and nasal airway obstruction. Perform the reduction in children within 3 to 7 days, as fracture fixation occurs faster than in adults.[6]

Suspect a nasal fracture in the blunt trauma patient with a history of epistaxis, new onset nasal blockage, or a change in nasal appearance. Determine whether the patient has a prior history of a nasal bone fracture, as repeat nasal bone fractures will be more difficult to reduce. An old photograph of the patient may aid this determination. One study revealed that 30% of injured noses had a preexisting nasal deformity.[7] At least 48% of the general population has a deviated nasal septum.[8] Physical examination may demonstrate skin lacerations, nasal tenderness and mobility, internal mucoperichondrial tears, ecchymosis, or a septal hematoma. A septal hematoma must be drained to avoid cartilage necrosis and the subsequent saddle nose deformity. Refer to Chapter 171 regarding the complete details of managing a nasal septal hematoma.

ANATOMY AND PATHOPHYSIOLOGY

The mechanism of injury, force of impact, direction of impact, and the history of any prior nasal deformity must be ascertained from the patient in order to understand the potential magnitude of the fracture. If possible, obtain photographic documentation before any attempts at nasal manipulation. The Waters and lateral nasal radiographs will often support the physical findings of a nasal fracture (**Figure 170-1**). Many Surgeons recommend radiographs as part of the medical legal documentation, although many do not agree. Plain radiographs can have a high false-negative rate due to the lack of fine resolution or a high false-positive rate from the misinterpretation of the normal bony sutures.[9,10] A CT scan is more sensitive and specific to identify a nasal bone fracture. Unfortunately, its cost and the radiation exposure are significant. A nasal fracture can often be diagnosed based upon the history and the physical examination. Reserve the CT scan for those patients with suspected nasal fractures that may have additional injuries requiring a CT scan.

The direction of the force to fracture the nasal bone is variable. There are several lateral and frontal force injury classifications, but no consensus exists.[5,11,12] One study demonstrated that 66% of nasal fractures were due to lateral forces, 13% from frontal forces, and 21% from mixed forces.[3] This predominance of lateral force fractures is due to several factors.[13] It takes more than twice the force, in cadavers, to cause a frontal impact fracture than to cause a lateral impact fracture.

Always rule out any associated maxillofacial injuries, especially when the patient presents with ocular hypertelorism and

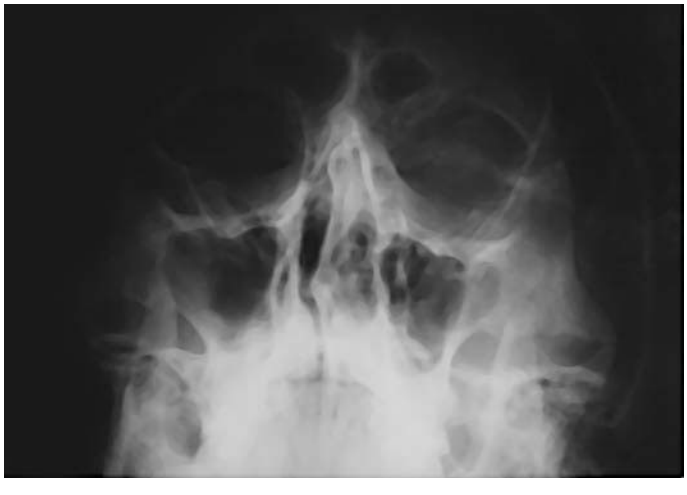

FIGURE 170-1. Radiograph demonstrating a Waters view of a deviated nasal septum and right nasal bone fracture.

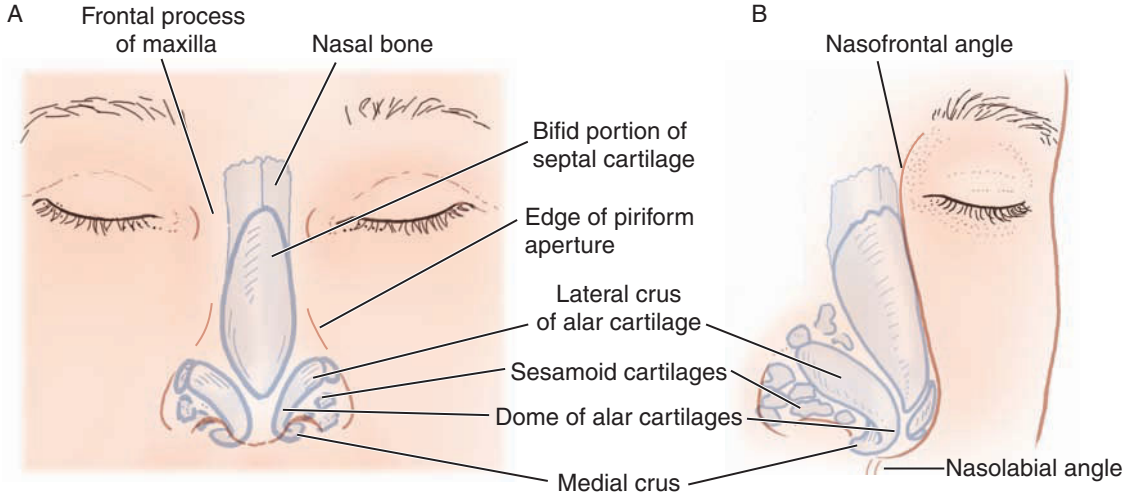

FIGURE 170-2. Anatomy of the external nasal cartilages. **A.** Frontal view. **B.** Lateral view.

lid lateral-pull laxity.[14] Thoroughly evaluate the patient for the presence of other head or neck injuries if they have a nasal fracture. Associated head and neck injuries take priority for management and evaluation as they can result in significant morbidity. Subcutaneous emphysema may be found in nasal trauma cases, as well as with simple lamina papyracea fractures, and nose blowing. Scleral chemosis, subconjunctival hemorrhage, eyelid edema, periorbital ecchymosis, or subconjunctival hemorrhage may all be associated with a complex facial fracture or an isolated nasal fracture. A history of anosmia indicates a possible cribriform plate fracture. Evaluate the patient for cerebrospinal fluid rhinorrhea and the presence of beta$_2$-transferrin.[1] Consider obtaining axial and coronal computed tomography scans of the paranasal sinuses with possible cisternography.

The nose consists of the external nose and the septum. The external nose consists of the bony upper third, the cartilaginous lower third, and the surrounding soft tissue and skin (**Figure 170-2**). The bony part consists of the paired nasal bones, the frontal processes of the maxillary bones, and the nasal processes of the frontal bones. The inferior nasal bones are thinner than the superior nasal bones. Thus, the lower bony portion is the most common area of the external nose to be fractured.

The cartilaginous components consist of the arched paired upper lateral cartilages and the horseshoe-shaped paired lower lateral cartilages. The former articulates with the cartilaginous septum and nasal bones, while the latter has ligamentous attachments to each other in front of the cartilaginous septum. The lower and upper lateral cartilages articulate with each other and form a crucial part of the nasal valve, the critical control point of nasal resistance, and obstruction. Any of these relationships can become dislocated from a traumatic impact and will require repair for an optimal functional and aesthetic outcome. The more lateral sesamoid cartilages are relatively unimportant in these regards.[15]

The bony nasal septum consists of the perpendicular plate of the ethmoid bone, the vomer, the anterior nasal spine, the maxillary crest, and the palatine bone (**Figure 170-3**). The perpendicular plate of the ethmoid bone is thin, except at its articulation with the vomer and cartilaginous septum. **The perpendicular plate of the**

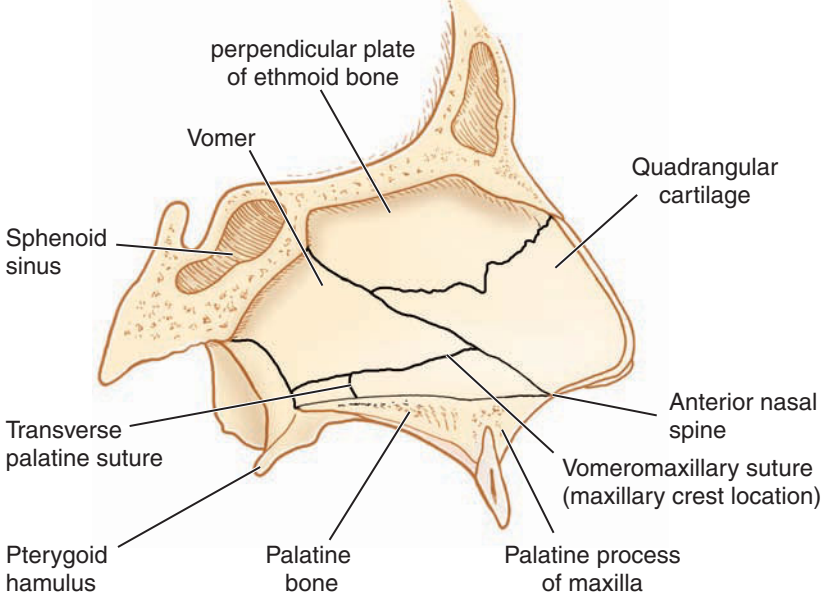

FIGURE 170-3. Anatomy of the nasal septum.

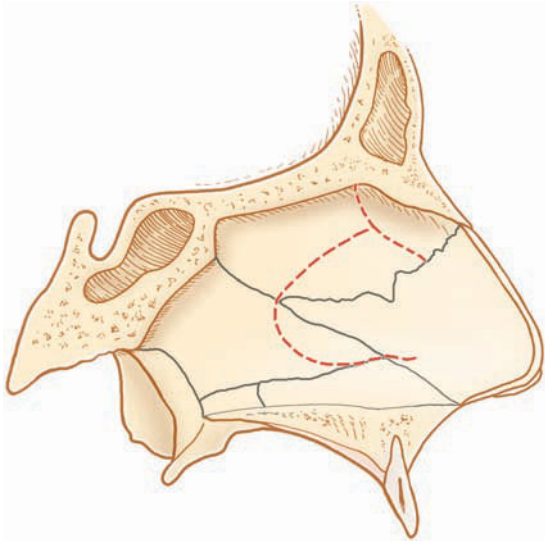

FIGURE 170-4. Schematic illustration of a common nasal septal fracture pattern. The fracture proceeds from the area of the maxillary crest, through the vomer, and up into the perpendicular plate of the ethmoid like a backward "C" going up into a "T".

ethmoid bone is the most common location for a septal fracture. The quadrangular cartilage of the septum is anteriorly located on the maxillary crest. It can be dislocated into either nostril with a significant force, especially from an inferior direction, and result in nasal airway obstruction.[5]

The bony nasal septal fracture is often similar, regardless of whether the etiology is a frontal or lateral impact (**Figure 170-4**). It usually begins just posterior to the nasal spine, at or just above the maxillary crest. The fracture can progress through this area and straight into the vomer where it curves like a "C," vertically upward and into the perpendicular plate of the ethmoid bone.[16]

Nasal fractures increase in severity from a unilateral depression without a septal fracture, to a nasal twist or deviation, to a significantly comminuted nasal fracture as the frontal or lateral force of impact increases (**Figure 170-5**). Between these extremes are the moderately severe bilateral fractures with the contralateral side being driven outward and more significantly impacted traumas, such as the previously described C-shaped septal fracture with overriding and interlocked fragments. This latter condition often appears as the classically shortened and twisted nose with tip ptosis from columellar retraction. There is often significant nasal airway obstruction as the quadrangular cartilage telescopes over the perpendicular plate of the ethmoid, causing thickening at this point and the appearance of a bilaterally deviated nasal septum.[17]

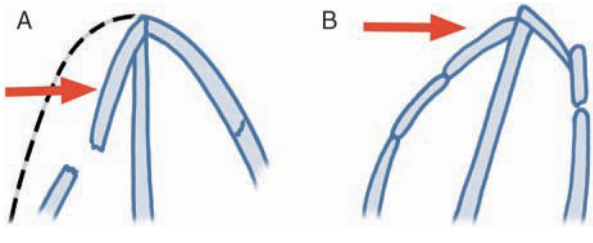

FIGURE 170-5. Nasal fractures resulting from lateral forces. **A.** Unilateral nasal fracture. **B.** Bilateral nasal fracture. The arrows depict the direction of the force of impact.

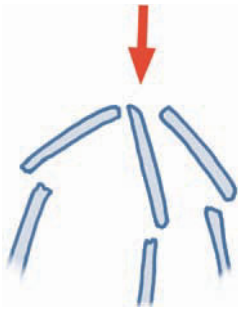

FIGURE 170-6. An "open book" nasal fracture resulting from a frontal impact.

The more common lateral force shifts the bony pyramid laterally (**Figure 170-5**), while a frontal impact broadens the nose. "Open book fractures" may occur in pediatric patients due to the open, midline suture of the nasal bones. This results in each of the nasal bones being shifted laterally (**Figure 170-6**). Children have fewer nasal fractures because of their smaller and more cartilaginous (i.e., more elastic) noses.[18,19] Greenstick fractures are more likely in children because of their resilient noses and can be present when it is not apparent externally.[20,21]

INDICATIONS

Attempt to reduce nasal fractures within the first 3 hours after the trauma, before significant edema develops. Otherwise, perform the reduction 3 to 10 days after the injury when the edema subsides. The indications for a closed nasal reduction include unilateral or bilateral nasal bone fractures, with or without a nasal septal fracture. Interestingly, one study found that 30% of nasal fractures that underwent closed nasal reduction were still malaligned postoperatively.[17] Strongly consider reduction under procedural sedation or general anesthesia for pediatric nasal fractures.

CONTRAINDICATIONS

There are no absolute contraindications to nasal fracture reduction as long as the timing, the patient's health status, and associated injuries are considered. The proper approach varies by the extensiveness of the fracture. Open nasal reduction is required for more severe nasal fractures, especially those with C-shaped septal fractures and cartilage telescoping over the perpendicular plate of the ethmoid bone.[3] Some authors have defined the indications for this more aggressive approach as being a nasal pyramid deviation exceeding one-half of the width of the nasal bridge.[17] Consider using an open approach, either during the same setting or within a few days, if deformities persist after closed reduction. Relative indications for the open approach include fracture-dislocations of the caudal septum, open septal fractures, septal hematomas, displaced fractures of the anterior nasal spine, associated alar cartilage deformities, or recent intranasal surgery. An open approach may be required if an extensive septal deformity exists.[2] Otherwise, the nasal deformity will be difficult to reduce against the interlocked forces.[2]

EQUIPMENT

- Headlight with light source, or overhead light
- 5 mL syringe
- 27 gauge needle, 1.5 inches long
- 25 gauge spinal needle
- Local anesthetic solution containing 1:100,000 epinephrine

FIGURE 170-7. Nasal fracture reduction instruments. From left to right: an elevator, a Walsham forceps, and an Asch forceps (with rubber tubing on one tong).

- Oxymetazoline nasal spray
- 4% cocaine, 4 mL
- Other nasal decongestants and anesthetics (Chapter 172 and **Table 172-1**)
- Surgical cotton paddies, 0.5 × 2 inches
- Bayonet forceps
- Walsham forceps (**Figure 170-7**)
- Asch forceps (**Figure 170-7**)
- Rubber tubing
- Boies nasal fracture elevator (**Figure 170-7**)
- Killian nasal speculum
- Silastic nasal splints or Goldsmith splints
- Antibiotic impregnated strip gauze or nasal tampon
- Plaster of Paris splinting/casting material
- 5-0 plain gut suture
- Paper tape, 1 inch wide
- Benzoin solution

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Significant complications include patient dissatisfaction, the possible need for open reduction within 2 weeks, and formal nasal reconstruction months later. Other potential complications (all of much lower probability) include adverse reactions to the local anesthetics, excessive bleeding, infection, saddle nose deformity, septal perforation, CSF rhinorrhea, and/or visual disturbances. Almost all of these complications can result from the reduction procedure, but also from the nasal fracture without and reduction attempts. Obtain an informed consent for the procedure.

Place the patient sitting upright in a multiposition procedure chair, or on a stretcher, with the head elevated to decrease blood flow and bleeding. Obtain an objective measure of the degree of lateral displacement. Draw a perpendicular line from the midpoint of the interpupillary line and extending downward to the base of the nasal columella. A point one-third of the way down from the cephalic end is the reference point for any deviation.[22] Consider the administration of parenteral analgesics, sedatives, or procedural sedation. Refer to Chapter 129 regarding the details of procedural sedation and analgesia. Obtain a prereduction photograph of the patient's face and nose, if possible.

NASAL ANESTHESIA

Anesthetize the nasal mucosa. Insert a nasal speculum. Apply oxymetazoline nasal spray bilaterally to decongest the nasal mucosa. Place 4 mL of 4% cocaine onto cotton pledgets. Cocaine is a vasoconstrictor, a decongestant, and an anesthetic. Insert the nasal speculum and pack the cocaine-soaked pledgets into the nose using a bayonet forceps (**Figures 170-8A, 9, & 10**). Ideally, place four

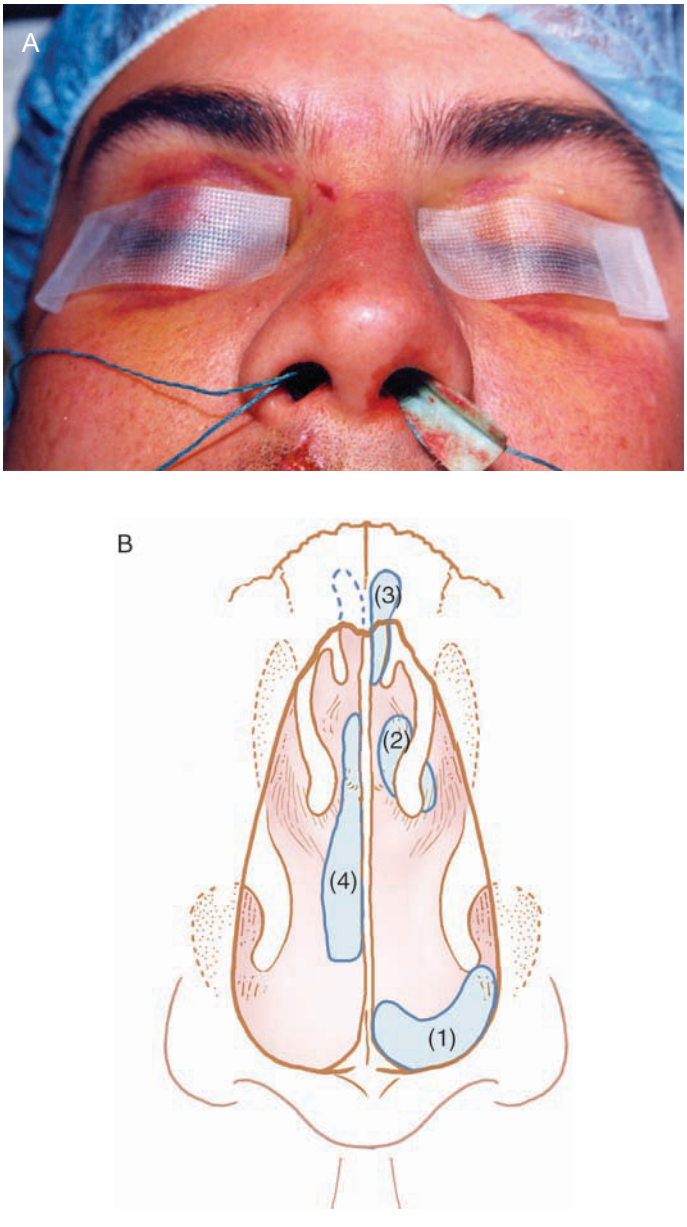

FIGURE 170-8. Topical anesthesia of the nasal mucosa. **A.** Surgical cotton pledgets soaked with cocaine placed in the nares. **B.** Typical sites for placement of the pledgets: (1) nasal floor, (2) posterior aspect of middle and inferior turbinate, (3) intranasal dorsum, and (4) along the nasal septum.

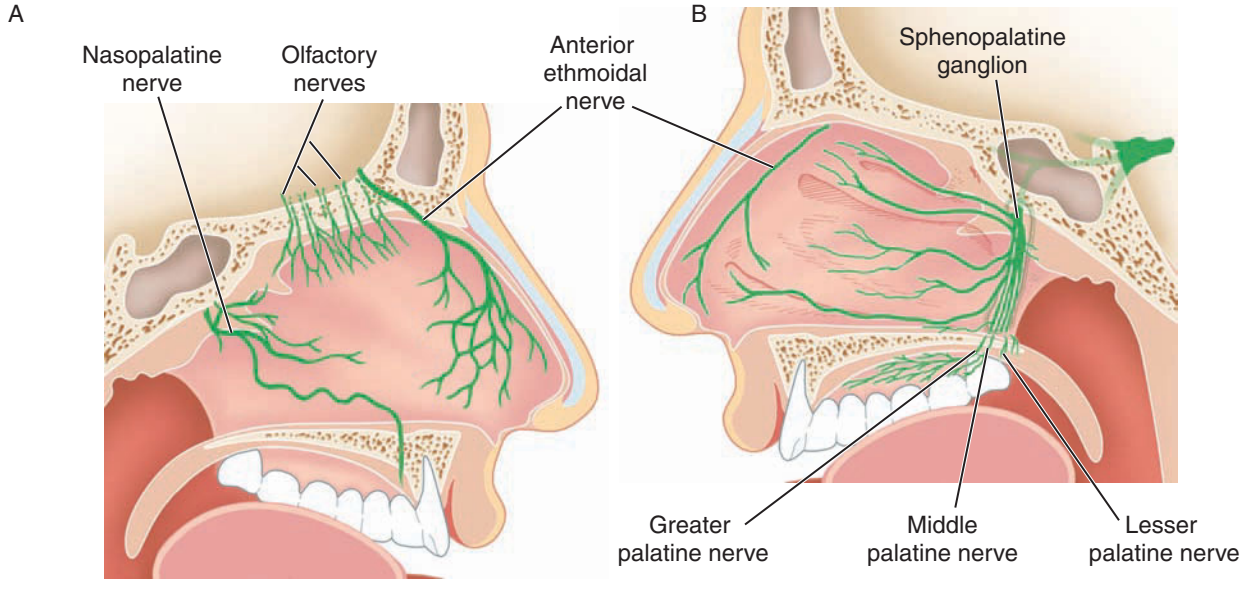

FIGURE 170-9. Nerve supply of the nasal mucosa. **A.** The nasal septum. **B.** The lateral nasal wall.

pledgets in each nostril at the strategic points of the neurovascular supply (**Figure 170-8B**). These areas include the posterior edge of the middle turbinate (sphenopalatine ganglion and artery), the anterior to middle turbinate and opposing septum (anterior ethmoid nerve and artery), the nasal floor (branches of both nerves and arteries), and the midseptum (branches of both nerves and arteries).[6,15] Allow the cocaine pledgets to remain in the nasal cavity for 10 minutes. Other anesthetics, decongestants, and anesthetic–decongestant combinations can be used depending upon availability. Refer to Chapter 172 for a more complete discussion of topical nasal anesthesia and decongestion.

Inject local anesthetic solution to anesthetize the remainder of the nose. The most commonly used agent is 1% or 2% lidocaine containing 1:100,000 epinephrine.[23] Acidosis from the injured tissues can make local anesthesia less effective. The addition of sodium bicarbonate, at a 1:10 dilution, will counteract the acidosis and lessen the discomfort from the injection.[24]

Perform the local anesthetic injections intranasally to avoid the added pain of puncturing through the skin (**Figures 170-11 & 12**). Infiltrate subcutaneously to anesthetize the external, nasal, infratrochlear, and infraorbital branches of the trigeminal nerve.[3,4] Insert the needle into the nasal cavity. Infiltrate along the nasal floor to anesthetize the superior alveolar nerve and ganglion. Infiltrate posterior to the inferior and middle turbinates to block the sphenopalatine nerve and ganglion. Allow 10 to 15 minutes for the local anesthetic agent to take effect. Assess the adequacy of the anesthesia using pinprick of the nasal mucosa. If intranasal injections are performed properly in a patient who is under procedural sedation and analgesia, the rare but potentially serious complications of using topical cocaine may be avoided. One

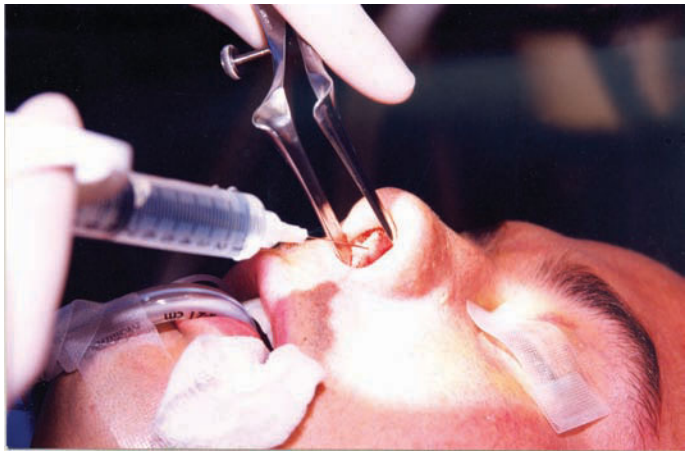

FIGURE 170-11. Intranasal injection with speculum exposure and a fine needle.

paper proposed using EMLA (eutectic mixture of local anesthetics) cream externally and cocaine intranasally.[25] This has yet to become a broadly accepted technique. The Emergency Physician may not feel comfortable with the technique of intranasal injection and the nerves may be anesthetized percutaneously as described in Chapter 126.

TECHNIQUES

NASAL BONE REDUCTION

Several studies have demonstrated that closed nasal reduction is 80% to 95% successful.[8,26] Measure the distance from the nostril rim to the nasofrontal angle in order to avoid putting the blade in too far (**Figure 170-13A**). Insert one blade of the Asch forceps, one blade of the Walsham forceps, or a Boies nasal fracture elevator into the nostril to the measured distance. Place the instrument against the depressed nasal bone. Apply a gentle upward and outward force while simultaneously applying digital counterpressure to guide the bone into reduction (**Figure 170-13B**). Alternatively, cover the other blade of the Asch or Walsham forceps with rubber tubing so that it can provide counterpressure to the intranasal blade during outward reduction (**Figure 170-14**).[6] Repeat the procedure on the contralateral side if there is a bilateral nasal bone fracture.

NASAL SEPTAL REDUCTION

A nasal septal fracture is often present if bilateral pyramidal fractures exist. **Always reduce the nasal bone fracture(s) before manipulating the septum.** Insert a nasal speculum and determine whether the reduction of the nasal bones results in a straightening of the septum. If not, withdraw the nasal speculum and reduce the septum with the Asch or Walsham forceps (**Figure 170-15**). Insert the forceps with one blade in each nostril. Gently close the blades of the forceps to grasp the septum. Elevate the septum upward and anteriorly to disimpact any interlocked fragments. Reinsert the nasal speculum and visualize the nasal septum. Insert a Boies or Freer elevator under direct visualization and straighten the septum more precisely.

ASSESSMENT

Thoroughly evaluate the nasal cavity and nose. Determine the adequacy of the reduction procedure. Determine visually whether the nasal bones and the nasal septum are reduced. Consult an Otolaryngologist if the manipulations fail to provide a satisfactory reduction, if the fracture appears too comminuted, or if the nose or septum is too deviated for a closed approach. The patient may require open reduction 2 weeks from the day of the trauma. **Perform a thorough examination to rule out an associated septal hematoma. This must be evacuated and managed to prevent complications.** Refer to Chapter 171 regarding the details of managing a nasal septal hematoma. Attempt to suture any nasal septal mucosal tears that exist from the fracture or the reduction procedure using 5-0 plain gut suture. Warn the patient of the potential for a septal perforation that can lead to chronic crusting, bleeding, or an audible whistling. Obtain postreduction photographs of the nose, if possible. Place the prereduction and postreduction photographs in the patient's medical record.

AFTERCARE

Brace the septum for stability with bilateral Silastic splints for 5 to 10 days. This also helps to prevent the formation of a nasal septal hematoma. Doyle or Goldsmith septal splints have lumens that

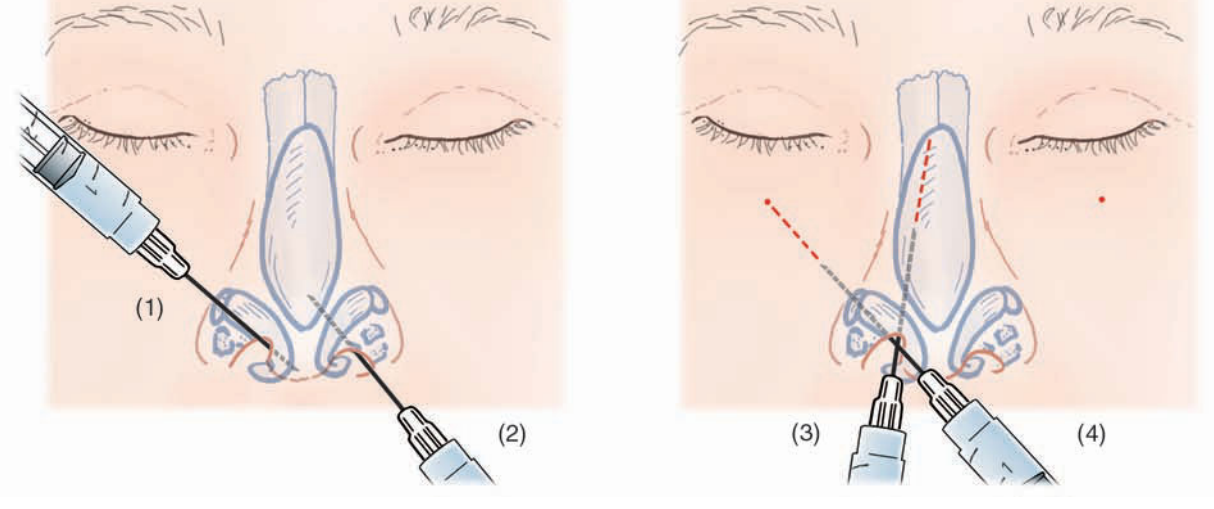

FIGURE 170-12. Intranasal injection of local anesthetic solution: (1) the nasal spine, (2) the nasal tip, (3) the nasal dorsum along the outside of the nasal bones, and (4) the infraorbital nerve.

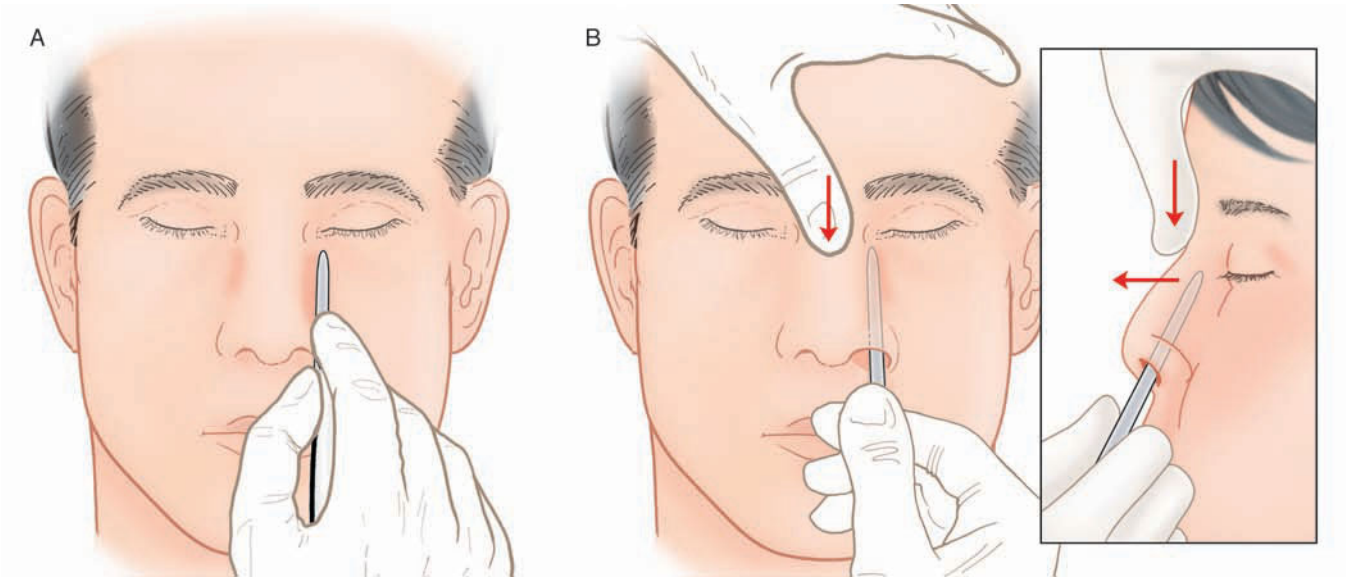

FIGURE 170-13. Closed reduction of a nasal fracture. **A.** Measure the nostril to nasofrontal angle (N-NFA) distance with the Boies elevator or another instrument. **B.** Place the elevator or forceps intranasally, just less than the N-NFA distance, and elevate the depressed bone. Simultaneously reduce the contralateral nasal bone downward.

allow the patient to nasally breathe in the postoperative period. These splints must be kept open by the patient applying six drops of hydrogen peroxide to each nostril three times a day, while avoiding swallowing this solution. A simpler and more convenient alternative is bilateral anterior nasal packing. The equipment is readily available in every Emergency Department. This is especially useful in cases of epistaxis. Apply bilateral petrolatum impregnated gauze ribbon, iodinated gauze ribbon, nasal sponges/tampons, or balloon catheters. **Avoid overpacking the nasal cavity as this can splay out the fractured nasal bones.**[6]

All patients with nasal packing must be placed on oral antibiotics with gram-positive and gram-negative coverage, such as cefazolin (Keflex), for the duration of the packing. This will aid in the prevention of a sinusitis or toxic shock syndrome. Leave the nasal packing in place for 1 to 7 days depending upon the amount of manipulation, the amount of bleeding, and Emergency Physician preference. Avoid nasal splinting and packing in patients with nasal fractures requiring a minor degree of manipulation, especially when patients are assessed to have a low probability of follow-up and compliance.

Consider applying an external splint in addition to the internal splint or nasal packing. Some authors do not advocate external splinting and its use is based on Emergency Physician preference. The splint serves to support the healing fracture and to remind the patient to keep their nose protected. Cleanse the skin of the nose and the surrounding area with alcohol. Apply benzoin solution to the nose and surrounding area. Allow the benzoin to dry and become tacky. Apply 1 inch wide paper tape in horizontal strips,

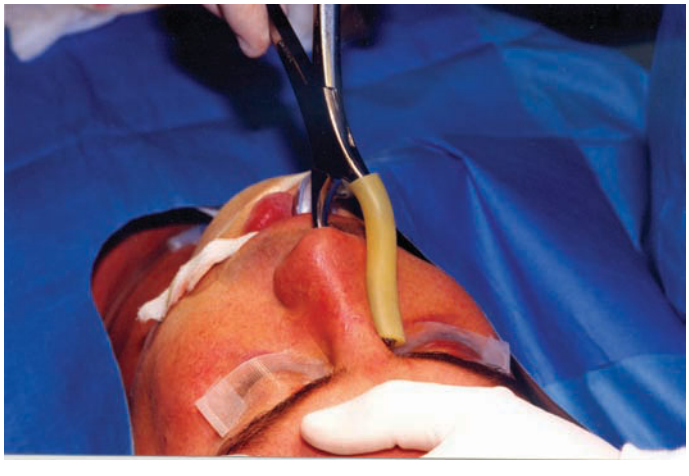

FIGURE 170-14. Placement of nasal reduction forceps. Note the rubber tubing over the outer tong to protect the skin.

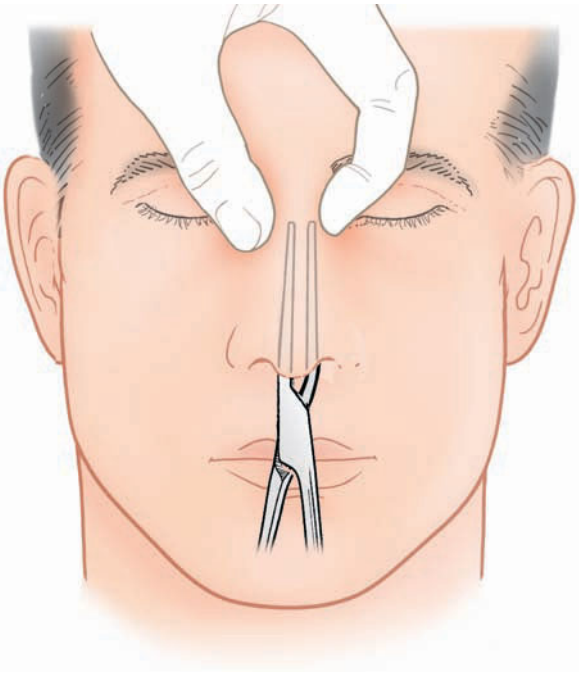

FIGURE 170-15. The Asch forceps to elevate a frontal/inferior force fracture and straighten the associated deviated nasal septum.

FIGURE 170-16. Postreduction Denver splint applied after appropriate taping and midline vertical foam rubber placement.

layered downward from the nasofrontal angle to the tip of the nose. Apply benzoin solution over the tape. Allow the benzoin to dry and become tacky. Apply three to five layers of 2 inch wide orthopedic plaster of Paris over the tape. Alternatively, apply an appropriately sized Denver aluminum or Thermoplast splint over the tape (**Figure 170-16**). Ensure that the foam rubber strut is placed vertically over the midline length of the nose to prevent any skin necrosis. Place tape over the splint to secure it.

Instruct the patient to return to the Emergency Department for excessive bleeding, increased pain, a purulent or foul nasal discharge, or a fever. Prescribe acetaminophen supplemented with narcotic analgesics as needed. Instruct the patient to avoid aspirin containing products and nonsteroidal anti-inflammatory drugs as they can increase the risk of bleeding. Arrange follow-up with an Otolaryngologist or Plastic Surgeon within 24 to 48 hours to assess the reduction and the need for further management.

COMPLICATIONS

Pack (or repack) the nasal cavity, after providing adequate local anesthesia, if bleeding occurs. A septal hematoma is likely if a patient complains of persistent or excessive pain, has noticeable nasal widening, and has an ecchymotic septum. This must be evacuated as described in Chapter 171. Infection, cartilage necrosis, and disfiguring nasal dorsal saddling may occur if the septal hematoma is not evacuated. A nasal dorsal hematoma can occur as well and must be recognized and evacuated. Cerebrospinal fluid rhinorrhea and visual impairment are rare complications of the nasal manipulation, but more likely complications of the original trauma. Cerebrospinal fluid rhinorrhea can be delayed from the initial trauma until the edema has subsided. The reduction may be inadequate and require further closed or open reduction.

SUMMARY

Nasal fractures may be reduced and repaired in the Emergency Department using a closed technique. Perform the reduction, ideally within 3 hours of the injury, before significant edema occurs. It is otherwise best to wait until the swelling subsides in approximately 1 week. Repair nasal septal fractures at the same time as the nasal reduction. Severe fractures sometimes require an open reduction. Photographic and radiographic documentation can be important medicolegally as part of the preoperative evaluation. Drain any septal or nasal dorsal hematomas. Internal and external splinting is useful to help insure good postoperative healing. Antibiotics are essential if nasal packing is applied.

171 Nasal Septal Hematoma Evacuation

Michael Friedman, Meghan Wilson, and George Chiampas

INTRODUCTION

Soft tissue and bony injuries of the nose are common because the nose is centrally located and the most anteriorly protruding structure of the face.[1] **Suspect a nasal septal hematoma, although an uncommon complication of nasal trauma, in any individual who has sustained a nasal injury.[2,3] All individuals who have sustained nasal trauma must undergo a careful examination of the septum and nasal passages, regardless of the mechanism of injury or the findings on external examination.[2]**

Blunt trauma, either intentional or unintentional, is the most common cause of a nasal septal hematoma. Consider a bleeding diathesis if the hematoma develops after a seemingly trivial injury.[2,4,5] Other etiologies include sports injuries and child abuse.[5,6] Iatrogenic nasal septal hematomas following nasal septal surgery are probably more common than reported in the literature. Evaluate patients who have had recent nasal surgery and present with complaints of pain and nasal obstruction for a possible nasal septal hematoma.

Nasal septal hematomas are characterized by severe localized nasal pain, tenderness on palpation of the nasal tip, and a cherry-like swelling or bluish discoloration of the nasal mucosa emanating from the septum that obstructs all or a portion of the nasal passage[1–3,7] (**Figures 171-1 & 2**). Evacuation must be performed to prevent complications.[1,2,4,5] Patients require bilateral nasal packing, oral antibiotics, and close follow-up with an Otolaryngologist to prevent complications following the evacuation of the hematoma.[2,4,8]

Distinguishing an uncomplicated nasal septal hematoma from one that has become infected is difficult, particularly if there has been a delay of several days in seeking medical attention following the injury.[2] Nasal septal abscesses are a rare complication of nasal septal hematomas that occur following nasal trauma. Nasal septal abscesses generally are larger and more painful than uncomplicated nasal septal hematomas. The overlying nasal mucosa is inflamed and occasionally has an inflammatory exudate.[2] Local extension of the infection, if left untreated, into the cavernous sinus with subsequent intracranial infection is the most important potential

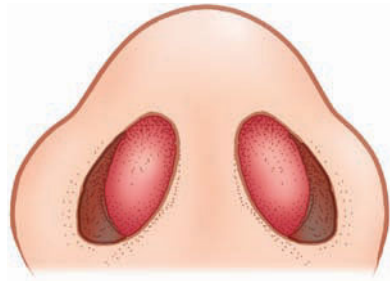

FIGURE 171-1. Bilateral nasal septal hematomas creating a partial obstruction.

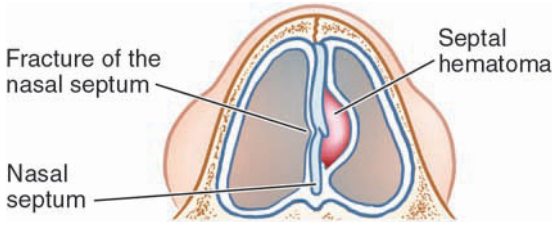

FIGURE 171-2. A small left-sided nasal septal hematoma.

complication.[5,8] The most common complication of a nasal septal abscess is cartilage necrosis that results in nasal structural collapse and a saddle nose deformity (**Figure 171-3**).

ANATOMY AND PATHOPHYSIOLOGY

The nose is both a sensory organ and a respiratory organ. It performs an important function for the entire body by providing both physical and immunologic protection from the environment.[9] The nose aids in the formation of basic speech sounds.[9] The supporting structure of the nose consists of bone, cartilage, and connective tissue. The nose, on frontal view, is in the shape of a pyramid of which approximately the upper two-fifths comprise the bony vault and the lower three-fifths comprise the cartilaginous vault. The upper narrow end joins the forehead at the glabella and is referred to as the root of the nose. The two nares are separated from each other by a skin-cartilage septum known as the columella.[9,10] The cartilaginous framework of the nose provides both its structure and function. **The septal cartilage is avascular and receives its blood supply from the adherent mucoperichondrium.**

The skin covering the external nose is thin and contains an areolar type of subcutaneous tissue. The skin is loosely attached over the upper half. The skin over the lower half of the nose is intimately bound to the lower lateral cartilage and may sometimes be thick, fatty, and contain sebaceous glands.[9,10]

The precise mechanism for a nasal septal hematoma formation following nasal trauma is not known. Nasal septal hematomas are thought to occur when a mechanical force to the nasal cartilage results in rupture or leakage from the perichondrial blood vessels of the nasal septum. In instances where the nasal cartilage is fractured, blood may dissect through the fracture line and form bilateral septal hematomas. Most nasal septal hematomas are secondary to a fracture or surgery. Thus, they almost always distend the mucoperichondrium on both sides of the nose. Accumulation of the extravasated blood strips the perichondrium from the cartilage, forming a closed space in which the blood accumulates (**Figure 171-2**). **The nasal septal hematoma, when not recognized initially and evacuated promptly, can expand and mechanically obstruct the blood vessels that supply the nasal cartilage. Pressure-induced avascular necrosis of the nasal septal cartilage can develop rapidly because there is no alternative blood supply to the cartilage.**[1–3,7] The accumulated blood and necrotic tissue can form a nidus for infection from bacteria that colonize the nasal mucosa.[1–3,7]

Cartilage necrosis subsequently leads to the saddle nose deformity. The term "saddle nose deformity" is a nonspecific description of a nose with a depression over its dorsal surface[9] (**Figure 171-3**). The saddle nose deformity is a result of the nasal septal cartilage becoming ischemic from loss of its blood supply, subsequent nasal septal cartilage resorption and collapse, and the lack of support for the nasal bridge. The deformity is the ultimate result of a nasal septal hematoma or abscess not being evacuated. Necrosis with subsequent fibrosis may develop causing a permanent thickening or absorption of the nasal septum with partial obstruction of the nasal airway.[7–9]

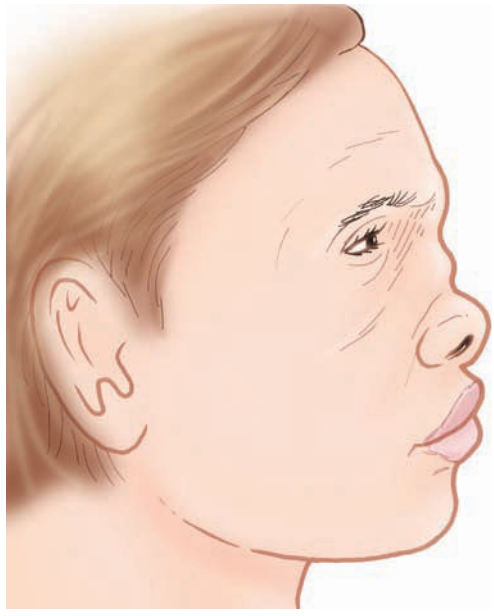

FIGURE 171-3. The saddle nose deformity.

The sphenopalatine branches of the internal maxillary artery and the ethmoidal arteries from the ophthalmic artery supply the internal nose. The veins terminate in the anterior facial and ophthalmic veins.[10] Venous drainage is clinically important in understanding the complications of a septal abscess. Branches of the trigeminal nerve provide sensory innervation to the nose.[9,10]

INDICATIONS

Any significant nasal septal hematoma requires evacuation. A nasal septal hematoma may progress to form an abscess with associated complications of avascular necrosis of the nasal septum, meningitis, or cavernous sinus thrombosis in as little as 3 to 4 days.[7,8] It is not urgent to evacuate a simple nasal septal hematoma in the Emergency Department as complications occur over a period of days. It is essential, however, to identify a nasal septal hematoma so that a treatment plan is initiated and to rule out a septal abscess that does require immediate evacuation.[5]

CONTRAINDICATIONS

There are no absolute contraindications to the evacuation of a nasal septal hematoma. Address any life-threatening or serious injuries or conditions prior to drainage of the nasal septal hematoma. This procedure requires a cooperative patient to prevent secondary iatrogenic injury. Any patient that is uncooperative, unable to follow instructions, very young, or that has an altered mental status may require evacuation under procedural sedation or general anesthesia.

EQUIPMENT

- Headlight
- Nasal speculum
- Nasal vasoconstrictor (e.g., 2% ephedrine. 0.25% oxymetazoline or phenylephrine)
- Nasal anesthetic (e.g., 4% cocaine, 2% pontocaine, and 4% lidocaine)

- Nasal atomizer device, optional
- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Cotton-tipped applicators
- 1 mL and 10 mL syringes
- 25 or 27 gauge needle, 1½ inches long
- Local anesthetic solution containing epinephrine, lidocaine, or bupivacaine
- #15 surgical blade on a handle
- Frazier suction catheter
- Suction source and tubing
- Nasal speculum
- Bayonet forceps
- Nasal tampon or sponge
- Iodoform gauze

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Obtain a signed consent for the procedure. Aseptic technique should be followed and maintained throughout the procedure. The procedure is considered clean, but not sterile, as the nasal mucosa can never be sterilized. It is crucial, however, that the instruments are sterile.

Administer anesthesia for the evacuation of a nasal septal hematoma by one of two routes: topical application with supplemental infiltration or a regional block. Some authors recommend using both techniques. However, most nasal septal hematomas can be adequately evacuated with topical anesthesia supplemented by local infiltration.[7] Dampen the swabs of four cotton-tipped applicators with either a solution of 2% pontocaine with ephedrine or cocaine. Insert a nasal speculum to expose one nostril. Gently insert the applicator beneath the roof of the nose so that it reaches the branches of the anterior ethmoidal nerve. Pause until some vasoconstriction and anesthesia takes place, if it meets resistance on insertion, and advance the applicator further (**Figure 171-4**). Pass an applicator into the nasal fossa and move it from the floor of the nasal vestibule, across the midportion of the inferior turbinate, and reaching the posterior aspect of the middle turbinate in the region of the sphenopalatine foramen.[11] Infiltrate a maximum of 0.5 mL of local anesthetic solution containing epinephrine, if additional anesthesia is desired, through the mucoperichondrium and circumferentially around the hematoma.

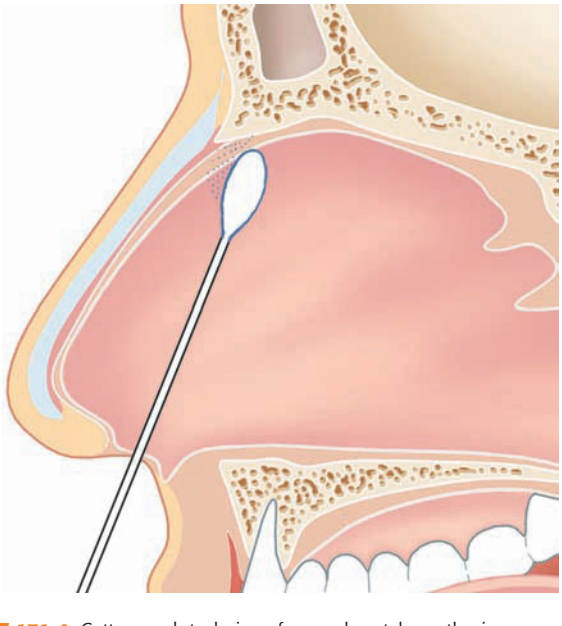

FIGURE 171-4. Cotton swab technique for nasal septal anesthesia.

An atomizer or nasal spray bottle can provide an alternative and commonly used method for nasal septal anesthesia. While an actual atomizer is not often available in the Emergency Department, its use is less painful to the patient than the application of cotton-tipped applicators into the nasal cavity. Alternatives to an atomizer are devices to attach to a syringe to atomize the contents or using a commercially available nasal spray container after emptying its contents. Mix equal amounts of 2% pontocaine or 4% lidocaine with ephedrine and place this in the atomizer or nasal spray bottle. Insert the nasal speculum to gain access to the entire nasal cavity. Open the nasal speculum vertically to expose as much of the nasal septum as possible. Insert the atomizer or nasal spray bottle into the nostril. Instill two puffs of solution into the nostril. Allow 5 to 10 minutes for the anesthetic to take effect. Infiltrate a maximum of 0.5 mL of local anesthetic solution containing epinephrine, if additional anesthesia is desired, through the mucoperichondrium and circumferentially around the hematoma.

Confirm the presence of a septal hematoma. Compress the area with a cotton-tipped applicator. The bulge from the hematoma is compressible with the applicator. It should not shrink with the application of a topical vasoconstrictor.[2,6]

TECHNIQUES

ASPIRATION

Some authors feel that simple aspiration with an 18 gauge needle may be adequate for a small, early hematoma. Most patients require a more extensive evacuation as clotted blood cannot be removed with aspiration. Since blood clots form within minutes and remain in clotted form for days, needle aspiration is generally not effective. Simple aspiration may, however, be used to diagnosis a septal hematoma.[6–8] Insert the nasal speculum. Open the nasal speculum vertically so that the nasal septum is maximally visible. Instruct an assistant to hold the nasal speculum in position and open, allowing the Emergency Physician to have both hands free to perform the procedure. Insert an 18 gauge needle, attached to a 10 mL syringe, into the nasal septal hematoma. Aspirate the contents of the hematoma. No additional procedure is necessary if the hematoma can be completely evacuated by aspiration. Simple clinical assessment of the septum is the guide to determine if the hematoma has been evacuated. Apply a nasal pack as described below.

INCISION AND DRAINAGE

The incision and drainage technique is the primary procedure to drain a nasal septal hematoma. Cleanse the skin surrounding the nares of any dirt and debris. Apply an alcohol swab, povidone iodine, or chlorhexidine to the area and allow it to dry. Insert the nasal speculum. Open the nasal speculum vertically so that the nasal septum is maximally visible. Instruct an assistant to hold the nasal speculum in position and open, allowing the Emergency Physician to have both hands free to perform the procedure. Make a 1.0 to 2.0 cm long vertical incision, with a #15 scalpel blade, in the septal mucoperichondrium overlying the hematoma (**Figure 171-5**). **Be cautious to not cut into the cartilaginous septum.** The length of the incision depends upon the size of the nasal septal hematoma. Some authors prefer to use an L-shaped incision in the mucoperichondrium.[12–16]

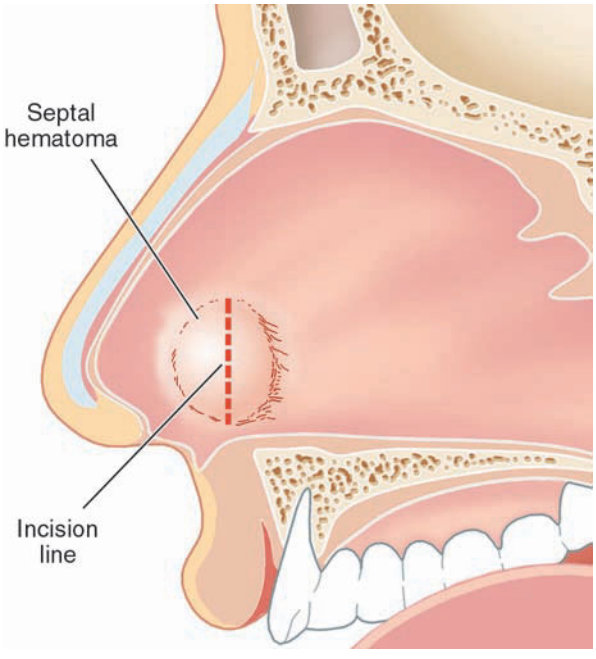

FIGURE 171-5. Nasal septal hematoma with markings for a vertical incision through the mucoperichondrium.

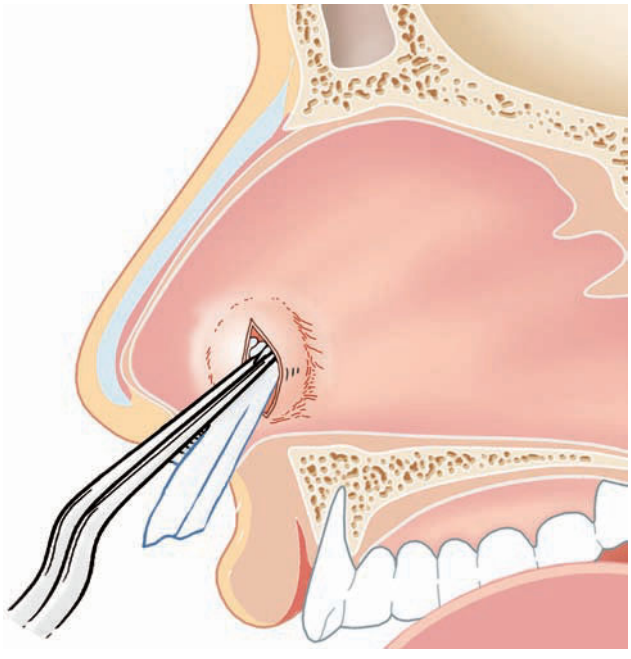

FIGURE 171-6. Iodoform gauze is placed between the separated mucoperichondrium and the cartilaginous septum.

These authors feel that this incision allows the mucoperichondrium to reposition flat against the cartilaginous septum. The choice of incision type is left to the preference of the Emergency Physician.

Use the Frazier suction catheter to gently evacuate any clot or necrotic debris from the hematoma cavity. Clots are difficult to evacuate by suction and may require mechanical removal. Always send a sample of the fluid or hematoma to the laboratory for Gram's stain, anaerobic cultures, and aerobic cultures.[2,7,8] Apply topical antibiotic ointment over the incision, a wick, and nasal packing as described below.

A bilateral septal hematoma can, almost always, be evacuated from one side. Apply gentle pressure to the contralateral hematoma to express it out the incision. Make a second vertical incision contralaterally, either anterior or posterior to the first incision to prevent septal perforation, if complete evacuation is not achieved unilaterally.

WICK INSERTION

Insert a wick of 1/8 inch iodoform gauze through the incision (**Figure 171-6**). Allow 1 inch of the wick to extend into the nasal cavity for easy removal. **Be careful to ensure that the wick is flat between the mucoperichondrium and the cartilaginous septum. Do not pack the cavity with the wick.** Some authors recommend inserting a Penrose drain, or a piece of one, instead of the iodoform gauze.[6] This has not been found to be beneficial when compared to iodoform gauze.[6] The Penrose drain can be a substitute if iodoform gauze is not available or the patient is allergic to iodine.

NASAL PACKING

Apply bilateral nasal packs following the successful drainage of a septal hematoma. Packing inhibits the reaccumulation of the hematoma, or serous fluid, thereby preventing the severe complications associated with a septal hematoma. The use of commercially available nasal packing devices, such as nasal tampons or sponges, provides adequate protection against reaccumulation. Patients report such devices to be significantly more comfortable than traditional gauze packing. This, coupled with the ease of insertion when compared to gauze packing, has made such devices very popular.

Place the patient's head in the sniffing position. Coat a nasal tampon with a water-soluble antibiotic ointment. Insert the nasal speculum to obtain adequate visualization of the nasal septum. Grasp the nasal tampon with a bayonet forceps. Introduce the forceps with the nasal tampon in a horizontal position through the speculum. **Be careful to not tear the incision in the mucoperichondrium open or to dislodge the wick.** Place the nasal tampon on the floor of the nasal cavity and against the nasal septum.[8] Withdraw the bayonet forceps and the nasal speculum. Repeat the nasal packing procedure on the contralateral side. Both nasal cavities must be packed to maintain the septum in the midline, prevent bowing of the septum into the contralateral nasal cavity, and the reaccumulation of the hematoma. Refer to Chapter 172 regarding the complete details of nasal packing.

PEDIATRIC CONSIDERATIONS

Nasal septal hematomas can occur at any age. The diagnosis and treatment are the same for adult and pediatric patients. Generally, however, any treatment for children would be done under procedural sedation in the Emergency Department or general anesthesia in the operating room.

AFTERCARE

Proper follow-up is vital to prevent any infectious process or cosmetic deformity. All patients must be reevaluated within 24 hours and again in 48 hours for removal of the nasal packs. Prescribe acetaminophen and narcotic analgesics for pain control. Prescribe broad-spectrum antibiotics, specifically those with staphylococcal coverage, as prophylaxis against infection and the development of a septal abscess.[6] Instruct the patient to avoid nonsteroidal anti-inflammatory drugs as they increase the risk of bleeding. Provide all patients with proper discharge instructions. They should

return to the Emergency Department immediately if they experience increased pain, bleeding, or a fever. Refer all patients to an Otolaryngologist within 24 hours.

COMPLICATIONS

The most common acute complication of a nasal septal hematoma is an abscess or cosmetic deformity. Complications are primarily related to incomplete evacuation or reaccumulation of the hematoma. This may be avoided by adequate removal of the hematoma with suction, placement of an iodoform gauze wick, and bilateral nasal packing. An abscess may result in ascending infections including meningitis and cavernous sinus thrombosis. *Staphylococcus aureus* is the primary pathogen isolated from the majority of reported cases, regardless of patient age. Prescribe appropriate prophylactic antibiotics.[2,5,6] Many patients cannot tolerate complete hematoma evacuation under local anesthesia. When complete evacuation is not performed, consult an Otolaryngologist and schedule the patient for evacuation under anesthesia within 24 hours. Early and/or appropriate treatment may not prevent complications if the nasal septal cartilage is already ischemic at the time of the procedure.

Other complications of nasal septal hematoma drainage are rare and include nasal bleeding, inadequate evacuation, and septal perforation. Nasal bleeding can usually be controlled with the prescribed packing. Incomplete removal of the hematoma is not a serious problem if identified. A nasal septal hematoma may reoccur if the incision is made on opposite sides of the septum. Limit the incision to one side if possible. The second incision, if required, on the contralateral side must not oppose the first incision.

SUMMARY

A nasal septal hematoma is a rare but potentially serious complication of nasal trauma. Proper management consists primarily of early recognition, prompt evacuation, wick insertion, and bilateral nasal cavity packing. Administration of antimicrobial therapy is necessary to prevent or treat a secondary nasal abscess. Follow-up with an Otolaryngologist is required within 24 hours of the procedure to evaluate for the reaccumulation of the hematoma and/or an abscess. These patients require continual follow-up until the nasal septum is healed.

172 Epistaxis Management

Stephen M. Kelanic, David D. Caldarelli, and Eric F. Reichman

INTRODUCTION

Epistaxis is an extremely common condition in the United States with an incidence estimated at 10 per 10,000 people per year.[1] It is a common reason for patient visits to the Emergency Department. There is an early peak in those less than 10 years of age.[2] The frequency of epistaxis decreases in the teens and begins to progressively increase after 20 years of age, with the highest frequency in the elderly.[2] Epistaxis usually is the result of well-localized intranasal trauma. However, it may be the initial sign of a more serious underlying systemic illness. Epistaxis is often self-limited and can be managed conservatively. Epistaxis can also manifest itself as a profuse spontaneous hemorrhage that is extremely difficult to control and result in aspiration, hypotension, cardiovascular collapse, syncope, and airway compromise.

The proper management of epistaxis and the prevention of adverse consequences depend on a timely and thorough evaluation of the patient as well as the appropriate intervention. The Emergency Physician must be familiar with a variety of techniques to control intranasal hemorrhage.

ANATOMY AND PATHOPHYSIOLOGY

An understanding of the vascular anatomy of the nasal cavity is essential to efficient and immediate control of nasal bleeding. The blood supply to the sinonasal cavity arises from both the internal and external carotid artery system (**Figure 172-1**). The sphenopalatine artery arises as one of the terminal branches of the internal maxillary artery, a branch of the external carotid system, and is the primary blood supply to the sinonasal cavities. The anterior and posterior ethmoid arteries, terminal branches of the internal carotid system, supply blood to the superior straits of the nose. The superior labial branch of the facial artery supplies the anterior nasal cavity and anastomoses with branches from the anterior ethmoid artery and the sphenopalatine artery in an area of the anterior nasal septum known as Kiesselbach's plexus or Little's area (**Figure 172-2**). **It has been estimated that 90% of all nasal bleeding occurs in the area of Kiesselbach's plexus.**[3] This is particularly true for children and young adults. Older adults tend to bleed from the posterior nasal cavity, from branches of the sphenopalatine and posterior ethmoidal arteries. This has been attributed to arteriosclerosis.[3]

Epistaxis may result from numerous local and/or systemic factors that damage the delicate mucosal lining of the nasal cavity and expose the underlying vasculature. The most common cause of epistaxis is accidental or self-inflicted trauma, often from digital manipulation of the nasal mucosa (i.e., nose picking). This eventually heals and crusts over but is subject to repeated irritation and bleeding when the patient sneezes or blows their nose. The anterior source of this bleeding makes it very easy to treat. High-velocity trauma to the region of the midface and skull base may be manifest as a severe, life-threatening hemorrhage that may be extremely difficult to control.

Local inflammatory reactions due to acute upper respiratory infections, allergic rhinitis, and chronic sinusitis may cause epistaxis.[4] The mucosa becomes inflamed, hypervascular, and is easily disrupted with forceful nose blowing. The presence of an intranasal foreign body may inflame the nasal mucosa, with consequent granulation tissue and bleeding. This should be expected if the bleeding is unilateral and associated with nasal obstruction and foul rhinorrhea.

Epistaxis may be attributed to a nasal septal deformity.[5] The deflected nasal septum creates turbulent airflow that desiccates the mucosa and leads to crusting and bleeding. Epistaxis attributed to nasal septal deviation presents just posterior to the deflection and may be difficult to control. Nasal septal perforations bleed frequently and easily from mucosal irritation and granulation tissue.

Postoperative bleeding as the result of sinonasal surgery—such as septoplasty, rhinoplasty, turbinectomy, and endoscopic sinus surgery—may also be encountered. Blood-tinged nasal secretions are to be expected for the first 2 weeks after surgery. Severe epistaxis may occur during the first postoperative week, with an estimated incidence ranging from 0.9% to 8.9%.[6] The bleeding is usually posterior, brisk, and may be difficult to control. Consult the Otolaryngologist who performed the procedure in all cases of postoperative bleeding.

Nasal bleeding may be the first sign of a sinonasal neoplasm. The bleeding is usually intermittent and often accompanied by nasal obstruction and pain. Severe bleeding is unusual except in

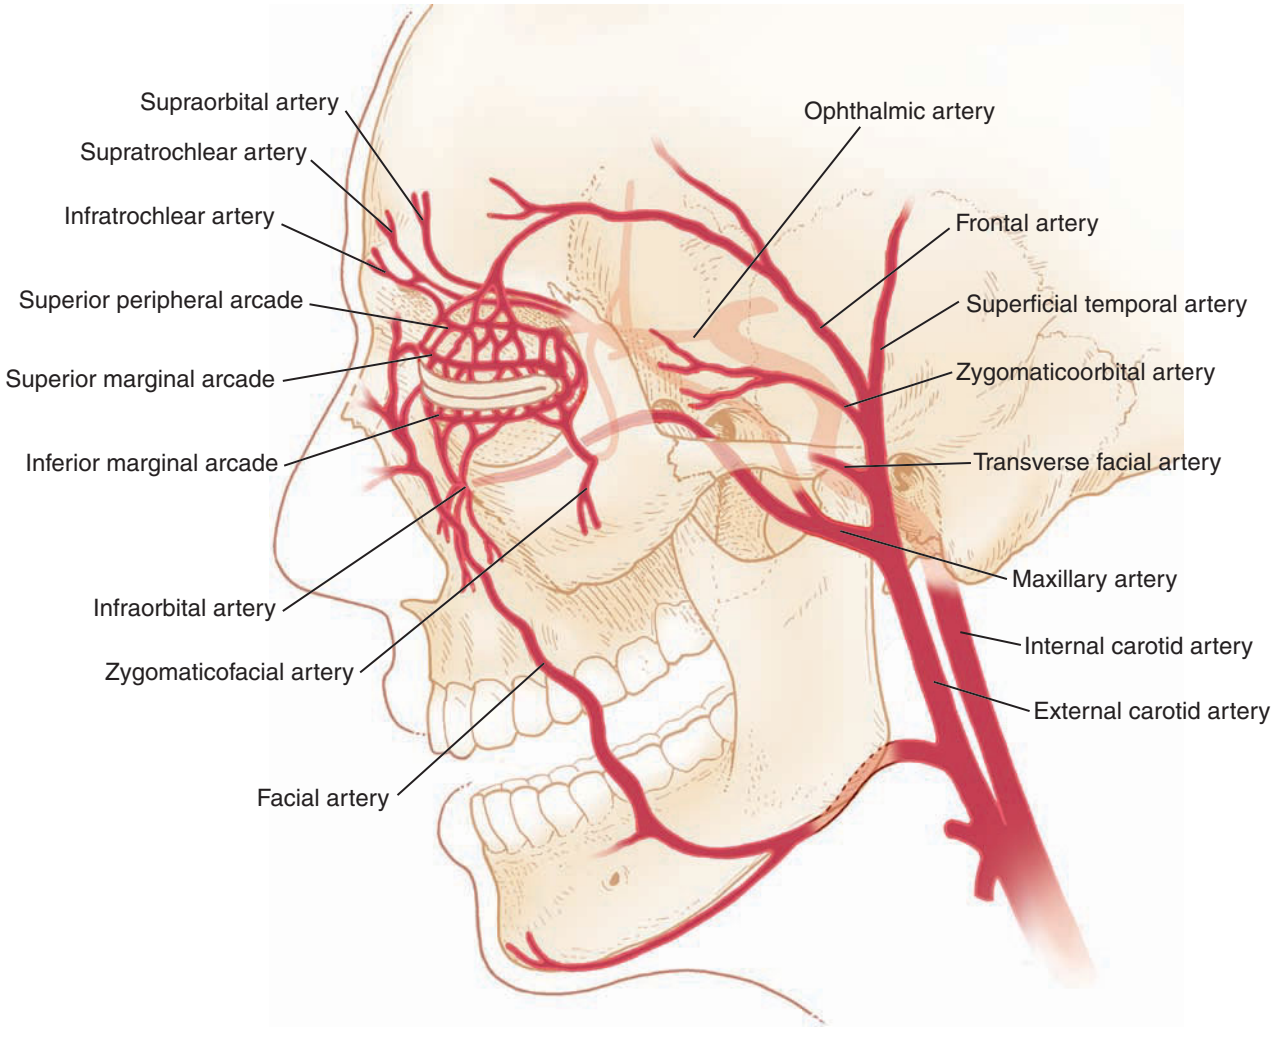

FIGURE 172-1. The blood supply of the nasal cavity arises from the internal and external carotid artery systems.

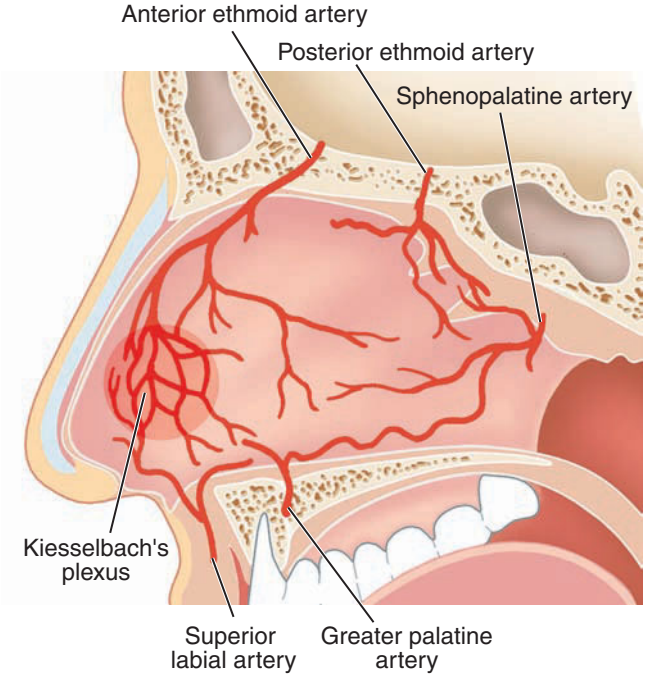

FIGURE 172-2. Arterial supply to the nasal septum and Kiesselbach's plexus.

the case of juvenile nasal angiofibromas, which should be suspected in adolescent males.

Patients without identifiable local causes for epistaxis most likely suffer from an underlying systemic process. Consider the possibility of a defect in the coagulation cascade. Hypertension is often cited as a significant factor for epistaxis. Studies have been unable to demonstrate a significant difference in the prevalence of epistaxis in patients with hypertension versus patients without hypertension.[7,8] Nonsteroidal anti-inflammatory drugs and aspirin containing products have been associated with epistaxis.[9,10] Osler-Weber-Rendu disease is an autosomal dominant inherited condition in which the blood vessel walls lack contractile elements. Consequently, prolonged heavy bleeding occurs from relatively minor insults, as the vessels are unable to contract and allow clotting to take place. The patient's coagulation profile is normal and the diagnosis is made by the family history. Other systemic etiologies include alcoholism, blood dyscrasias, liver disease, malnutrition, and pregnancy.

INDICATIONS

A patient with epistaxis must be evaluated expediently. All patients with epistaxis require a thorough examination and control of the bleeding. Epistaxis that has resolved still requires management to prevent rebleeding.

CONTRAINDICATIONS

There are no contraindications to the management of epistaxis. **Manage any unstable vital signs, unstable airway, life- or limb-threatening injuries, or any complications related to blood loss (e.g., hypotension, chest pain, syncope, etc.) before managing the epistaxis.** In the interim, apply a nose clip or a nasal sponge/tampon to control the bleeding. A thorough examination and more definitive means of control can be performed after the patient has been stabilized.

EQUIPMENT

- Nose clip
- Headlight or overhead light source
- Yankauer suction catheter
- Frazier suction catheters, #5 and #7
- Nasal speculum, short and medium lengths
- Bayonet forceps
- Kidney basin
- Weeder metal tongue blade or wooden tongue depressors
- Gown, gloves, face mask with an eye shield or goggles
- Cotton balls
- Topical anesthetics and vasoconstrictors (**Table 172-1**)
- Silver nitrate applicator sticks
- Petrolatum (e.g., Vaseline) impregnated gauze ribbon, 0.5 inches wide
- Synthetic nasal sponges/tampons, various lengths
- Nasal balloons (anterior, posterior, anterior and posterior)
- 14 French Foley catheter with a 30 mL balloon
- Umbilical clamp
- Gelfoam
- 4 × 4 gauze squares
- Surgicel
- ENTaxis nasal packing
- 3 inch long dental rolls or tonsil packs, or 3 × 36 inch Vaseline gauze
- Umbilical tape or 0 silk suture
- Red rubber catheters
- Lubricant

TABLE 172-1 Anesthetics and Vasoconstrictors of the Nasal Mucosa

Anesthetics
4% cocaine
4% lidocaine
2% pontocaine
Topical anesthetic spray (e.g., Cetacaine)
Vasoconstrictors
4% cocaine
3% ephedrine
1:1000 epinephrine
0.5% oxymetazoline
0.5% to 1.0% phenylephrine
0.05% to 0.10% xylometazoline
Anesthetic and vasoconstrictor combinations
4% cocaine
0.25 mL of 1:1000 epinephrine and 20 mL lidocaine mixture
4% lidocaine and 0.05% oxymetazoline, 50:50 mixture
4% lidocaine and 0.5% to 1.0% phenylephrine, 50:50 mixture

The list of equipment required to manage a patient with epistaxis is quite long. Most Emergency Departments keep all the required equipment, except medication, in a rolling cart or tackle box. This system allows for more efficient stocking and restocking. It is also more efficient to have all the required equipment readily available in one convenient and portable location. Single patient use and disposable nosebleed trays are commercially available (e.g., Centurion ENT/Nosebleed Tray, Tri-State Hospital Supply Corp., Howell, MI). They contain all the required instruments but lack the medications and other supplies.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Ensure that the patient has a thorough understanding of the postprocedural care instructions and follow-up requirements.

Position the patient sitting in an upright multipositional procedure chair. Alternatively, place the patient sitting upright on a gurney with the back elevated. Prepare the wall suction unit to make sure that it is working. Apply suction tubing and a suction catheter to the suction source.

The importance of good lighting cannot be overemphasized. Apply a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. The overhead light often hits the examiner in the head, casts shadows, and is too bright for the patient's eyes. It is also difficult to position properly as both of the examiner's hands must be used for the procedure.

Instruct the patient to blow their nose firmly, one nostril at a time, in order to evacuate the nasal cavities before the examination. This allows the anterior nasal septum, Kiesselbach's plexus, the nasal vestibule, the inferior turbinate, and the floor of the nasal cavity to be examined. Inspect the posterior oropharynx for active bleeding using the Weeder tongue blade or a wooden tongue blade. Insert a short nasal speculum to evaluate each side of the anterior nasal cavity. Open the speculum vertically. Suction out any blood and blood clots with the Frazier suction catheter. Consider a posterior site of bleeding if the source is difficult to localize. A patient will occasionally present with bilateral epistaxis. It is sometimes difficult to determine from which side the bleeding is originating. Ask the patient which side started bleeding first. This is usually the side where the bleeding point can be found.

Vasoconstrict and anesthetize the nasal mucosa (**Table 172-1**). Decongest the nasal mucosa with an aerosolized agent. Instruct the patient to sniff in deeply after the spray is applied. Allow 3 to 5 minutes to pass for the vasoconstriction to occur. Apply a topical anesthetic spray to the nasal passageway. Spraying achieves excellent vasoconstriction and anesthesia as the agents diffuse through the entire nasal cavity and pharynx. It is possible to anesthetize and vasoconstrict the nasal mucosa in one step by using cocaine or a combination of an anesthetic and vasoconstrictor agent (**Table 172-1**). Alternatively, place cocaine-soaked pledgets into the nasal cavity. Direct the pledgets along the floor of the nose, against the nasal septum, and toward the superior straits of the nose. Monitor the patient's vital signs when vasoconstrictors are applied.

There are numerous techniques to manage epistaxis. These include the use of absorbable packs, electrocautery, Foley catheters, gauze rolls, intranasal balloon catheters, petrolatum impregnated ribbon gauze, nasal tampons or sponges, and silver nitrate. The technique and material of choice depend upon the location of the bleeding (anterior vs. posterior) and Emergency Physician preference. Different techniques and equipment are required to control anterior versus posterior bleeding.

RADIOLOGIC STUDIES

Imaging is not routinely indicated for the initial evaluation and management of epistaxis in the majority of cases. Damrose and Maddalozzo reviewed CT scans of pediatric patients who were referred for evaluation of epistaxis.[11] While 79% of the studies demonstrated some abnormality, none of the patients were found to have a neoplasm. They concluded that routine imaging of the sinuses is not recommended. CT imaging of the paranasal sinuses and facial bones should be considered when there is a history of facial trauma or when there is a high index of suspicion for a neoplasm.

ANTERIOR EPISTAXIS MANAGEMENT TECHNIQUES

Anterior nasal packing is required when local measures fail to control epistaxis. This may be due in part to anterior or structural problems in which the bleeding source cannot be identified. It may also be due to heavy or profuse bleeding. **The premise behind placing nasal packing is that it provides mechanical pressure and tamponades the bleeding site.**[12] Note that this is an uncomfortable procedure; therefore, the previously described steps for applying topical anesthesia should be undertaken.

ABSORBABLE PACKING

Diffuse bleeding is frequently encountered in patients with coagulopathies and blood dyscrasias. The trauma of inserting the nasal packing (e.g., a tampon or petrolatum gauze) can lead to more serious bleeding. A piece of Gelfoam sponge or oxidized cellulose (e.g., Surgicel) is often effective. These substances, coated with an antibiotic ointment (e.g., Bacitracin), provide adequate pressure and hemostasis without extreme trauma to the nasal mucosa. This packing does not need to be removed and will slowly dissolve with the use of a topical saline spray, which may be started within 24 hours of the packing being placed.

The two most commonly used absorbable dressings are Gelfoam and Surgicel. Gelfoam is an absorbable gelatin sponge that is readily available and inexpensive. It forms a scaffold for the formation of a blood clot. Surgicel is composed of oxidized and regenerated cellulose. It promotes coagulation better than Gelfoam. Unfortunately, Surgicel results in delayed healing and its use should be reserved for persistent bleeding or when Gelfoam is not available.

Absorbable packs may be used for primary and secondary hemostasis. Apply a piece of Gelfoam or Surgicel directly over the site of discrete bleeding or diffuse oozing. The material may be used for secondary hemostasis and be placed over an area that has clotted and stopped bleeding. This can serve as a "Band-Aid" to help prevent the clot from dislodging prematurely and the bleeding to restart. It can be placed over areas that have been chemically or electrically cauterized. An absorbable pack can be placed prior to packing the nasal cavity with a sponge/tampon or gauze. The absorbable pack will prevent the clot from becoming dislodged when the sponge/tampon or gauze is removed.

Insert the nasal speculum and identify the scabbed or bleeding site. Apply a piece of Gelfoam or Surgicel over the site. Allow a clot to form onto the absorbable packing. The nasal cavity may then be packed with a sponge/tampon, petrolatum gauze, or a balloon catheter if the Emergency Physician chooses.

Two additional absorbable dressings are topical thrombin and collagen. They are expensive, not usually available in the Emergency Department, and should be limited to circumstances where other hemostasis methods have failed. Topical thrombin is made from bovine thrombin. Place a piece of Gelfoam saturated with thrombin over the bleeding site. Thrombin converts fibrinogen to fibrin, bypassing the coagulation cascade, to form a clot. Collagen is available in multiple forms from a variety of sources. It promotes platelet aggregation and forms a scaffold for the formation of a clot. Cover the bleeding site with collagen followed by a piece of Gelfoam.

CHEMICAL CAUTERIZATION

The location of the bleeding is usually within the anterior nasal cavity, specifically on the anterior nasal septum. Sometimes no active bleeding is found at the time of the evaluation. Suctioning of the nasal cavity will remove clots and may allow the site to bleed and be visualized. A scabbed excoriation or an exposed blood vessel may be found along the nasal septum. Chemically cauterize these areas using silver nitrate applicators.

Insert the nasal speculum and identify the scabbed site or the exposed vessel. Apply the silver nitrate under direct vision by rubbing the applicator on the area immediately surrounding the scab or blood vessel. Apply the silver nitrate for 3 to 10 seconds. **Do not apply the applicator in any one spot for more than 10 seconds. This may cause mucosal necrosis and damage to the underlying cartilaginous septum. Do not apply the silver nitrate too excessively or in the same spot on both sides of the septum, as this may result in a septal perforation.** Apply a topical antibiotic ointment to the area. Consider placing a piece of Gelfoam or Surgicel over the site to help stabilize the clot.

A relatively dry field is required to use the silver nitrate applicator. Moderate-to-severe bleeding results in the silver nitrate coagulating the blood. It will not contact the mucosal tissue and bleeding will continue. Attempt to simultaneously suction the blood while using the silver nitrate applicator. Unfortunately, the suction often pulls off the coagulum and the bleeding continues. A final technique is to apply the silver nitrate centripetally around the bleeding site. This will cauterize the feeder vessels and may stop the bleeding. **Do not cauterize an area over 0.75 cm in diameter, as this can result in damage to the underlying cartilaginous septum.** Pack the nasal cavity with a sponge/tampon, petrolatum gauze, or a balloon catheter if these techniques fail.

ELECTRICAL CAUTERIZATION

Electrocautery can effectively control bleeding if the site is identified. **This technique is reserved for the experienced Otolaryngologist.** It can cause significant damage to the mucosa and cartilage in inexperienced hands. The technique of electrocautery is not discussed for these reasons.

RIBBON GAUZE PACKING

The traditional technique of anterior nasal packing consists of using 0.5 inch wide petrolatum impregnated gauze ribbon (**Figure 172-3**). This technique is extremely effective but not often used as it is cumbersome, time-consuming, and simpler methods exist (e.g., silver nitrate cautery, sponges/tampons, and balloon catheters).

Insert the nasal speculum. Grasp one end of the petrolatum gauze with a bayonet forceps. Insert the petrolatum gauze into the nasal cavity and along the nasal floor (**Figure 172-3A**). Tightly pack the nasal cavity in a layered fashion from bottom to top, extending as far back as possible toward the choanal arch (**Figure 172-3B**). **Be careful to avoid injuring the mucosa overlying the septum and the turbinates.** Cut the petrolatum gauze so that it protrudes approximately 2 cm from the nostril. Tape this loose end to the patient's cheek so that it does not accidentally pull the packing out. The

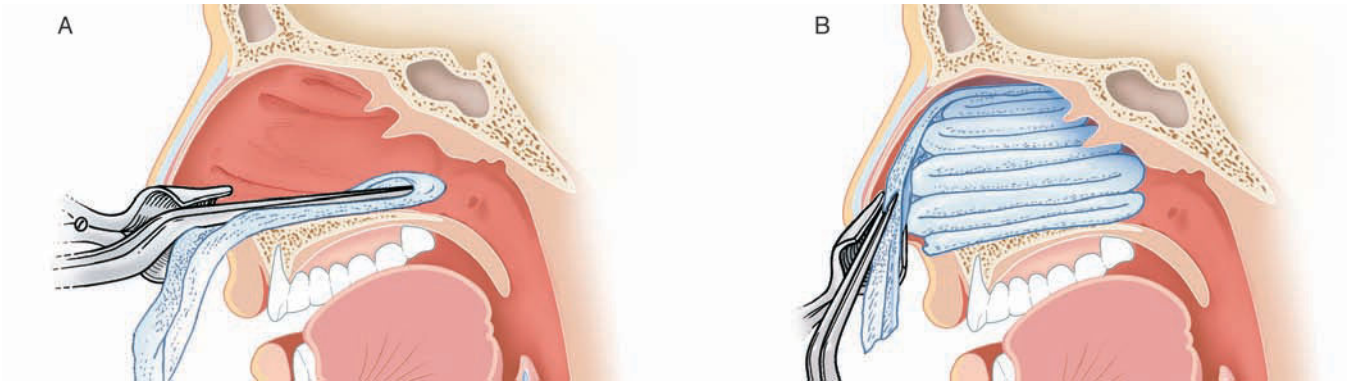

FIGURE 172-3. Anterior nasal packing using petrolatum (e.g., Vaseline) impregnated gauze ribbon. **A.** Insert a nasal speculum and begin packing inferiorly to superiorly. **B.** The gauze-packed anterior nasal cavity.

packing is later removed by gently pulling on this free end of gauze ribbon protruding from the nostril.

The pressure of one-sided anterior nasal packing can bow the septum contralaterally, allowing the packing to "loosen" and the bleeding to restart. Consider packing the contralateral anterior nasal cavity to maintain the septum in the midline and exert pressure on the bleeding site.

EXPANDABLE NASAL SPONGES/TAMPONS

One of the easiest, quickest, and most effective techniques to control anterior epistaxis is to insert an expandable sponge or tampon (e.g., Merocel packing). These packs are particularly useful when the bleeding is diffuse, a specific site cannot be clearly identified, or the bleeding is heavy. The packs come in various sizes (4.5, 6, 8, and 10 cm), shapes, and styles (**Figure 172-4**). Initially quite rigid, they soften and expand with the absorption of saline or surrounding blood. A 4.5 or 6 cm sponge is generally adequate for anterior epistaxis.

Prepare the sponge/tampon. Cut the string from the sponge/tampon as it is not necessary to remove the packing. The sponge/tampon is barely visible when properly inserted. The string hanging from the nostril is irritating to the patient and not cosmetically appealing. Lightly coat two-thirds of the sponge/tampon with a non-water-soluble lubricant (e.g., Vaseline) or antibiotic ointment (e.g., Neosporin). This will prevent premature expansion of the tampon from a water-soluble lubricant or antibiotic ointment, nasal secretions, or blood.

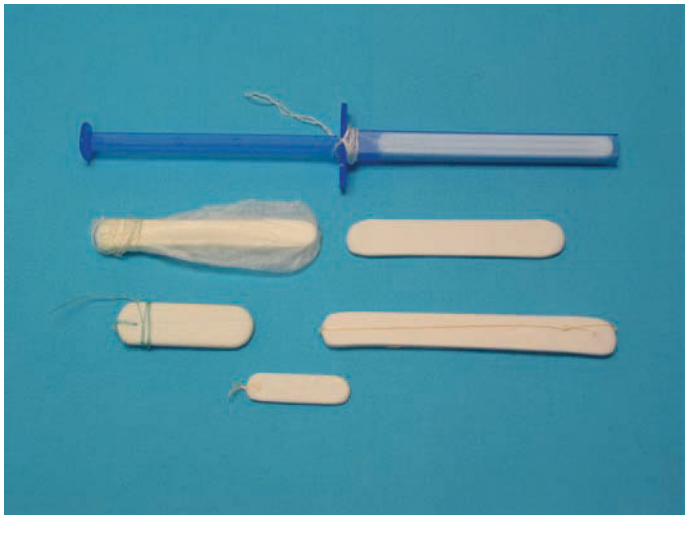

FIGURE 172-4. Various sizes, shapes, and styles of nasal sponges/tampons.

Insert and open the nasal speculum within the affected nasal cavity. Grasp the unlubricated end of the sponge/tampon with a bayonet forceps or the dominant thumb and index finger. Insert and advance the sponge/tampon just lateral to the nasal septum, in a vertical position, with the length of the pack directed along the floor of the nose (**Figure 172-5A**). Advance the sponge/tampon until it is completely within the nasal cavity. The sponge/tampon will expand from the blood and secretions within the nasal cavity (**Figure 172-5B**). Slowly drip 1 to 3 mL of tap water or saline onto the unlubricated tip of the sponge/tampon to help it expand more rapidly.

Inspect the oropharynx for bleeding. Persistent bleeding may be due to the septum bowing contralaterally. Pack the contralateral anterior nasal cavity with a sponge/tampon of equal length and size. Observe the patient for oozing or bleeding anteriorly or posteriorly. Continued bleeding requires removal of the sponge/tampon from the bleeding nasal cavity and insertion of a larger one, two small ones, or Vaseline gauze packing.

Keep several helpful hints in mind when using the nasal sponges/tampons. Trim large sponges/tampons to 5 to 6 cm in length. The extra length is not required for anterior epistaxis, is uncomfortable for the patient, and is more difficult to remove. The Rhino Rocket is a sponge/tampon within a plastic syringe-like device. Remove the sponge/tampon from the syringe-like device before inserting it. The device can generate significant force and result in mucosal tears, septal injuries, and turbinate injuries. Insert and advance the sponge/tampon rapidly to prevent premature expansion. There is no advantage to using a non-water-soluble antibiotic ointment versus a lubricant. The antibiotic ointment is more expensive and its antibacterial activity lasts only 2 to 4 hours. Insert two sponges/tampons side by side if the patient has a large nasal cavity.

Removal of the sponge/tampon is simple and quick. Apply 1 to 2 mL of tap water, saline, or a vasoconstrictor in a dropwise fashion to the tip of the sponge/tampon in the nostril. This will thoroughly hydrate the packing and ensure that it can be withdrawn atraumatically. Allow 5 to 10 minutes to ensure that the packing is completely hydrated. Grasp the end of the sponge/tampon with a hemostat. Place a kidney basin under the patient's nose. Pull quickly and parallel to the floor of the nasal cavity to remove the packing. Epistaxis after removal is often due to dislodgement of the clot. Use an absorbable pack or silver nitrate to stop the bleeding.

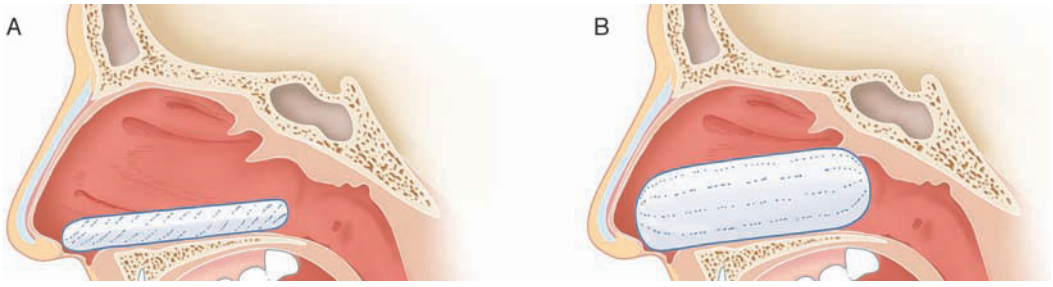

FIGURE 172-5. The expandable nasal sponge/tampon. **A.** Insertion along the floor of the nasal cavity. **B.** The expanded state.

Look at the sponge/tampon to identify the blood spot and the location of the bleeding.

INFLATABLE NASAL BALLOON CATHETERS

The development of plastic inflatable balloon catheters has simplified the management of epistaxis. The nasal balloons are easy to use and quick to place. They are available in a variety of sizes and shapes (**Figure 172-6**). They are available with anterior balloons, posterior balloons, or dual balloons. The anterior balloon fills the nasal cavity and acts as an anterior pack. The posterior balloon occludes the nasopharynx and acts as a posterior pack. The inflatable balloons are more expensive than other methods used to manage epistaxis. The increased cost is offset by decreased Emergency Physician contact time as compared with that required for petrolatum (e.g., Vaseline) gauze packing. The balloons have a maximal inflatable volume that is manufacturer-specific, noted on the packaging, and noted on the balloon's inflation hub.

Prepare the equipment. Select an anterior balloon catheter. A dual-balloon catheter may be used if an anterior balloon catheter is not available. Inflate the balloon with air to just below its maximum capacity. Observe and palpate the balloon for leaks. It may also be inflated in a cup of water to look for leaks. Completely deflate the balloon. Apply a lubricant over the catheter and balloon.

Insert the nasal speculum. **Insert the catheter with the distal bevel toward the nasal septum.** This prevents the distal end of the catheter from getting caught on the turbinates, damaging the mucosa overlying the turbinates, and causing a second source of epistaxis. Advance the catheter along the floor of the nasal cavity until just the inflation hub is protruding from the nostril (**Figure 172-7**). Inflate the balloon with air and 10 mL less than the maximum volume of the balloon (**Figure 172-7**). **Do not use saline or water to inflate the balloon.** Rupture of the balloon can result in aspiration if it is filled with liquid. **Do not inflate the balloon with more than the manufacturer's recommended volume.** If the patient complains of pain, the balloon may have been inflated larger than the nasal cavity. Slowly deflate the balloon in 2 mL increments until the pain subsides.

Observe the patient for continued bleeding. Increase the volume of the balloon to the maximum volume if the patient does not complain of pain. The balloon may cause a bowing of the septum to the contralateral side. If the bleeding continues, pack the contralateral anterior nasal cavity to keep the septum in the midline. Observe the patient for further bleeding from the nostril or into the nasopharynx. Continued bleeding suggests that the source is high in the nasal cavity or posterior. **The inflatable balloons do not always fill the upper portion of the nasal cavity.** Deflate the balloon, pack the high anterior nasal cavity with petrolatum gauze, and reinflate the balloon. Observe the patient for continued bleeding that would require a posterior pack, as described in the following sections.

RAPID RHINO

The Rapid Rhino Nasal Pac (Applied Therapeutics Inc., Tampa, FL) is a form of balloon catheter. The balloon is covered with a

FIGURE 172-6. Examples of some inflatable nasal balloon catheters.

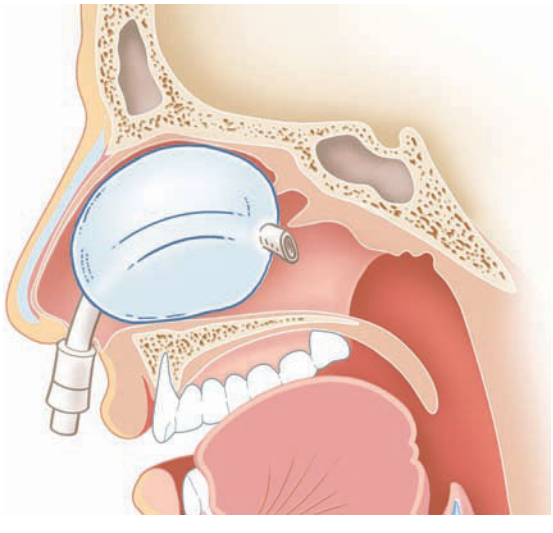

FIGURE 172-7. Inflation of an anterior balloon catheter to control anterior epistaxis.

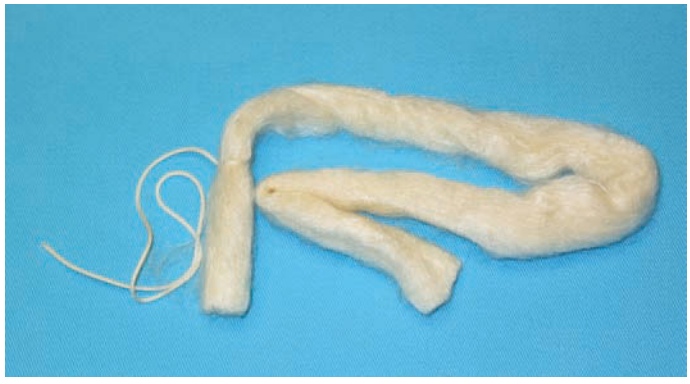

FIGURE 172-8. The ENTaxis nasal packing (Boston Medical Products, Westborough, MA).

hydrocolloid fabric that is self-lubricating, easy to insert, and promotes platelet aggregation. It is available in different lengths to accommodate children, anterior epistaxis, and posterior epistaxis. It is also available in a variety of sizes in both a unilateral balloon design and a bilateral balloon design with a single inflation port. The bilateral model allows for bilateral nasal packing with a single inflation port, maintaining equal pressure on both sides of the nasal septum. Dip the fabric covered balloon in sterile water for approximately 30 seconds to prelubricate it before insertion. Insert the balloon and inflate it as described previously. The advantage to this product is the ease of insertion, minimal bleeding upon removal, and patient comfort.[13]

ENTaxis NASAL PACKING

A relatively new anterior nasal packing is the ENTaxis (**Figure 172-8**). It is a natural polymer derived from seaweed and contains calcium alginate.[14] The packing provides hemostasis, has healing properties, and is atraumatically inserted and removed. Hydration with normal saline activates the calcium alginate and makes it pliable. The packing expands 300% and conforms to the anterior nasal cavity. It activates platelet aggregation to provide hemostasis, keeps the nasal mucosa moist, and gels into a smooth surface that allows easy removal.

Prepare the packing. The ENTaxis is packaged in a plastic tray with a tear-off paper lid. Peel the lid completely off the tray. Fill the tray with normal saline to saturate the packing. Remove the hydrated packing from the tray. Squeeze out the excess saline from the packing.

Insert a nasal speculum. Grasp the packing on the end opposite the string with a bayonet forceps. Insert the packing along the floor of the nasal cavity. Continue to insert the packing in an accordion-like fashion until the entire packing is within the nasal cavity. The packing will expand and gel to fill the nasal cavity. Secure the string to the patient's cheek or nose with a piece of tape.

Removal of the packing is simple and quick. The packing remains hydrated and in a gelled state while within the nasal cavity. Place a kidney basin under the patient's nose. Untape the string from the patient's face. Grasp the packing with a bayonet forceps. Gently withdraw the packing from the nasal cavity.

THROMBIN-JMI

THROMBIN-JMI Epistaxis Kit (Pfizer Pharmaceuticals, New York, NY) is a topical bovine thrombin approved for the management of epistaxis. It works on sites of minor bleeding and oozing. The thrombin causes fibrinogen in the blood to clot without the requirement of platelet activation. The kit contains one vial of thrombin, one vial of diluent, a needle and syringe, and a nasal delivery device.

Open the outer packaging to reveal a sterile inner tray with the kit components. Use the syringe with the needle to draw up the saline diluent. Inject the saline diluent into the THROMBIN-JMI vial. Gently swirl the vial to mix the components and reconstitute the thrombin powder. When completely dissolved, draw the thrombin solution into the syringe. Remove the needle from the syringe and attach the nasal delivery device. Insert the nasal delivery device into the nares. Depress the plunger to spray the thrombin solution onto the nasal mucosa. Remove the device. Allow the solution to form a clot. Apply additional thrombin solution if the bleeding continues. Consider applying a piece of Gelfoam to the newly formed clot to support it.

FLOSEAL

The Floseal Hemostatic Matrix (Baxter Healthcare Corporation, Hayward, CA) is composed of human-derived thrombin and bovine-derived gelatin. It stops bleeding fast and in up to 97% of cases.[15] The thrombin–gelatin matrix begins to break down in 3 to 5 days and is gone by 7 days. Floseal does not require platelet activation, allowing it to function in patients taking aspirin and other antiplatelet medications.

Floseal is provided in components that must be mixed. The process is more complicated than other thrombin products and can take several minutes. The kit contains all of the required components and supplies. Use the 5 mL syringe and attached needle to draw up the calcium chloride solution. Inject the calcium chloride solution into the lyophilized thrombin vial. Gently swirl the vial to mix the components and reconstitute the thrombin. Draw up the thrombin solution into the syringe. Gently transfer it into the bowl in the kit. Use the empty 5 mL syringe with a female Luer lock to aspirate the thrombin solution from the bowl into the syringe. Connect this syringe to the syringe containing the gelatin matrix granules. Push the plunger to fully transfer the thrombin solution into the gelatin containing syringe. This is considered "one pass." Transfer the gelatin–thrombin solution back and forth between the syringes for at least 20 passes. Disconnect the syringes. Attach one of the two applicator tips to the syringe containing the gelatin–thrombin solution.

Apply a small mound of the Floseal to the bleeding source. The Floseal must remain at the site for 2 minutes. Place a sterile saline-moistened gauze sponge over the Floseal mound to ensure it maintains a seal against the bleeding site. After 2 minutes, remove the gauze and inspect the site. If the gauze adheres to the clot or the Floseal, moisten it with sterile normal saline. If bleeding persists, insert the applicator tip through the Floseal mound and deliver fresh Floseal to the bleeding site. Remove any excess Floseal by gentle irrigation after the bleeding is controlled. Consider applying a piece of Gelfoam to the newly formed clot to support it.

WOUNDSEAL

WoundSeal for Nosebleeds (Biolife LLC, Sarasota, FL) was previously marketed as NoseBleed QR. It is an over-the-counter product that comes in a variety of applications to control bleeding. It is marketed to control epistaxis and external wounds of all types. It consists of a powder containing a hydrophilic polymer and potassium ferrate. When the powder comes in contact with blood, the polymer absorbs liquid and concentrates the red blood cells and plasma proteins under the powder to form a clot. The potassium ferrate releases iron to bind the blood proteins into a clot.

The WoundSeal powder is simple to apply. Open the blister pack. Roll the tip of the applicator stick in the powder to completely coat

it. Roll the powder coated applicator onto the nasal mucosa. Remove the applicator stick from the nasal cavity. Pinch the nostrils closed for 30 seconds. Reassess the nasal cavity for continued bleeding and the need for additional applications of the powder. Consider applying a piece of Gelfoam to the newly formed clot to support it.

ANKAFERD BLOOD STOPPER

Ankaferd Blood Stopper (ABS, Ankaferd Health Products LTD, Istanbul, Turkey) is a medicinal plant extract. It is approved in Turkey for the management of postsurgical dental bleeding and external hemorrhage.[16] ABS is not currently available in the United States and most other countries. It induces the rapid formation of a hemostatic protein network to control hemorrhage that is not dependent upon coagulation factors and platelets.[16] It has been successfully used to control epistaxis.[17] ABS may provide a new method to control epistaxis in the future.

POSTERIOR EPISTAXIS MANAGEMENT TECHNIQUES

A posterior source of the bleeding must be sought when epistaxis is bilateral, brisk, and not controlled with anterior nasal packing. It is estimated that 5% of all cases of epistaxis originate from a posterior source.[18] **The placement of a posterior nasal pack is extremely uncomfortable.** The patient may require, on some occasions, intravenous sedation and analgesia in addition to the topical anesthesia previously described. Consider spraying the patient's soft palate, uvula, and oropharynx with a topical anesthetic spray (e.g., Cetacaine). This will minimize their gag reflex during the placement of the posterior pack.

The rationale behind placing a posterior pack is that the occlusion of the choanal arch provides a semirigid buttress against which anterior nasal packing may be placed, allowing adequate hemostasis to be achieved. This buttress may be formed from either a gauze pack, a 30 mL Foley catheter, an expandable nasal sponge/tampon, or an inflatable nasal balloon catheter. From a practical standpoint, the Foley catheter and inflatable nasal balloon catheter are most easily tolerated by the patient. The inflatable nasal balloon catheter is definitely the easiest to place, as it has two balloons that serve as both anterior and posterior packs. **An anterior nasal pack is always required on the side of a posterior pack.** Strongly consider inserting a contralateral anterior nasal pack to maintain the septum in the midline.

TRADITIONAL (GAUZE ROLL) PACKING

The traditional technique of posterior nasal packing involves using rolled gauze, dental rolls, or tonsil packs placed through the oropharynx (**Figure 172-9**). This technique is difficult, time-consuming,

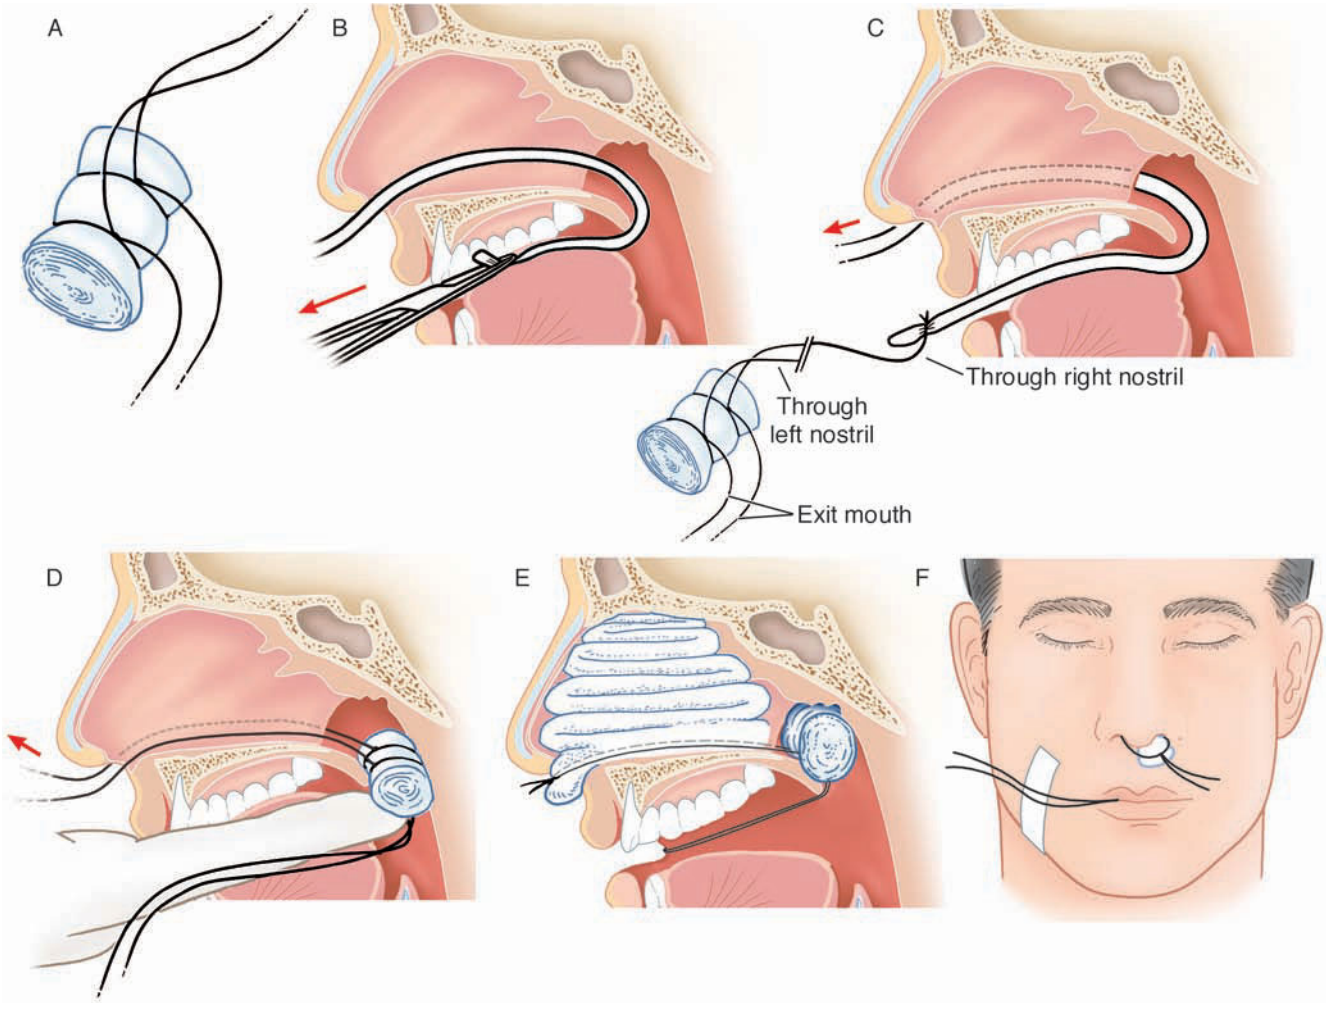

FIGURE 172-9. The traditional technique of placing a posterior nasal pack. **A.** Preparation of the pack. **B.** A red rubber catheter inserted through the nostril and pulled out the mouth. **C.** The pack is attached to the two red rubber catheters. **D.** The pack is pulled into place. Use a finger to pass the pack around the soft palate and uvula. **E.** An anterior nasal pack has been placed. **F.** The ties of the posterior pack are secured.

messy, requires many supplies, and is not well tolerated by the patient. Easier and quicker techniques exist. For these reasons, this technique is not often performed.

Prepare the equipment. Gather the required equipment on a bedside procedure table. Use 3 inch long dental rolls or tonsil packs. An alternative is to use 3 inch wide and 36 inch long petrolatum gauze. Form a tight cylindrical roll with the gauze (**Figure 172-9A**). Tie two pieces of umbilical tape or 0 silk suture around the pack to divide it into thirds (**Figure 172-9A**).

Anesthetize and vasoconstrict both nasal cavities. Apply a topical anesthetic spray to the soft palate, uvula, and oropharynx. Lubricate a red rubber catheter. Pass the red rubber catheter through one nostril and along the floor of the nasal cavity. Advance the catheter so that the tip is visible in the patient's oropharynx. Grasp the tip of the catheter with a hemostat or forceps and pull it out the patient's mouth (**Figure 172-9B**). Clamp the free ends of the catheter together. Pass a second red rubber catheter through the other nostril and out the patient's mouth.

Insert the posterior pack. Tie the free end of one piece of the umbilical tape or silk surrounding the packing to the distal end of one red rubber catheter exiting the patient's mouth (**Figure 172-9C**). **Tie the knots tightly.** Tie the second piece of umbilical tape or silk to the second red rubber catheter. Pull the proximal ends (i.e., the portion exiting the nostrils) of both red rubber catheters until the packing is against the choanae (**Figure 172-9D**). It may be necessary to place a finger into the patient's mouth and push the pack behind the soft palate and uvula if it gets caught (**Figure 172-9D**). Place a hemostat on both pieces of umbilical tape exiting the nostrils. Apply slight traction with the hemostat to maintain the posterior pack against the choanae. Instruct an assistant or the patient to hold the hemostat. Untie or cut the red rubber catheters from the umbilical tape or silk sutures.

Place an anterior pack and secure the posterior pack. **An anterior nasal pack is always required when placing a posterior nasal pack.** The anterior pack may be an expandable sponge/tampon, petrolatum gauze, or a balloon catheter (**Figure 172-9E**). Tie the umbilical tape or silk exiting each nostril together (**Figure 172-9F**). **Always place a piece of cotton or gauze between the knot and the columella to prevent pressure necrosis (Figure 172-9F). Tie the umbilical tape or silk snugly but not too tight to hold the posterior pack in place and not apply pressure to the choanae or the columella.** Tape the umbilical tape or silk exiting the patient's nostril and mouth to their face (**Figure 172-9F**).

Removal of this packing is simple and requires several stages. Remove the anterior packing. Thoroughly examine the mucosa to make sure that the epistaxis has not restarted. Suction any clots and blood from the nasal cavity. Rebleeding requires the placement of a new anterior pack if it cannot be controlled with an absorbable dressing or silver nitrate. Cut the knot, securing the umbilical tape or silk around the columella. Pull the pieces of umbilical tape or silk exiting the patient's mouth to remove the posterior pack completely.

FOLEY CATHETER TECHNIQUE

A Foley catheter may be used to provide a posterior buttress. Using a Foley catheter is easy, quick, and simple. Select a 14 French Foley catheter with a 30 mL balloon. Inflate the balloon with air. Ensure the integrity of the balloon. Some Emergency Physicians cut off the portion of the Foley catheter distal to the balloon. They believe that the distal tip is irritating to the patient and may stimulate their gag reflex. The practice of cutting off the distal tip is based purely on Emergency Physician preference. Be careful to not cut the balloon or its attachment to the catheter.

Lubricate the distal third of the Foley catheter. Insert the Foley catheter into the nostril and along the floor of the nasal cavity. Advance the catheter until the tip is visible in the patient's oropharynx. Inflate the balloon with 7 to 10 mL of air. **Do not use saline, as the fluid can result in aspiration if the balloon ruptures.** Withdraw the catheter to lodge the balloon against the choanal arch (**Figure 172-10A**). If the balloon withdraws into the nasal cavity, advance it back into the nasopharynx. Add an additional 3 to 5 mL of air and withdraw the catheter. Continue the process by adding 3 to 5 mL aliquots of air until the balloon lodges against the choanal arch. Inflate the balloon with an additional 3 to 5 mL of air and the soft palate just begins to bulge. The balloon is overinflated if the soft palate bulges or the patient experiences pain.

Place an anterior pack and secure the Foley catheter. Apply slight traction to maintain the balloon against the choanal arch. Instruct an assistant or the patient to hold the Foley catheter. Place the anterior pack using an expandable sponge/tampon, petrolatum gauze, or a balloon catheter. **Place a piece of cotton or gauze against the columella and nasal ala to prevent pressure necrosis.**[19] Place an umbilical clamp on the Foley catheter and over the protective padding (**Figure 172-10B**). **The clamp must hold the**

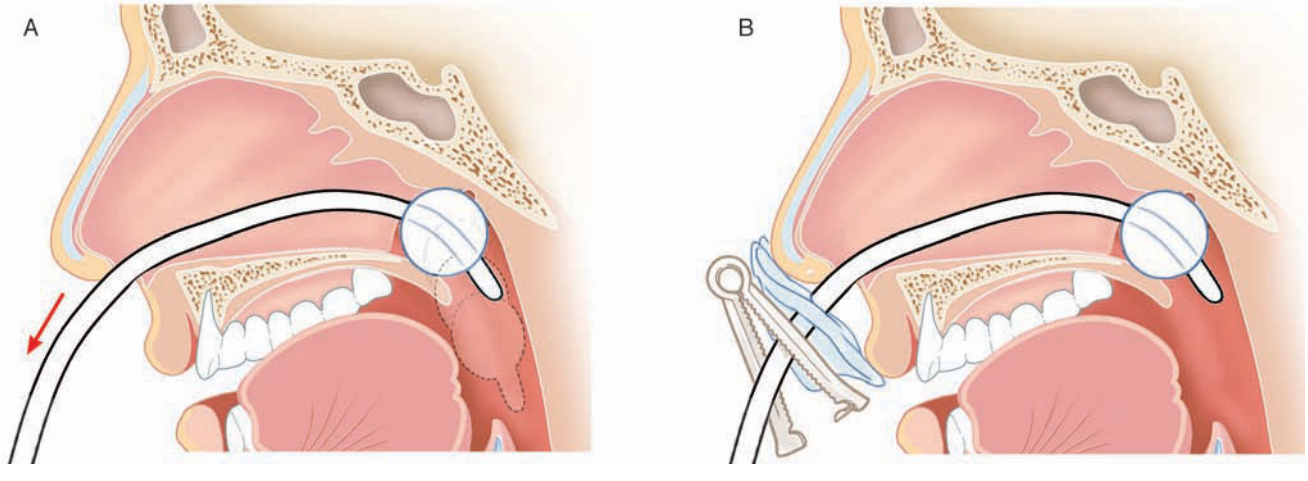

FIGURE 172-10. The Foley catheter technique. Insert a Foley catheter along the floor of the nasal cavity until the tip is visible in the patient's oropharynx. **A.** Inflate the balloon and withdraw the catheter to lodge the balloon against the choanal arch. **B.** Secure the Foley catheter.

balloon against the choanal arch without applying pressure to the choana or columella.

Removal of this packing is simple and requires several stages. Cut the open loop of the umbilical clamp with a scissors. Open the jaws of the clamp and remove them from the Foley catheter. Always maintain a grasp of the catheter and apply slight traction to keep the balloon in place. Remove the anterior packing. Thoroughly examine the mucosa to make sure that the epistaxis has not restarted. Suction any clots and blood from the nasal cavity. Rebleeding requires the placement of a new anterior pack if it cannot be controlled with an absorbable dressing or silver nitrate. Deflate the balloon and pull the catheter out the patient's nostril.

EXPANDABLE NASAL SPONGES/TAMPONS

Many Emergency Physicians prefer to use an 8 or 10 cm sponge/tampon rather than the other techniques of posterior packing. This technique is easy, quick, simple, and inexpensive. The technique for insertion and removal is exactly the same as for the anterior packing technique described previously. The Epistat II (Medtronic Xomed Inc., Jacksonville, FL) is a combination device with an anterior nasal sponge/tampon and a posterior balloon. It provides better posterior hemostasis than a sponge/tampon alone.

INFLATABLE NASAL BALLOON CATHETERS

A dual-balloon catheter can be used when a posterior pack is required. These catheters come in many types and styles (**Figure 172-6**). They are expensive but easy to use and quickly placed. The smaller distal balloon obstructs the choanal arch and acts as a posterior pack (**Figure 172-11**). The larger proximal balloon fills the nasal cavity and acts as an anterior pack (**Figure 172-11**). The distal balloon holds 10 mL and the anterior balloon holds 30 mL in most dual-balloon systems. Note the manufacturer's maximum volume recommendations on the package and on the inflation ports of the balloons.

Prepare the equipment. Fully inflate both balloons with air. Observe and palpate the balloons for leaks. They may also be inflated in a cup of water to look for leaks. Completely deflate both balloons. Apply a lubricant over the catheter and balloons.

Insert the catheter with the distal bevel toward the nasal septum. This prevents the distal end of the catheter from getting caught on the turbinates, damaging the mucosa overlying the turbinates, and causing a second source of epistaxis. Advance the catheter along the floor of the nasal cavity until the distal tip is visible in the patient's oropharynx.

Inflate the distal balloon with 4 to 5 mL of air. **Do not use saline or water to inflate the balloon.** Rupture of the balloon can result in aspiration if it is filled with liquid. Withdraw the catheter to lodge the balloon against the choanal arch (**Figure 172-11**). If the balloon withdraws into the nasal cavity, advance it back into the nasopharynx. Add an additional 2 to 3 mL of air and withdraw the catheter. Continue this process until the balloon lodges or the maximum balloon volume is reached. Inflate the anterior balloon with 20 to 25 mL of air.

Observe the patient for bleeding. Inflate both balloons with additional aliquots of air until the bleeding stops or the maximum balloon volume is reached. The balloon does not always fill the high anterior nasal cavity. Deflate the anterior balloon, pack the high anterior nasal cavity with Vaseline gauze, and reinflate the anterior balloon. Place an anterior pack contralaterally if the bleeding continues to maintain the septum in the midline and apply pressure to the ipsilateral nasal cavity.

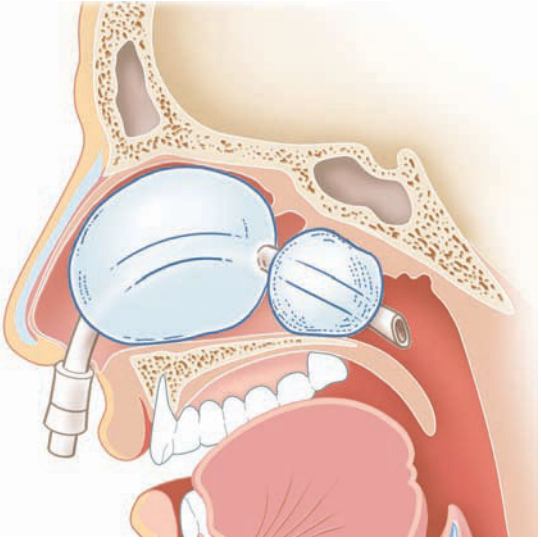

FIGURE 172-11. Placement of a dual-balloon catheter.

SPHENOPALATINE ARTERY BLOCK

This technique is a last resort when an Otolaryngologist is not available, the hemorrhage is unremitting, and other methods to control the hemorrhage have failed. Local anesthetic solution is injected into the pterygopalatine canal to occlude the sphenopalatine artery. The local anesthetic solution can cause pressure necrosis of the adjacent nerves within the bony canal.

Place the patient supine with their mouth open. Apply a topical anesthetic spray to the hard palate. Identify the greater palatine foramen. Insert a 27 gauge needle into the mucosa of the hard palate, 1 cm medial to the gum line between the junction of the second and third maxillary molars. Probe this area with the needle until it falls into the greater palatine foramen. Inject 0.25 mL of local anesthetic solution containing epinephrine into the mucosa overlying the greater palatine foramen. Arm a 3 or 5 mL syringe containing local anesthetic solution with epinephrine with a 22 or 25 gauge needle. Insert the needle approximately 25 to 28 mm into the greater palatine foramen. Inject 3 mL of the local anesthetic solution.

SURGICAL INTERVENTION

Consult an Otolaryngologist when the epistaxis is difficult to control by the described methods, as surgical intervention is then indicated. Surgical therapy may include septoplasty, endoscopic cauterization, arterial ligation (internal maxillary artery, sphenopalatine artery, anterior and posterior ethmoid arteries, external carotid artery), or embolization.[20]

PEDIATRIC CONSIDERATIONS

Epistaxis is a common childhood symptom that may prompt an evaluation in the Emergency Department. Generally, the management of a child with acute epistaxis is straightforward. The source of bleeding is from the anterior one-third of the nasal septum, just posterior to the squamous-mucosal junction in the majority of children. The etiology is often due to digital manipulation, infection, allergic rhinitis, a coagulopathy, a foreign body, trauma, medications, a neoplasm, and surgery.

The principles of management in the pediatric population are similar to those of adult patients. Active bleeding requires immediate attention. The child needs to be assessed for any hemodynamic instability or airway compromise. A brief history should be

obtained during the initial stages of treatment. The minimal equipment required for initial evaluation includes a headlight, Yankauer suction, Frazier tip suction, a small nasal speculum, and a tongue depressor. Additional supplies may be required, as well. A more comprehensive list of equipment and medications has been outlined earlier in this chapter.

After managing any life-threatening injuries and ensuring hemodynamic stability, the goal is to identify the bleeding source. Apply an anesthetic and vasoconstrictor. Evacuate any remaining clot from the nasal airway and inspect the mucosa. If the bleeding source is identified, the vessel should be cauterized with silver nitrate. Once the mucosa has been cauterized, apply a thin piece of oxidized cellulose (i.e., Surgicel) or Gelfoam that has been impregnated with an antibiotic ointment over the site to help stabilize the clot. Place an anterior nasal pack if chemical cauterization fails to control the bleeding. Expandable nasal sponges/tampons are readily available and are relatively easy to place. Trim the sponge/tampon to an appropriate length prior to insertion. Consult an Otolaryngologist if the bleeding cannot be controlled, if there are concerns that the bleeding source is from a posterior location, and for any postsurgical patient.

Once the presenting symptoms have been addressed, the underlying cause should be identified and treated. For patients with epistaxis secondary to digital manipulation, antibiotics ointment and nasal saline should be used to minimize crusting and to hydrate the mucosa. Antibiotic therapy is indicated in cases of acute sinusitis and adenoiditis. Coagulopathy must be considered when a patient presents with recurrent epistaxis. Sandoval et al found that 30% of children who presented with recurrent epistaxis had a diagnosable coagulopathy.[21] Von Willebrand's disease was noted to be the most common disorder identified. Serology should include a CBC, PT, PTT, and INR in patients whose history suggests heavy bleeding, recurrent bleeding, or a personal or family history of bleeding abnormalities.

AFTERCARE

The postprocedural care of patients with anterior epistaxis is just as important as the initial control of bleeding. All patients with nasal packing require prophylactic oral antibiotic therapy with adequate coverage for *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae*, and *Moraxella catarrhalis*. This is due to the significant risk of developing sinusitis and toxic shock syndrome. Arrange follow-up with an Otolaryngologist within 24 to 48 hours. Remove the packing in 48 to 72 hours if the patient experienced only minimal blood loss and was hemodynamically stable.

Inform the patient that the anterior pack is "uncomfortable." Acetaminophen will provide any required analgesia. Avoid aspirin containing compounds and nonsteroidal anti-inflammatory drugs, as they can contribute to further bleeding. Instruct the patient to apply saline nasal spray to the packing or each nostril three or four times per hour while awake. The use of a humidifier at home will aid in preventing drying of the packing or the nasal mucosa. The patient must avoid nose picking and nose blowing. Instruct the patient on the proper technique to apply pressure on the nose if bleeding restarts. Such pressure should be maintained for 20 minutes. Continued bleeding calls for a return to the Emergency Department. The patient should also return for increased nasal pain, fever, or any symptoms related to blood loss (e.g., chest pain, dyspnea on exertion, dizziness, light-headedness, presyncope, shortness of breath, and syncope).

Patients with unstable vital signs, uncontrollable bleeding, posterior packing, or serious concomitant medical problems will require hospitalization. Patients with posterior nasal packs require consultation with an Otolaryngologist and admission to a telemetry or intensive care unit. They must be monitored for respiratory distress, hypoxia, hypotension, anemia, and cardiac sequelae. It has been estimated that 40% of patients with posterior nasal packing eventually require intubation.[18] The nasal ala and columella must be evaluated continually in order to prevent pressure necrosis.

Patients with a posterior nasal pack may experience hypoxemia and hypercarbia. The etiology of these phenomena, called the nasopulmonary reflex, is unknown. The PaO_2 may decrease 7.5 to 15 mmHg. The $PaCO_2$ may increase 7 to 15 mmHg. The nasopulmonary reflex is more worrisome in patients with underlying lung disease or comorbid conditions.

COMPLICATIONS

The complications associated with epistaxis are variable, wide-ranging, and estimated to be from 2% to 69%.[22] Epistaxis may be complicated by hemorrhage, hypoxemia, hypovolemia, circulatory collapse, and airway compromise. Complications resulting from the treatment of epistaxis include nasal septal perforation, sinusitis, otitis media, toxic shock syndrome, aspiration, alar necrosis, and hypoxia from intrapulmonary shunting due to the stimulation of the nasopulmonary reflex.[23]

The majority of complications can be prevented by using proper technique, providing supplemental oxygen when not contraindicated, ordering appropriate prophylactic antibiotics, arranging appropriate hospitalization if indicated, obtaining an Otolaryngology consultation, and arranging for adequate follow-up.

SUMMARY

Epistaxis is a common condition that affects 10% to 13% of the general population. The key to successful management includes a prompt and thorough evaluation of the patient, an accurate diagnosis of the problem, and rapid control of the bleeding. Ninety percent of cases of epistaxis stem from an anterior source and can be controlled with either chemical cautery or nasal packing. Posterior bleeding requires the use of both a posterior pack and anterior packing. All patients with nasal packing require prophylactic antibiotics to prevent sinusitis and toxic shock syndrome. Follow-up is required in 24 to 72 hours with an Otolaryngologist or the Emergency Department to remove the nasal packing.

173 Laryngoscopy

Steven Charous

INTRODUCTION

Evaluation of the larynx can be crucial in the diagnosis and management of common and life-threatening disorders. The approach to the patient with laryngeal dysfunction begins with obtaining a complete history. Symptoms may be related to any of the three primary functions of the larynx. These are protection of the lower airway from aspiration, a conduit of the airway, and phonation. Symptoms may include aspiration, cough, dysphagia, odynophagia, dyspnea, or hoarseness. Otalgia may be a referred symptom from the larynx and transmitted by a branch of the vagus nerve. Information regarding patient age, onset, duration, severity, and progressive nature of the process is necessary. Determine the patient's past medical history including prior intubations, neck trauma, reflux esophagitis, similar previous episodes, and other

TABLE 173-1 Summary of the Advantages and Disadvantages of the Different Techniques used to Perform Indirect Laryngoscopy

	Handheld mirror	Per-oral flexible endoscopy	Per-oral rigid endoscopy	Nasal flexible endoscopy

systemic diseases. The social history, including smoking and alcohol usage, needs to be investigated. Medications, allergies, and over-the-counter drugs should be reviewed.

Perform a physical examination, including a complete head and neck examination, once the history has been obtained.[1] Listen for stridor and watch for accessory muscle breathing. Consciously and critically evaluate the patient's voice to hear breathiness, clarity, and volume. Inspect the ears, nose, oral cavity, oropharynx, and nasopharynx. Careful palpation of the neck is extremely important. Note any lymphadenopathy and neck masses. This must include their size, location, tenderness, and mobility. Palpate the larynx and note any crepitus (the lack of crepitus on lateral movement of the larynx over the vertebral bodies can be indicative of a laryngeal or hypopharyngeal mass), movement with swallowing, and asymmetry. This can help in determining the extent of a disease process.

Visualize the larynx after performing a complete history and physical examination, with the exception of true airway emergencies. This allows the Emergency Physician to examine the larynx in context to the patient's symptoms and other physical findings. It also allows a rapport to develop between the patient and Emergency Physician prior to undergoing a mildly invasive procedure.

There are four methods of performing indirect laryngoscopy: mirror laryngoscopy, nasal flexible fiberoptic laryngoscopy, oral flexible fiberoptic laryngoscopy, and rigid telescopic laryngoscopy. The following is a complete description of the procedure involved in performing each of these techniques. An excellent pictorial source for viewing normal and pathological conditions of the larynx may be found in Bruce Benjamin's *Diagnostic Laryngoscopy: Adults and Children*.[2] **Table 173-1** reviews the advantages and disadvantages of each procedure. Each method allows visualization of the larynx with different degrees of distortion (**Figure 173-1**).

ANATOMY AND PATHOPHYSIOLOGY

The larynx occupies the central neck and is located within the hypopharynx[3,4] (**Figures 173-2 & 173-3**). Lateral to the larynx are the pyriform sinuses, the pharyngeal recesses that are the primary route for food to pass into the esophagus. The basic framework of the larynx consists of the thyroid cartilage, cricoid cartilage, epiglottic cartilage, arytenoid cartilage, and the hyoid bone. The shield-like thyroid cartilage supports the soft tissues of the larynx. It is connected to the hyoid bone via the thyrohyoid membrane and is attached to the cricoid cartilage via the cricothyroid membrane and at the cricothyroid joint. The signet ring-shaped cricoid cartilage is the only complete cartilaginous ring in the larynx. On top of its posterior portion sits the paired arytenoid cartilages. The arytenoid cartilages are somewhat shaped like an inverted "T." Each has a body, a muscular process, and a vocal process. The aryepiglottic folds connect the epiglottis to the top portion of the arytenoid body. The vocal ligament attaches the vocal process to the thyroid cartilage. The cricoarytenoid muscles attach to the

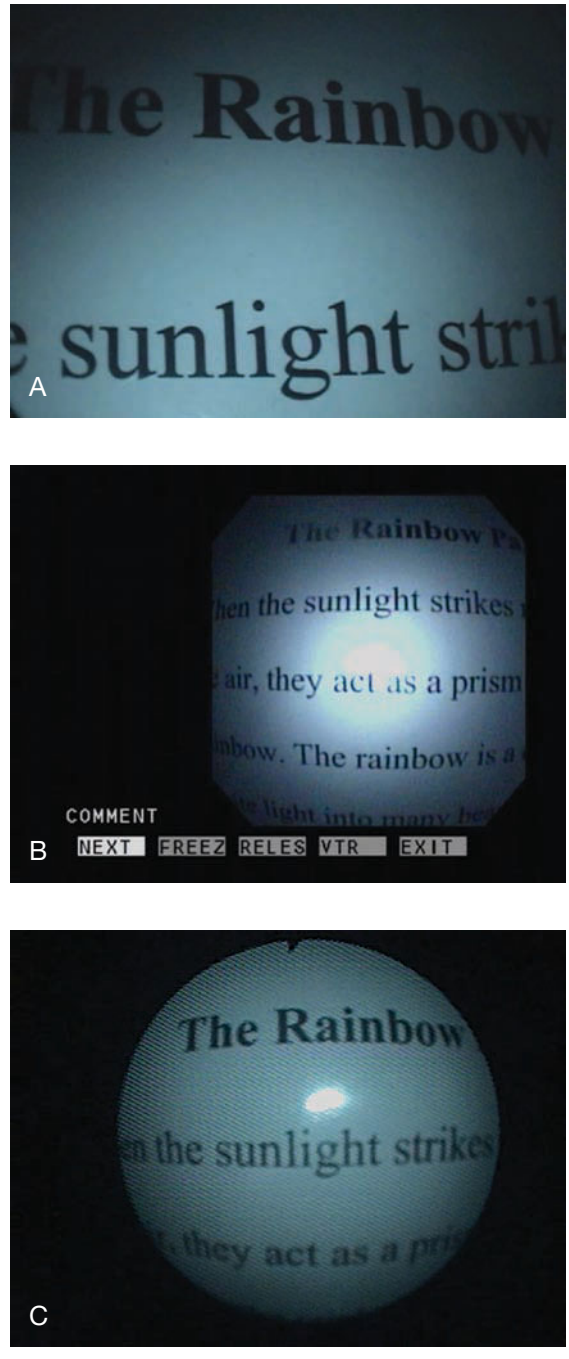

FIGURE 173-1. Visualization through the endoscopes. **A.** Endoscopic view through the 90° rigid telescope. Note the magnification, clarity, and breadth of view. **B.** Endoscopic view through flexible fiberoptic scope. Note the distortion and limited view as compared to the view through the rigid scope. **C.** Endoscopic view through the "chip-in-tip" scope. Note the larger field of vision with minimal distortion.

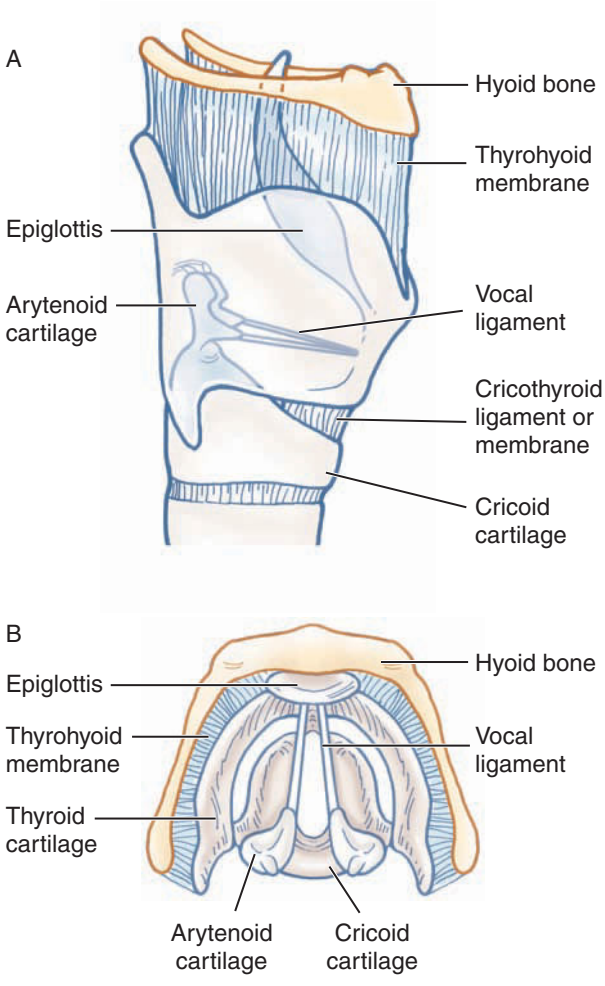

FIGURE 173-2. The laryngeal framework. **A.** Lateral view. **B.** Superior view.

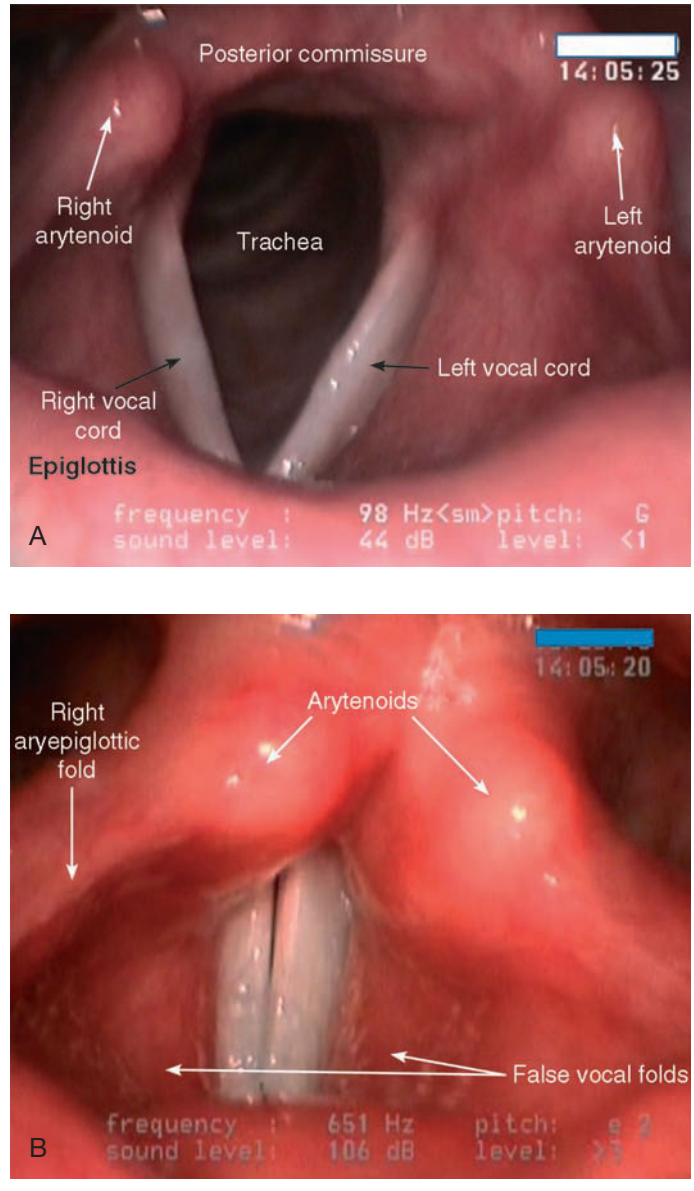

FIGURE 173-3. Endoscopic view of the laryngeal anatomy. **A.** Vocal cords open. **B.** Vocal cords closed.

muscular process. The epiglottic cartilage is leaf-shaped and forms the anterior wall of the laryngeal entranceway. Its main portion projects posterior to the tongue base. It folds downward over the larynx during swallowing to aid in protecting the laryngeal opening from aspiration.

The muscles associated with the larynx may be divided into extrinsic muscles and intrinsic muscles. The extrinsic muscles move the larynx as a unit and can be further subdivided into those muscles that elevate the larynx (stylohyoid, digastric, geniohyoid, and stylopharyngeus) and those that depress the larynx (omohyoid, sternohyoid, and sternothyroid). The intrinsic muscles are involved with vocal cord mobility and all cause adduction with the exception of the cricoarytenoid muscle that causes abduction. Innervation to the intrinsic laryngeal muscles is via the recurrent laryngeal nerve, a branch of the vagus nerve (cranial nerve X). The cricothyroid muscle is the only muscle innervated by the external branch of the superior laryngeal nerve, a branch of the vagus nerve. All of the laryngeal muscles and cartilages are covered with respiratory epithelium.

Just superior to the vocal cords is a recess called the laryngeal ventricle. Just superior to the ventricle are the false vocal folds. These are rounded protrusions rich in mucous secreting glands. The supraglottic larynx is defined as that portion of the larynx extending from the tip of the epiglottis to the laryngeal ventricle. The glottic larynx contains the true vocal cords and extends approximately 5 to 7 mm inferiorly. The subglottis extends from the inferior glottis to the inferior edge of the cricoid cartilage.

The primary function of the larynx is to protect the airway from the aspiration of food particles. A complex reflex arc, with the glossopharyngeal nerve (cranial nerve IX) mediating the sensory arm and the vagus nerve (cranial nerve X) mediating the motor arm, occurs with swallowing. With each swallow the larynx elevates, the aryepiglottic folds squeeze medially, the epiglottis folds posteriorly over the larynx, and the true and false vocal folds close tightly. This allows the food bolus to pass around the larynx, into the pyriform sinuses, and subsequently into the esophagus. Any alteration or disturbance in the reflex arc may predispose a patient to aspiration.

Phonation occurs with adduction of the vocal cords as air passes from the trachea through the vocal cords. The mucosa overlying the muscles of the vocal cords undulates and the two vibrating vocal cords produce sound. Anything that alters the mucosal wave of the vocal cords, impairs adduction, or changes the configuration of vocal cord alignment will result in decreased phonatory performance. Note that mucosal wave abnormalities can only be observed with videostroboscopy of the larynx. Many things can change a person's voice. This includes inflammation, thick mucous, vocal cord

paralysis, and tumors. Be careful and define hoarseness as a change in the patient's vocal quality. What may be normal for one patient may not be for another.

The larynx is crucial in respiratory activity. Inspiration signals the recurrent laryngeal nerve to stimulate vocal cord abduction. Impairment in abduction, unilaterally or bilaterally, can lead to respiratory compromise.

INDICATIONS

Have a very low threshold for examining the larynx. The diagnostic value of laryngoscopy greatly outweighs the minimal discomfort associated with the quick procedure. Any patient presenting with an allergic reaction, angioedema, acute hoarseness or voice changes, symptoms of aspiration, shortness of breath, a foreign body sensation, hemoptysis, stridor, exposure to ingested caustic agents, exposure to hot fumes or gasses, exposure to caustic fumes or gasses, or any other symptom that may be related to the larynx should have laryngoscopy performed as part of a complete physical examination.

CONTRAINDICATIONS

There are no absolute contraindications for laryngoscopy. Patients with severe respiratory compromise, such as a child with suspected epiglottitis, should have laryngoscopy performed in the Operating Room (or in a controlled area) with an Anesthesiologist, intubation equipment, and tracheotomy instrumentation ready for use. Performing laryngoscopy in the respiratory distressed patient can lead to increased distress and ventilatory collapse if laryngospasm ensues. Use caution when performing laryngoscopy in a patient with a high-grade airway obstruction, a supraglottic expanding hematoma, or significant laryngeal trauma. In general, the patient must be able to follow instructions and cooperate with the examination.

EQUIPMENT

Anesthesia and Vasoconstriction

- 10% lidocaine spray
- 20% benzocaine spray
- 2% tetracaine spray
- 4% cocaine
- 3% ephedrine or Neo-Synephrine spray
- Cotton pledgets

Scopes

- #4 or #5 dental mirror, with or without magnification
- 3 to 5 mm diameter flexible fiberoptic laryngoscope; 3 mm is better for children
- 90° rigid laryngoscope

Light Sources

- Headlight for mirror examinations
- 125 to 250 watt halogen or xenon light sources for fiberoptic laryngoscopes

Miscellaneous

- Alcohol lamp, heated beads, or glass of warm water for mirror examination
- 4 × 4 gauze squares
- Water-soluble lubricant
- Antifog solution
- Video camera and equipment for teaching and photodocumentation, optional

FIGURE 173-4. Basic equipment required for examination of the larynx in the ambulatory setting. Included are the rigid 90° telescope, dental mirror, flexible fiberoptic scope, gauze, oral anesthetic, antifog solution, and a light source. Not included is topical spray for nasal decongestion and anesthesia.

Set up all of the required equipment on a bedside procedure table (**Figure 173-4**). Prepare several different endoscopes, if available. If one fails, or is inadequate, another will be immediately available. The availability of multiple endoscopes allows the Emergency Physician to choose the scope and technique of their choice.

The flexible fiberoptic scopes are comprised of fiberoptic strands and lenses along its length. Do not manipulate or bend it into acute angles. Do not place objects onto the scope. Do not use abrasive materials (i.e., gauze, paper towels) to wipe the lens at the end of the fiberoptic cord.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. **Patient reassurance and relaxation is of the utmost importance in obtaining excellent visualization of the larynx.** This can be achieved by reviewing what can be expected from the patient's perspective, by reassuring them of the minimal discomfort, and by reassuring them of the short duration of the procedure.

Patient positioning is crucial in obtaining laryngeal visualization in any per-oral technique. Place the patient sitting upright in a multipositional procedure chair or on a gurney with their legs together. Instruct the patient to lean slightly forward and to draw their chin forward. This aligns the larynx and the oropharynx in a vertical plane to allow visualization of the anterior portion of the larynx. Raise or lower the multipositional chair, or the gurney, so that the patient's mouth is at the examiner's eye level.

Patient cooperation and positioning is not crucial for flexible fiberoptic examination of the larynx performed through the nose. Place the patient, optimally, sitting upright with their head against a headrest. The headrest will prevent the common occurrence of the patient's head backing away during the examination. The examination with the patient in the supine position is technically more challenging as gravity pushes the tongue posteriorly and the scope falls against the posterior pharyngeal wall; both of which make visualization of the anteriorly placed larynx more difficult. However, in most instances, it can still be performed without significant problems.

The use of good lighting cannot be overemphasized when performing a mirror examination. Apply a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. The overhead light often hits the examiner in the head, casts shadows, and is too bright for the patient's eyes. It is also difficult to properly position as both of the examiner's hands must be used for the procedure.

TECHNIQUES

THE MIRROR EXAMINATION

Determine whether the patient has a significant gag reflex. If so, apply topical anesthesia. Spray a topical local anesthetic agent (e.g., benzocaine, lidocaine, or tetracaine) onto the patient's palate, tonsillar pillars, posterior pharyngeal wall, and base of the tongue. The application of a topical anesthetic agent is optional if the patient does not have a significant gag reflex. Instruct the patient to keep their eyes open and focus on a distant object to diminish the gag reflex. Practicing the entire procedure once with the patient, without inserting the mirror, is often a more reassuring and efficient manner of performing indirect laryngoscopy.

Instruct the patient to protrude their tongue. Grasp the tongue firmly, between the nondominant thumb and index finger, with a neatly folded gauze square (**Figure 173-5**). **Do not apply excessive traction on the tongue.** This is counterproductive as it elevates the tongue and makes the patient uncomfortable. Place the nondominant middle finger against the upper teeth as a brace. It may also be used to elevate the upper lip if needed. Instruct the patient to breathe through their mouth in a slow "panting-like" manner and to try to relax their tongue. This maneuver diminishes the gag reflex, elevates the palate, and lowers the tongue giving better access and visualization of the oropharynx.

Warm the mirror over an alcohol lamp, in heated beads, or in a cup of warm water to prevent fogging during the examination. Test the mirror back, if any type of heat is used, on the examiner's wrist for excessive heat that can injure the patient. An alternative is to use a mirror that has antifog solution placed on it to prevent fogging during the examination. Grasp the mirror with the dominant hand midway down the shaft like a pen (**Figure 173-5**). Brace the dominant fifth finger against the patient's face.

Introduce the mirror into the oral cavity with the glass surface parallel to the tongue (**Figure 173-5**). Instruct the patient to say a high-pitched "e-e-e" and hold it for 5 seconds just before the mirror touches and elevates the uvula and soft palate. The high-pitched "e-e-e" tilts the epiglottis forward and brings the vocal cords into view and apposition. Inform the patient that the "e-e-e" may sound like "ahhhhhh" while their tongue is held. This is helpful to them as they try to cooperate fully with the instructions. The Emergency Physician should simultaneously demonstrate the high-pitched sound as patients invariably will phonate in too low of a pitch for too short of a time period. Prevent gagging by asking the patient to phonate before the mirror actually touches the soft palate, avoiding touching the base of the tongue, and avoid touching the anterior tonsillar pillars.

Focus the headlight (or overhead light), as the patient phonates, on the mirror. Gently and slightly maneuver the mirror until the larynx is visualized. **Remember the orientation through the mirror. Left and right are the same but anterior and posterior have reversed orientation.**

Perform a quick and systematic evaluation of the larynx and hypopharynx. Assess the airway structures including the base of the tongue, vallecula, epiglottis, aryepiglottic folds, true and false vocal cords, arytenoids, posterior pharyngeal wall, and pyriform sinuses. Visualize adduction and abduction of the vocal cords during phonations and inspirations. Several reinsertions of the mirror are often required to obtain a complete examination.

PER-ORAL FLEXIBLE FIBEROPTIC LARYNGOSCOPY

The examiner will often have a more leisurely view of the larynx with this technique, as compared to the mirror exam. Patients usually gag less and can tolerate this examination for longer periods of time.

Position the patient the same as for the mirror examination. All patients undergoing this procedure, in contrast to the mirror examination, must be topically anesthetized with an aerosolized local anesthetic agent as described above. Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, to provide better contrast.

Instruct the patient to protrude their tongue and to grasp it with a gauze square (**Figure 173-6**). Hold the eyepiece of the scope in the dominant hand. Use the dominant thumb to manipulate the

FIGURE 173-5. Proper positioning for an indirect mirror examination of the larynx. Both of the examiner's hands should be braced against the patient for stability once the mirror is positioned in the oropharynx.

FIGURE 173-6. Positioning for an oral flexible fiberoptic examination of the larynx. The patient grasps their tongue with a gauze square. The examiner's left hand is braced against the patient's face.

tip controller. Grasp and hold the middle portion of the fiberoptic scope with the thumb and index finger of the nondominant hand. Brace the remaining fingers of the nondominant hand against the patient's face (**Figure 173-6**). Instruct the patient to breathe slowly through their mouth in a "panting-like" manner.

Advance the scope with both hands until the tip is situated within the middle of the mouth and over the base of the tongue. Use the hand control to direct the tip of the scope downward. Look through the scope and visualize the base of the tongue, the vallecula, and the tip of the epiglottis. Direct the scope posteriorly over the epiglottis. The larynx and hypopharynx will come into view (**Figure 173-3**). Adjust the eyepiece, if necessary, to focus the scope. **Avoid touching the epiglottis as this may induce gagging.** Entry into the laryngeal vestibule will allow a more detailed examination, but may also induce laryngospasm if the vocal cords are touched. Perform a systematic examination of the laryngeal and hypopharyngeal anatomy. Instruct the patient to say "e-e-e" while viewing abduction and adduction of the vocal cords.

PER-ORAL RIGID FIBEROPTIC LARYNGOSCOPY

Position the patient the same as for the mirror examination. All patients undergoing this procedure, in contrast to the mirror examination, must be topically anesthetized with an aerosolized local anesthetic agent as described above. Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, or dim them to provide better contrast. Apply antifog solution onto the laryngoscope lens.

Instruct the patient to protrude their tongue. Either the patient or the examiner may grasp the patient's tongue with gauze as it protrudes (**Figure 173-7**). Hold the scope with both hands while stabilizing the nondominant hand against the patient's face if the patient holds their own tongue. Hold the scope with the dominant index finger and thumb if the examiner is grasping the patient's tongue (**Figure 173-7**). Stabilize the scope with the dominant fifth finger against the patient's face. Instruct the patient to breathe slowly through their mouth in a "panting-like" manner.

Insert the laryngoscope into the center of the mouth. Advance it straight backward and over the tongue. Stop advancing the scope when the circumvallate papillae are reached. Instruct the patient to phonate as described above. Advance the scope until the larynx is visualized (**Figures 173-2 & 173-8**). Tilt and gently rotate the scope to visualize the entire larynx and hypopharynx during phonation and quiet breathing.

FIGURE 173-7. Positioning for a rigid telescopic examination of the larynx. Note that the telescope is stabilized on the left thumb and the left fifth finger is braced against the patient's face.

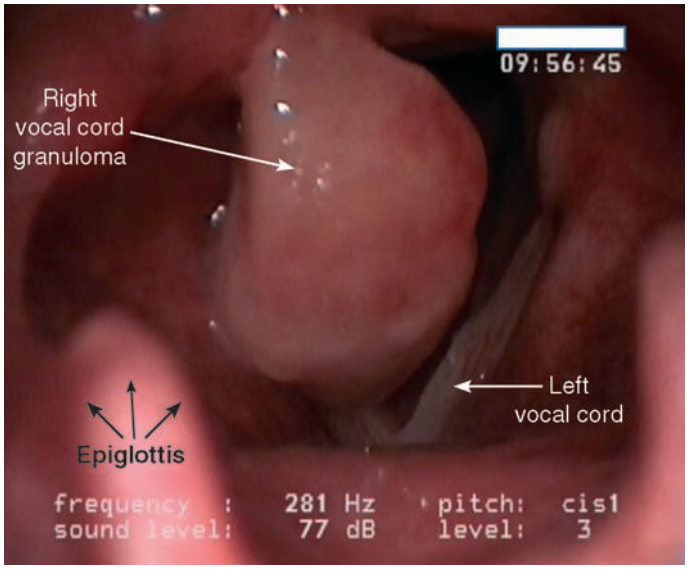

FIGURE 173-8. Endoscopic view of the larynx through a rigid 90° telescope.

FLEXIBLE NASOPHARYNGOSCOPY OR NASOLARYNGOSCOPY

A relatively new technology for laryngeal visualization is the "chip-in-tip" laryngoscopes. Rather than fiberoptic cables, these flexible scopes have the video and lens apparatus at the tip of the scope and transmits the data to a processor. The processor converts the data into video images onto a screen. This scope produces a picture that is significantly brighter and less distorted (**Figure 173-1C**). It is an excellent tool for teaching. However, the cost for a complete digital unit is three to four times the cost of a traditional fiberoptic laryngoscope.

Patient positioning is not crucial with this technique. Anesthetize the nasal passage so that the procedure is best tolerated. Visualize both nasal cavities with a nasal speculum to determine which nasal passageway will be easier to pass the scope through. Decongest the nasal mucosa with aerosolized oxymetazoline, 3% ephedrine, or cocaine. Instruct the patient to sniff in deeply after the spray is applied. Allow 3 to 5 minutes to pass for the vasoconstriction to occur. Apply a topical anesthetic spray to the nasal passageway. Spraying achieves excellent vasoconstriction and anesthesia as the agents diffuse through the entire nasal cavity and pharynx. Alternatively, place cocaine-soaked pledgets into the nasal cavity inferior and superior to the inferior turbinate for 10 minutes to achieve excellent anesthesia and vasoconstriction.

Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, to provide better contrast. Apply water-soluble lubricant onto the fiberoptic cord. Do not get the lubricant on the lens or it will blur visualization. Hold the eyepiece of the scope in the dominant hand (**Figure 173-9**). Use the dominant thumb to manipulate the tip controller. Grasp and hold the middle portion of the fiberoptic scope with the thumb and index finger of the nondominant hand. Brace the remaining fingers of the nondominant hand against the patient's cheek (**Figure 173-9**).

Insert the tip of the scope into the nose. Advance the scope with both hands and directed either along the floor of the nose or along the superomedial aspect of the inferior turbinate, depending

FIGURE 173-9. Positioning for a nasal flexible fiberoptic examination of the larynx. Note that the left, nondominant, hand is stabilized against the patient's face.

FIGURE 173-11. Nasopharyngoscopy using an external monitor for visualization of endoscopic images.

upon the nasal anatomy (**Figure 173-10**). Instruct the patient to breathe through their nose as the nasopharynx is encountered. This lowers the soft palate and opens the nasopharynx. Direct the tip of the endoscope downward and advance it past the oropharynx. Slide the tip of the scope behind the epiglottis, along the posterior pharyngeal wall, and into the hypopharynx and larynx. **Avoid touching the epiglottis to prevent gagging and the vocal cords to prevent laryngospasm.** Almost all patients can tolerate this procedure. Gagging is unusual. Apply a topical anesthetic agent to the oral cavity and oropharynx if the patient gags. Perform a leisurely and thorough examination of the airway. This is the only laryngoscopy technique in which normal speech can be observed.

ALTERNATIVE TECHNIQUES

The Emergency Physician must be looking through the rigid or flexible scope during the procedure. This in combination with holding, stabilizing, and advancing the scope makes fiberoptic laryngoscopy awkward if the Emergency Physician does not have much experience with this technique. An alternative, if available, is to connect the scope to a portable monitor (**Figure 173-11**). This makes the procedure less cumbersome and easier to perform. This type of setup is especially helpful in training situations (e.g., medical students, residents, and midlevel providers) as well as educating the patient and their family to the examination findings.

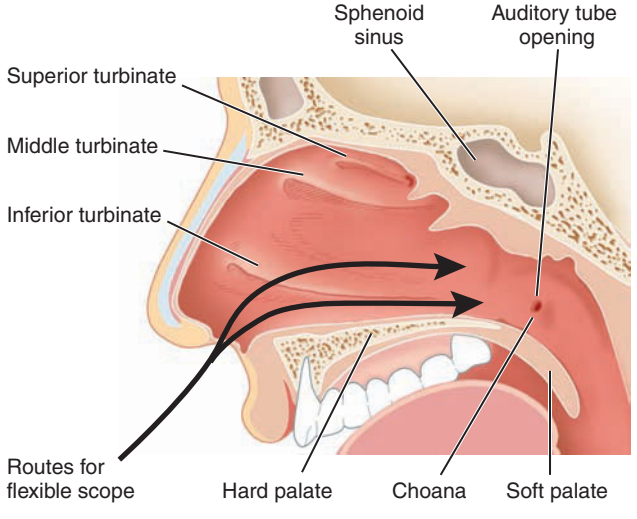

FIGURE 173-10. Anatomy of the lateral nasal wall and the two routes that the flexible scope can follow to gain access to the nasopharynx and subsequently the larynx.

AFTERCARE

Inform the patient that the effects of the topical anesthetic persist an average of 30 to 45 minutes. Alert the patient that they may experience symptoms of aspiration, such as coughing or choking, when swallowing. Liquids are more likely to cause problems than solids. Instruct the patient not to ingest any solid or liquid substances until the topical anesthetic agent wears off. Mild bleeding from the scope abrading the mucosa is usually minimal and self-limited. The patient will need reassurance as rarely is any treatment required.

Scopes require cleaning and disinfection between uses. Gently wipe any blood, lubricant, mucous, and other body fluids off the scope. Disinfect the scope per the manufacturers' recommendations and hospital guidelines.

COMPLICATIONS

Few complications arise from laryngoscopy. Epistaxis is possible with nasal endoscopy. It is uncommon when using vasoconstrictive agents and careful manipulation of the scope. Emesis is rare, even in the patient with an extremely sensitive gag reflex. Laryngospasm can be avoided as long as care is taken to avoid direct contact with the vocal cords. Although rare, the patient can have an adverse reaction to the local anesthetic agent or the decongestant. These should be evaluated and managed similar to any other allergic reaction.

Aspiration during or after the procedure is extremely rare. Aspiration can be minimized by performing laryngoscopy on patients with an empty stomach, although this is often impractical in the Emergency Department.

Other complications are minor and result from mechanical trauma. The tip of the scope can rub against and abrade the mucosa. This can result in mild irritation, rhinorrhea, and hemorrhage. Inappropriate technique or patient movement during the procedure can result in mucosal lacerations.

SUMMARY

Visualization of the larynx is a basic and often crucial component in the physical examination of the patient. A variety of techniques have been described, all of which are adequate in evaluating the larynx and hypopharynx. Risks and complications are rare. Maintain a very low threshold when deciding whether or not to perform laryngoscopy. Patient education and preparation are as, if not more, important than equipment and instrumentation in obtaining a thorough examination.

174 Airway Foreign Body Removal

David L. Walner

INTRODUCTION

The presence of an airway foreign body is a common cause of morbidity and mortality in children, especially those younger than 3 years of age. Over 70% of foreign body aspirations occur in children.[1] The mortality rate following foreign body aspiration is estimated at 1% to 2%. In the year 2000, ingestion or aspiration of a foreign body was the cause of 160 unintentional deaths and more than 17,000 Emergency Department visits in the United States.[2] Other reports have estimated the death toll as high as 2000 per year in the United States.[1] The most likely cause of death is complete airway obstruction, generally at the level of the larynx or trachea. Food objects have been associated with 41% and nonfood substances have been associated with 59% of reported deaths.[2] Globular objects such as hot dogs, candies, chewing gum, nuts, and grapes are the most commonly aspirated food objects.[3] Rubber balloons and toys are the most commonly aspirated nonfood objects.[3]

Parents and caregivers should be educated and aware of the types of food and objects that pose a choking risk for children. They should become familiar with the methods to reduce this risk. All parents and caregivers should learn the techniques to treat a choking child. Basic life support classes are often available free or at a minimal cost at hospitals, churches, and community centers.

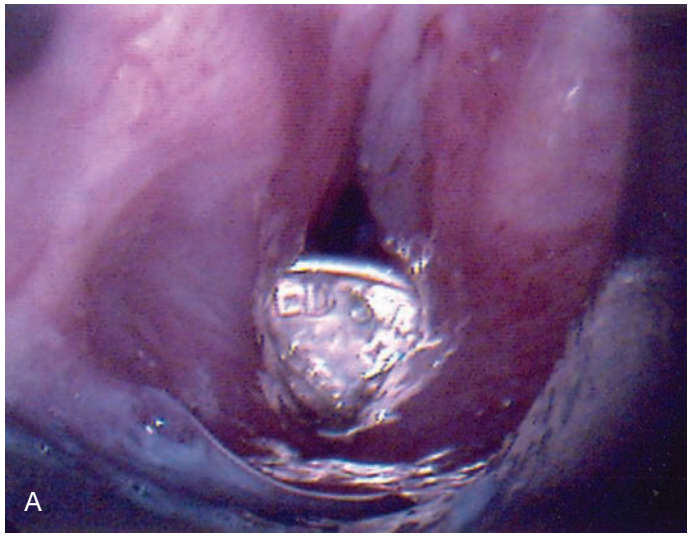
The management of airway foreign bodies requires specific expertise and training. Airway foreign bodies must be managed by an Otolaryngologist or other qualified Physician, depending on the institution, with experience in airway endoscopy and the knowledge to deal with the potential complications related to airway obstruction. Cases involving children require specialized expertise in pediatric airway endoscopy. Prior to the twentieth century, aspiration of a foreign body resulted in a 24% mortality rate. The morbidity and mortality associated with airway foreign body retrieval has greatly declined due to the development of safe endoscopic techniques, rod-lens telescopes, and optical forceps.

The burden of proof lies in the Emergency Physician's hands in order to diagnose an airway foreign body. Keep in mind that information gained from the history, physical examination, and radiologic studies may not clearly define the presence of a foreign body.[4] Thirty-three percent of airway foreign body cases are neither observed nor suspected. The physical examination may be normal in up to 39% of patients. Radiographic studies may be normal in up to 20% of the patients. The only definitive test when considering the diagnosis of an airway foreign body is endoscopy to evaluate the entire laryngotracheobronchial tree.

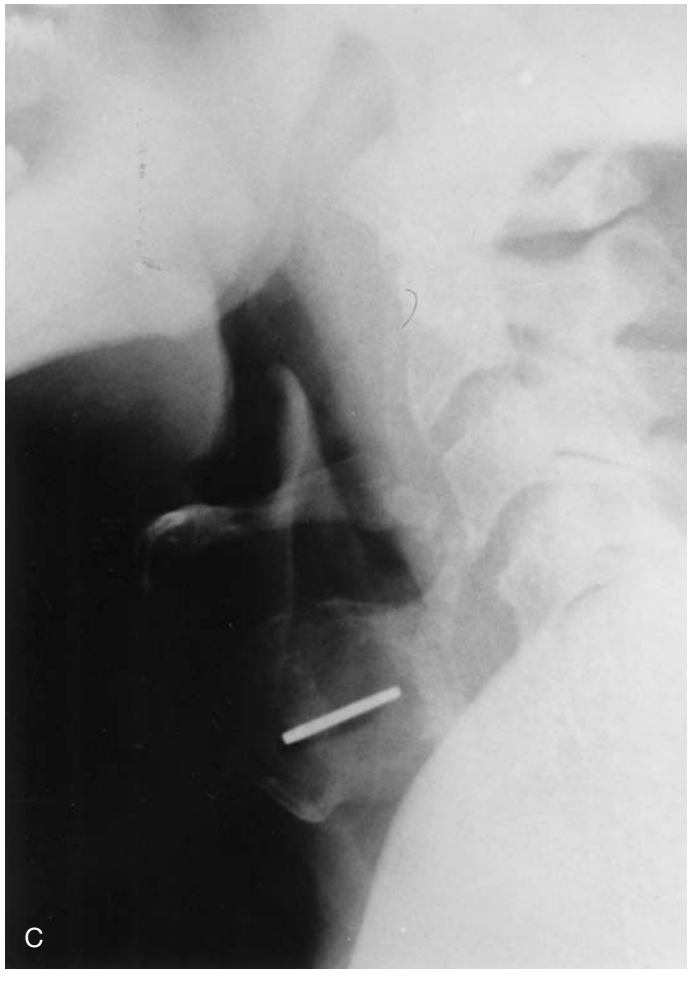
ANATOMY AND PATHOPHYSIOLOGY

The airway is divided into three anatomic regions: the larynx, the trachea, and the bronchi. The laryngeal aditus is formed by the epiglottis anteriorly, the aryepiglottic folds laterally, and posteriorly by the corniculate cartilages and upper border of the arytenoid muscle. The larynx extends from the level of the aditus to the lower border of the cricoid cartilage, where it is continuous with the trachea.[5] The infant larynx is located higher in the neck than the adult larynx. The cricoid cartilage descends in the neck through childhood. Due to the superior position of the infant larynx, the epiglottis is located with the tip often resting on the soft palate.[6] The infant larynx is approximately one-third the size of the adult larynx. Laryngeal foreign bodies are most common in infants due to the small size of the inlet. Refer to Chapter 6 for a more complete discussion regarding the differences between the child and adult larynx.

The trachea begins at the lower border of the cricoid cartilage, extending downward from about the level of the sixth cervical vertebra in adults or the fourth cervical vertebra in infants. The trachea extends inferiorly to the level of the carina. The inferior end of the trachea is located at the level of the fifth thoracic vertebra or the sternal angle. The trachea is 4 cm long in a full-term newborn infant and 11 to 13 cm long in an adult. The diameter of the trachea is 3.6 mm in a newborn and 12 to 23 mm in an adult.[7]



The trachea divides into two mainstem bronchi.[7] The right mainstem bronchus is shorter, straighter, and larger in diameter than the left mainstem bronchus. This explains why right mainstem foreign bodies are more common than left mainstem foreign bodies. The mainstem bronchi divide into three lobar bronchi on the right and two on the left. The lobar bronchi divide into segmental bronchi. There are, usually, 10 segmental bronchi on the right, and 8 on the left.[7]



Airway foreign bodies commonly become lodged in one of three locations: the larynx, the trachea, or the bronchi. Laryngeal foreign bodies account for 4% to 5% of airway foreign bodies.[8] Laryngeal foreign bodies have a mortality rate of 45% due to complete airway obstruction.[9] Approximately one-third of survivors of transient airway obstruction suffer from hypoxic encephalopathy.

Most choking victims are able to generate a forceful cough to expel an airway foreign body. Some patients are unable to relieve the obstruction themselves. The use of the Heimlich maneuver has further decreased mortality.[10] **It should be emphasized that the relief of an airway obstruction should only be attempted if signs of a complete airway obstruction are observed.[11] Only perform oral cavity finger sweeps if a foreign body is seen within the oral cavity.[11] Immediate intervention is not only unnecessary, but may be potentially dangerous if a patient is able to breathe, speak, or cough.[12]**

Laryngeal foreign bodies can present with only mild or moderate respiratory distress. They may be located, or wedged, between the laryngeal ventricles, the true vocal folds, or the immediate subglottis (**Figure 174-1A**). Plain radiographs of the neck will detect radiopaque foreign bodies (**Figures 174-1B & C**). Flexible awake fiberoptic laryngoscopy allows visualization of the larynx and supraglottic structures.

Tracheal foreign bodies account for 9% and bronchial foreign bodies account for 81% of airway foreign bodies.[8] The classic diagnostic triad of a tracheobronchial foreign body consists of the sudden onset of paroxysmal coughing, wheezing, and diminished breath sounds on the affected side. However, these symptoms may only be present in 50% of cases. Approximately 33% of airway foreign bodies are neither observed nor suspected.[13] Tracheal foreign bodies may present with audible biphasic or expiratory stridor. Audible expiratory wheezing is more likely associated with a

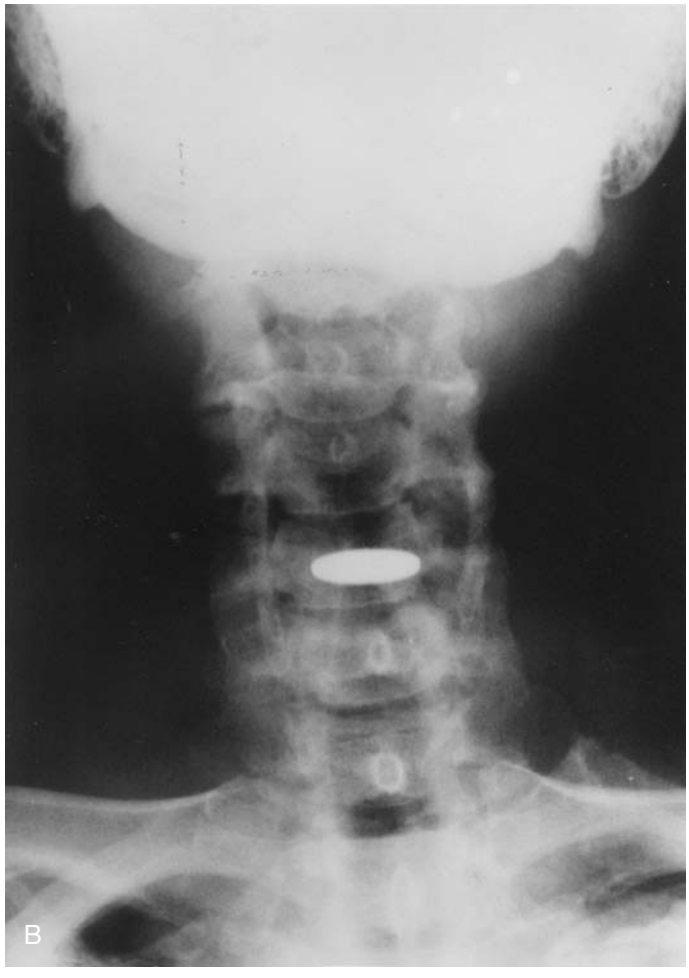


FIGURE 174-1. Laryngeal foreign body. **A.** Coin lodged within the laryngeal ventricles resulting in a partial airway obstruction. **B.** Anteroposterior neck radiograph. **C.** Lateral neck radiograph.

main bronchus obstruction. Tachypnea and cyanotic episodes may occur, generally when larger obstructing objects are present. Small foreign bodies may travel distally to a secondary bronchus and produce the more subtle symptoms of mild wheezing, cough, pneumonia, or fever. No abnormalities are found in up to 39% of patients.[4] It is estimated that only 70% of patients with a foreign body aspiration seek treatment within the first week of the aspiration.[14]

The most common airway foreign bodies are food items and toys. Peanuts account for nearly 40% of tracheobronchial foreign bodies[15] (**Figure 174-2**). Other common foreign bodies include plastic toys, pins, tacks, watermelon seeds, sunflower seeds, nails, screws, carrots, and popcorn. More than 80% of airway foreign bodies are radiolucent and can be difficult to diagnose. The most common radiologic findings are identified using both inspiratory

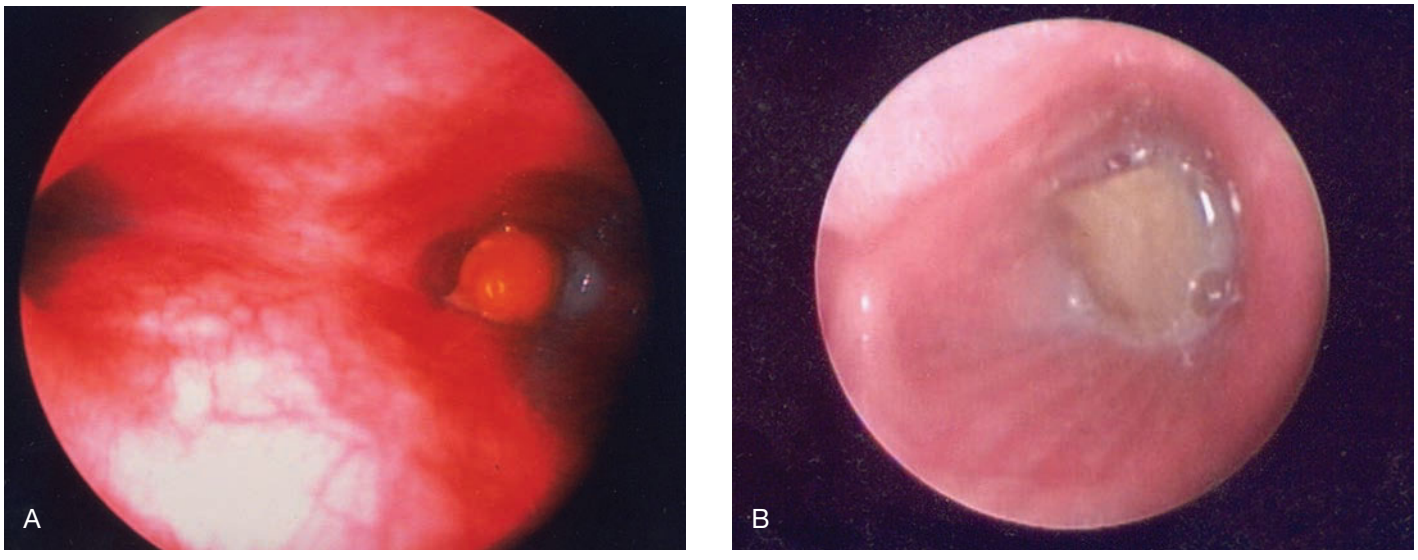

FIGURE 174-2. Endoscopic view of a peanut in the right main-stem bronchus. **A.** Endoscopic view from just superior to the carina. Note that both mainstem bronchi are visible. **B.** Close-up view of the foreign body.

and expiratory chest radiographs. This can be in the form of a check valve with postobstructive hyperinflation and mediastinal shift to the contralateral side (**Figure 174-3**). It may also be seen in the form of a ball valve with atelectasis, collapse of the distal airways, and mediastinal shift to the ipsilateral side. Pneumonia can be present in 9% of cases, generally when the foreign body has been present for weeks or months. Chest radiographs can be normal in up to 11% to 20% of patients with tracheobronchial foreign bodies.[4]

Suspect an airway foreign body based upon the history, physical examination, and radiologic findings. **However, the diagnosis is not always clear-cut. It is the responsibility of the Emergency Physician suspecting an airway foreign body to confer with the appropriate specialist and to strongly suggest endoscopy consisting of laryngoscopy and bronchoscopy.** Endoscopy remains the gold standard to rule in or rule out an airway foreign body.

INDICATIONS

The indications for airway endoscopy must take into account the patient's history, physical examination, radiologic findings, and the suspected location of the foreign body. An accurate history is of the utmost importance in the diagnosis of foreign body aspiration as the remainder of the assessment, physical examination, and radiographic studies can be deceptively unremarkable. The characteristic history consists of an incipient choking or gagging episode. Caretakers often describe subsequent coughing spells when the event was witnessed. Aspiration must be assumed if the patient was eating peanuts, seeds, or beans during the episode. All witnessed aspirations with nuts or nondissolvable food matter require endoscopy and removal if the foreign material is identified.

CONTRAINDICATIONS

The majority of patients presenting to the Emergency Department with airway foreign bodies are in stable condition. This allows time to adequately access the patient and formulate the best possible treatment plan. Infants and children with airway foreign bodies require an institution with the capability for comprehensive pediatric care. This includes a Physician who is experienced with

FIGURE 174-3. Chest radiograph of a patient with a left mainstem bronchus foreign body and a check valve-type of obstruction. Marks delineate the trachea and the mainstem bronchi.

airway endoscopy and foreign body retrieval in children, a facility with pediatric endoscopic equipment, pediatric anesthesia capabilities, and pediatric intensive care capabilities. This often will require transfer to a specialized pediatric center. Attempting removal of airway foreign bodies in a less-than-adequate environment can be catastrophic for the patient and is not advised. This same philosophy applies to adult airway endoscopy and to having qualified personal who are experienced in this area.

Follow basic life support protocols, including the section on a choking victim, in the rare situation of an acutely obstructed airway. Any patient with a suspected laryngeal foreign body or impending airway obstruction requires emergent endoscopy and control of the airway in the Operating Room, if possible. If urgent endoscopy is not possible and a laryngeal foreign body is suspected, direct laryngoscopy in the Emergency Department and removal of a visualized foreign body with a McGill forceps can be attempted. A cricothyroidotomy or percutaneous transtracheal jet ventilation may be required as a lifesaving measure for a laryngeal foreign body if attempts at resuscitation and/or removal are unsuccessful. However, these two procedures are unlikely to be beneficial if the foreign body is located in the distal tracheal or bronchi. **If urgent endoscopy is not available, and a lifesaving measure is required due to total airway obstruction of a distal tracheal or bronchial foreign body, orotracheal intubation with the tube positioned into one of the mainstem bronchi may be lifesaving. Based on the facility and the situation of total airway obstruction, ECMO could also be lifesaving.**

EQUIPMENT

Emergency Department Equipment

- Intubation equipment
- Percutaneous transtracheal jet ventilator
- Cricothyroidotomy kit
- Suction source, tubing, and catheter
- Magill forceps
- Laryngoscope with a variety of blades or a video laryngoscope
- Topical anesthetic spray
- Fiberoptic nasopharyngoscope

OPERATING ROOM EQUIPMENT

The proper equipment must be selected based upon the patient's age and size, as well as the suspected composition of the foreign body. Laryngoscopes are selected to allow visualization of the larynx and the passage of a bronchoscope. Rigid, ventilating bronchoscopes with fiberoptic telescopes provide optimal visualization. This allows direct access to the airway, excellent visualization, continuous administration of anesthetic agent and oxygen, and a conduit for the introduction of instruments (forceps) to retrieve the foreign object. Multiple sizes of laryngoscopes and bronchoscopes are essential to have available in the operating room. Numerous extraction instruments (of different sizes and shapes) must be available and include smooth, toothed, cupped, angled, open mouth, and optical forceps. The optical forceps allow a magnified and direct view through the forceps improving visualization and ease of foreign body removal.

PATIENT PREPARATION

Timing of endoscopy and airway foreign body retrieval must be based upon each individual patient. Do not waste time if impending airway obstruction exists. Immediately notify and mobilize an Anesthesiologist, Otolaryngologist, and the Operating Room, as this is an emergent situation. It is appropriate to wait for NPO status to be present and the stomach empty prior to proceeding to the Operating Room if the diagnosis of an airway foreign body is highly suspected and the patient is stable. This is considered a timely approach and may take up to 6 hours for children or 8 hours for adults. Waiting this time in the stable patient decreases the risk of aspiration and further compromising the situation. It is also appropriate to wait, in a stable patient, in order to assemble the appropriate and best nursing and anesthesia team to care for the patient. Using personnel who are unfamiliar with endoscopy can create a compromised and stressful situation.

TECHNIQUES

EMERGENCY DEPARTMENT TECHNIQUES

The foreign body airway obstruction protocol based upon the Pediatric Basic Life Support textbook treats conscious infants (younger than 1 year of age) with four back blows while the infant is in a prone position on the rescuer's forearm, face down, and the head lower than the trunk. This is combined with four rapid chest thrusts (as in infant CPR), if the obstruction persists, while the infant is supine with the head lower than the body.[11] Treat unconscious infants by opening the airway and attempting rescue breathing based on basic life support protocols.[11] Treat children and adults with the standard Heimlich maneuver, using gentle thrusts in smaller children to decrease the likelihood of injury to the abdominal organs. Finger sweeps to remove a foreign body in the oral cavity should only be performed if the foreign body is directly visualized. Blind finger sweeps are not recommended as they can further impact the foreign body and obstruct the airway.

It is always best not to manipulate the airway or attempt intubation in a stable patient with an airway foreign body and who is moving air and breathing. The airway is best controlled in the Operating Room at the time of the actual foreign body removal. Once the airway is manipulated a foreign body can become dislodged, turning a partial airway obstruction into a complete airway obstruction. If this occurs in the Operating Room, the bronchoscopy equipment is available for urgent use by the endoscopist if needed.

Attempt orotracheal intubation in the Emergency Department if the airway obstruction progresses rapidly and the patient cannot ventilate. Intubation can be used to force the foreign body into one mainstem bronchus and allow ventilation of the other lung. One-lung ventilation will keep the patient alive until the foreign body can be removed in the Operating Room. Position the laryngoscope to visualize the larynx. If a foreign body is visualized, grasp the foreign body with a McGill forceps and remove it. If no foreign body is visualized, intubate the patient. Insert and advance the endotracheal tube as far as it will advance if the foreign body is not visualized or unable to be grasped. If the endotracheal tube will not pass, try a smaller size tube. Withdraw and position the endotracheal tube with the tip above the carina to optimize ventilation. As an alternative, properly insert and position the endotracheal tube above the carina then advance a bougie through the endotracheal tube in an attempt to move the foreign body distally. **Always be prepared to perform a cricothyroidotomy or transtracheal jet ventilation.** Transtracheal jet ventilation allows for short-term oxygenation, is temporary, and may allow time for safe transport to the Operating Room so that endoscopy and foreign body retrieval can be performed in a more controlled environment with appropriate equipment at hand. Refer to Chapters 11, 25, and 24 regarding the details of orotracheal intubation, cricothyroidotomy, and transtracheal jet ventilation, respectively.

Direct laryngoscopy and bronchoscopy in a child or adult with an airway foreign body is a dangerous situation. The procedure may result in a partial airway obstruction becoming a complete airway obstruction. **Always have a cricothyroidotomy tray immediately available.** All equipment must be selected, assembled, and ready for use.

It is possible to remove foreign bodies located within the hypopharynx in the Emergency Department. Typical foreign bodies that may be removed include pieces of food and fishbones. **The patient must be stable and in no risk of airway compromise.** Obtain anteroposterior and lateral soft tissue radiographs of the neck to localize, if possible, the foreign body. The use of CT scans to attempt to identify potential fish or chicken bones that may be lodged in the pharynx, hypopharynx, or esophagus is an option in the stable patient. Perform indirect laryngoscopy to identify the foreign body and its location. Refer to Chapter 173 regarding the complete details of laryngoscopy. Obtain intravenous access.

Place the patient in full monitoring (i.e., pulse oximeter, cardiac monitor, noninvasive blood pressure cuff). Apply a topical anesthetic spray to the oropharynx and the base of the tongue. Place the patient supine. Administer a small dose of an intravenous sedative if required. Slowly and gently insert a #3 Miller laryngoscope blade. An alternative to a traditional laryngoscope, if available, is a video laryngoscope. The video laryngoscope may provide a better field of view with less manipulation. **Do not immediately insert the laryngoscope blade all the way.** Stop frequently to lift the laryngoscope and look for the foreign body. This slow insertion and frequent looks will prevent the laryngoscope blade from pushing the foreign body further into the airway. Elevate the patient's tongue and jaw. Grasp the foreign body with a McGill forceps. Withdraw the McGill forceps followed by the laryngoscope.

OPERATING ROOM TECHNIQUES

The procedure begins with the induction of general anesthesia. It cannot be overemphasized that anesthesia should only be administered by an Anesthesiologist who is competent and comfortable with the situation. Pediatric patients require an Anesthesiologist with pediatric airway experience if the patient is stable. Full monitoring and mask induction allow the patient to maintain spontaneous respiration. Muscle relaxants are avoided as they can induce complete airway obstruction.

The Otolaryngologist begins the procedure. Place the patient supine with a shoulder roll to position the airway. Insert the laryngoscope into the larynx. Expose the larynx by elevating the laryngoscope. Topical anesthetic is applied to the larynx to avoid laryngospasm. The bronchoscope with telescope is then passed under direct vision through the mouth and into the laryngeal introitus. Ventilation can continue via a port on the scope. The foreign body is visualized. Forceps are inserted through the scope and used to grasp the foreign body. Small objects can be removed directly through the scope, whereas larger objects require simultaneously removing the bronchoscope along with the forceps and foreign body. The bronchoscope is passed again, after removal of the foreign body, to identify any mucosal injury or second foreign body that may occur in as many as 5% of patients.[4] If purulent secretions are noted, a culture may be obtained and antibiotics administered appropriately.

A specific type of foreign body, such as a tack or sharp object, may become lodged in the larynx or upper trachea. Extraction with the forceps using standard endoscopic techniques may not be possible. Patients may require a tracheotomy and an open approach (laryngotomy) to remove the foreign body.

ALTERNATIVE TECHNIQUE

The use of a flexible fiberoptic bronchoscope to retrieve bronchial foreign bodies may be acceptable for Physicians who are well trained with this technique. The mainstay of tracheobronchial foreign body retrieval remains to be rigid bronchoscopy.

AFTERCARE

After the retrieval of an airway foreign body, most patients should be breathing spontaneously. An endotracheal tube may rarely, in the presence of significant laryngeal or tracheobronchial edema, need to remain in place temporarily. This would require admission to an intensive care unit. Humidified oxygen is helpful to keep the airway moist and prevent mucous crusts from forming. A postprocedural radiograph will help to determine any subcutaneous air, air in the soft tissues, a pneumothorax, or any changes to the lung fields following the extraction.

All patients who have undergone foreign body removal require at least a few hours of airway observation in a monitored setting. Racemic epinephrine treatments and intravenous Decadron can be administered as needed. Discharge from the hospital is acceptable when the patient is breathing comfortably and no longer in danger of airway compromise. Some patients may be discharged home the same day, while others may require multiple days of airway support and observation.

In cases where a bronchial foreign body has been present for a prolonged period of time, granulation tissue and severe inflammation can form around the foreign body making removal difficult or impossible. It may be necessary to treat the patient with intravenous steroids and antibiotics for 48 hours, with or without intubation, followed by a repeat bronchoscopy and a repeat attempt to remove the foreign body.

COMPLICATIONS

Complications from the foreign bodies themselves include hypoxia leading to cerebral anoxia if not identified. Intraoperative complications can occur in the hands of an inexperienced endoscopist or even an experienced endoscopist who loses control of a foreign body in the airway and is faced with obstruction or respiratory arrest. Cardiac arrhythmias can occur from hypoxia or direct pressure on the left main-stem bronchus. Postoperative problems can include laryngeal or tracheobronchial edema from the foreign body or the instrumentation of the airway. Mucosal irritation can instigate a tracheitis or bronchitis. Pneumonia can develop. Pneumomediastinum has been reported in as many as 13% of aspirations and a pneumothorax slightly less frequently.[16]

A foreign body pulled up from a main stem bronchus can become dislodged in the larynx or trachea and cause a complete airway obstruction. A foreign body in the hypopharynx can be pushed distally and result in a total airway obstruction. The foreign body needs to be quickly removed, pushed back down into one of the mainstem bronchi to allow ventilation of at least one lung, or a surgical airway performed. Failure to react appropriately in this situation can result in asphyxiation and death.

SUMMARY

Airway foreign bodies pose a diagnostic and therapeutic challenge. The initial encounter in the Physician's office, clinic, or the Emergency Department must uncover any historical fact, physical abnormality, or radiographic abnormality that may lead to a definitive or presumed diagnosis of an airway foreign body. Endoscopy

must be performed by a skilled team to allow safe and efficient removal of the foreign body. Hypopharyngeal foreign bodies may be safely removed in the Emergency Department by a trained Emergency Physician.

175 Peritonsillar Abscess Incision and Drainage

Eric F. Reichman, Kellie D. Hughes, and Jehangir Meer

INTRODUCTION

A peritonsillar abscess is the most common deep infection of the head and neck encountered in young adults in the Emergency Department.[1] The incidence is approximately 45,000 cases per year.[2] This infection can occur in all age groups, although it is a relatively rare before the age of 5 years. The highest incidence occurs in adults 20 to 40 years of age. There remains a fair amount of controversy in the literature regarding the optimal antibiotic choice and the mechanism of drainage. The objective for the Emergency Physician remains to make an accurate diagnosis, to institute appropriate care, and to arrange timely follow-up.

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of oropharynx anatomy is imperative. The anatomy of the oral cavity is relatively simple (**Figure 175-1**). The peritonsillar abscess can be found posterolateral to the palatine tonsil and posterior to the palatoglossal fold (or arch). **Note the close proximity of the internal carotid artery and the facial artery to the peritonsillar abscess (Figure 175-2). Use extreme care to not penetrate too deeply and lacerate these arteries.**

Most patients will have had symptoms for approximately 4 days by the time abscess formation has occurred. The most common symptoms include fever, sore throat, dysphagia, muffled voice (the "hot potato" voice), and trismus. Physical examination will reveal a nonexudative pharyngitis in the majority of cases, soft palate edema, a bulging prominent tonsil, and uveal deviation away from the abscessed tonsil (**Figure 175-3**). The differential diagnosis includes intratonsillar abscess, peritonsillar cellulitis, infectious mononucleosis, leukemias, odontogenic infections, and aneurysms of the internal carotid artery.

Intraoral ultrasound (US) for a peritonsillar abscess has been performed since the 1990s. It was first described in the Otolaryngology literature and subsequently in the Emergency Medicine literature. The first case series of patients whose peritonsillar abscesses were drained under US guidance was described by Blaivas and colleagues.[3] Since that time, US guidance has been shown to have a high degree of sensitivity (85% to 92%) and specificity (80% to 100%).[4,5] US offers the advantage of confirming the presence of an abscess prior to aspiration attempts as well allowing visualization of important neighboring structures (e.g., the internal carotid artery). Some patients with a peritonsillar abscess may be misdiagnosed with cellulitis and not undergo drainage. The use of US can prevent this. A significant proportion of patients (10% to 24%) have false-negative results on blind aspiration because the peritonsillar abscess can be multilocular and its location can vary.[4,6,7] US will identify the location of the abscess to limit the number of false-negative aspirations.

The peritonsillar abscess has been attributed to progression and direct extension of an acute exudative pharyngitis. More recent work has described a group of salivary glands, Weber's glands, located in the supratonsillar space as the actual site of bacterial invasion and subsequent abscess formation.[8,9] The glands clear the tonsillar area of debris and assist with the digestion of food particles trapped in

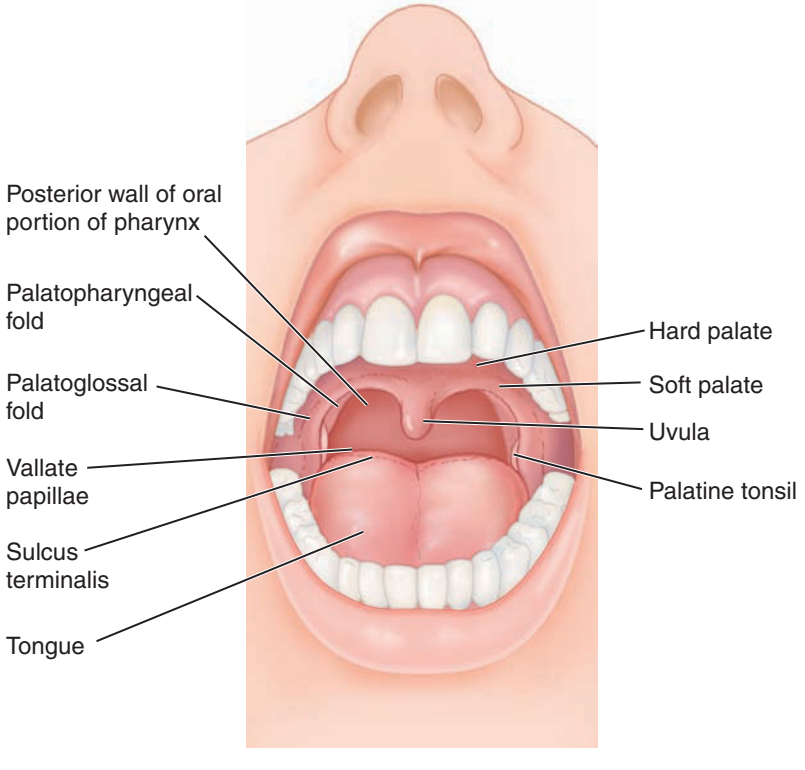

FIGURE 175-1. Anatomy of the oropharynx as seen through the open mouth.

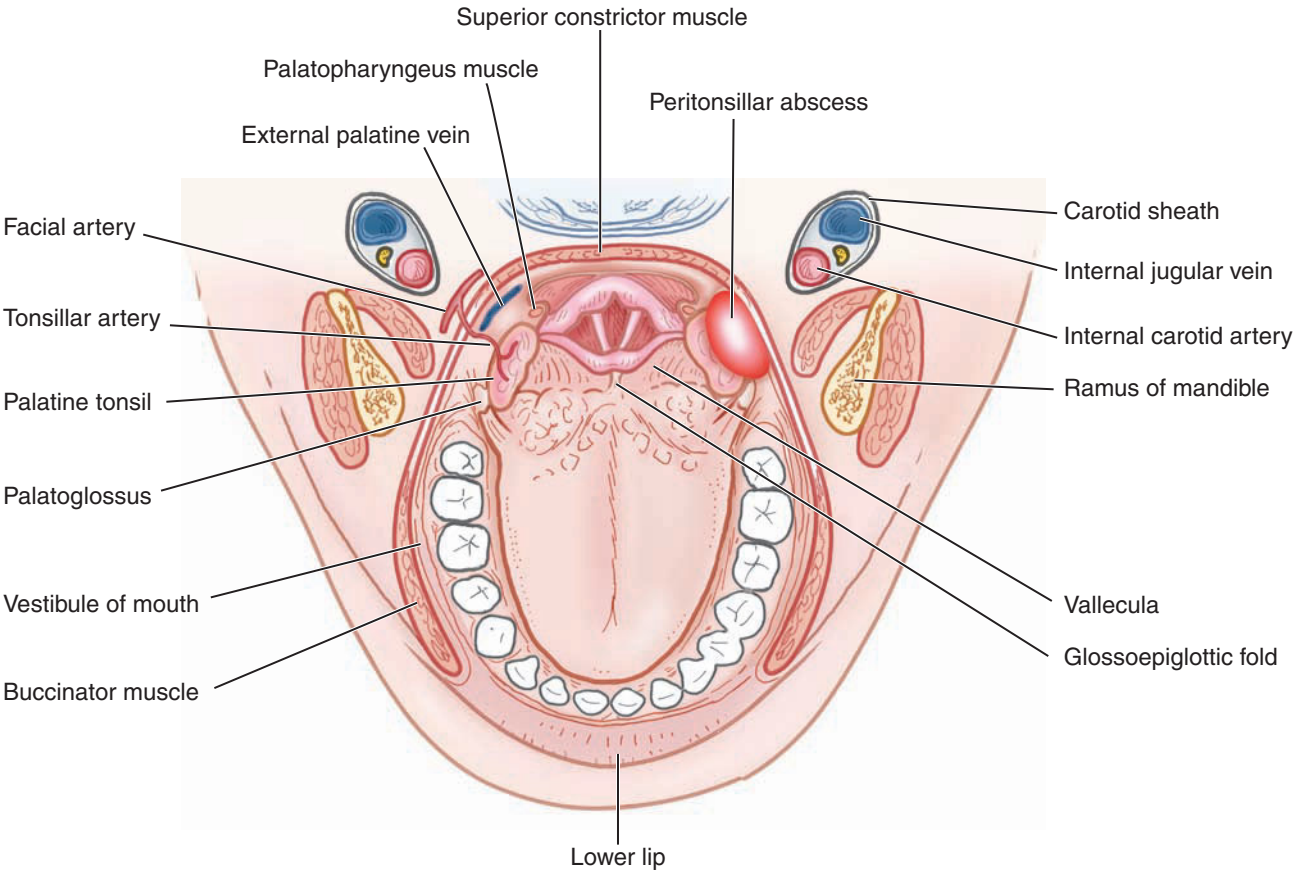

FIGURE 175-2. Horizontal section through the mouth and oropharynx. Note the close proximity of the peritonsillar abscess to the internal carotid artery and the facial artery.

the tonsillar crypts. If the Weber's glands become inflamed, a local cellulitis can develop.[9] The bacterial inoculum results in tissue necrosis and pus formation typically located between the tonsillar capsule and the lateral pharyngeal wall and/or the supratonsillar space. Progression of pus formation and cellulitis within the supratonsillar space results in a gradual involvement of the surrounding musculature, particularly the internal pterygoids, leading to spasm and trismus.

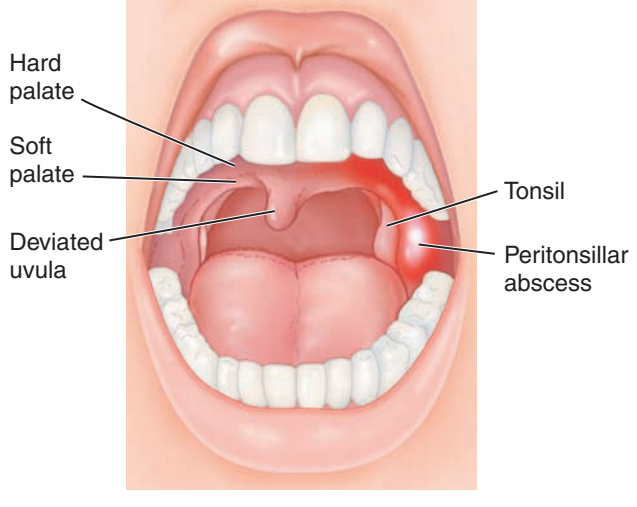

FIGURE 175-3. A peritonsillar abscess. The abscess displaces the tonsil forward and medially. The uvula is deviated toward the contralateral side.

Most peritonsillar abscesses are caused by a mixed profile of aerobic and anaerobic organisms.[10] The most common aerobic isolate found on culture remains group A beta-hemolytic streptococci.[1,9–11] The most common anaerobic species are peptostreptococcus, prevotella, and Fusobacterium.[1] Other isolates include *Staphylococcus aureus*, *Bacteroides fragilis*, and *Bacteroides melaninogenicus*. There is an increasing prevalence of beta-lactamase producing organisms.[11]

Treatment options for a peritonsillar abscess have undergone a significant amount of debate in the literature. Treatment requires appropriate antibiotic selection and removal of purulent fluid. Techniques of fluid removal range from simple or single aspiration of the abscess, repeated aspirations, and incision and drainage. Patients treated with aspiration alone have success rates ranging from 85% to 100%.[2,12,13] The cure rates for simple aspiration versus incision and drainage are similar.[14–18] The overall recurrence rate is less in patients undergoing incision and drainage.[2,12,13]

INDICATIONS

All peritonsillar abscesses require either aspiration or incision and drainage. The gold standard to diagnose a peritonsillar abscess remains the collection of pus through needle aspiration or the identification of a peritonsillar fluid collection using US. The decision regarding the drainage technique is left to the Emergency Physician's preference and, when possible, in consultation with an Otolaryngologist.

US may be used to confirm the presence of a peritonsillar abscess, to guide needle aspiration of a confirmed peritonsillar abscess, and/or rescue a failed blind needle aspiration. The use of US can confirm the presence of a cellulitis with no underlying abscess. It will also confirm that the "mass" is not an aberrant internal carotid artery.[19]

CONTRAINDICATIONS

There are no absolute contraindications to draining a peritonsillar abscess. Patients with severe trismus limiting visibility and access may require intravenous analgesics and muscle relaxants, procedural sedation, or intraoperative drainage. Consult an Otolaryngologist for all patients who are coagulopathic, taking oral anticoagulants, or with a known bleeding disorder. These patients are at risk for significant bleeding and associated complications. Admit children to the hospital for intravenous antibiotics, incision and drainage under general anesthesia, and possible tonsillectomy. The procedure should be avoided in patients who are uncooperative, unable to follow instructions, unable to sit upright, and those that are very young to prevent iatrogenic complications.

EQUIPMENT

General Supplies

- #11 scalpel blade on a handle
- Curved hemostat
- Frazier suction catheter
- Suction source and tubing
- Tongue depressors
- Topical anesthetic spray (Cetacaine, lidocaine, tetracaine, or benzocaine)
- Syringe, 3 or 5 mL
- 25 or 27 gauge needle, 2 inches long
- Local anesthetic solution with epinephrine
- 10 mL syringe
- 18 gauge needle
- Culturettes or culture bottles
- Headlamp or adjustable overhead light source
- Gloves
- Face mask with an eye shield
- Gown
- Oral rinse solution, hydrogen peroxide or Peridex

Us Guidance

- US machine
- High frequency, endocavitary US probe
- Sterile US gel
- US probe cover

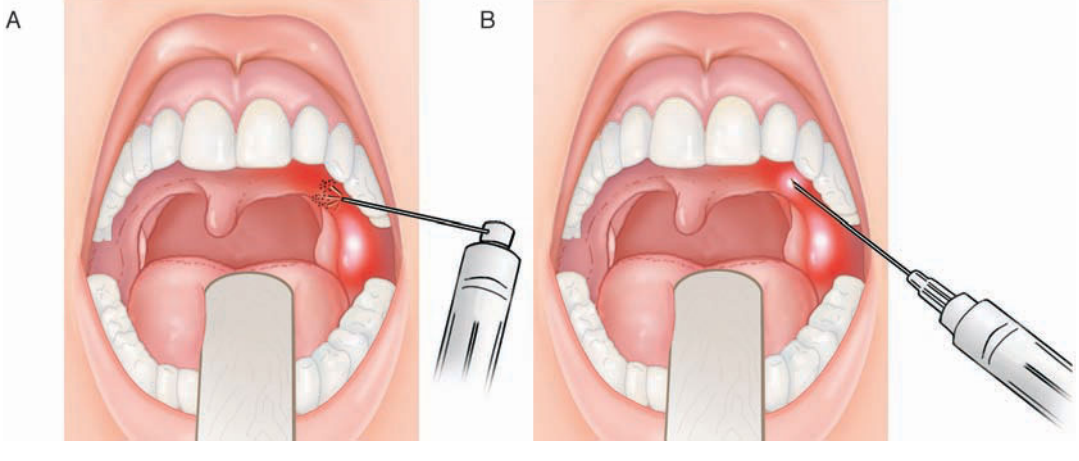
PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Ensure that the patient has a thorough understanding of the postprocedural care instructions and follow-up requirements.

Position the patient sitting in an upright multipositional procedure chair. Alternatively, place the patient sitting upright on a gurney with the back elevated. Prepare the wall suction unit to ensure it is working. Apply suction tubing and a suction catheter to the suction source. The Emergency Physician should wear gloves, a gown, and a face mask with eye protection. This protective wear will prevent against becoming exposed or contaminated with oral secretions or abscess contents during the procedure if the patient coughs.

The use of good lighting cannot be overemphasized. Apply a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. The overhead light often hits the examiner in the head, casts shadows, is too bright for the patient's eyes, and is also difficult to properly position because both of the Emergency Physician's hands must be used for the procedure. An additional alternative is to use the bottom half of a vaginal speculum with a fiberoptic light source.[25] This requires an assistant to position and hold the speculum against the tongue and apply downward pressure.

Incision and drainage must be preceded by adequate anesthesia to the abscess site. Determine the most fluctuant region of the abscess. Anesthetize this area. Spray topical anesthetic over the abscess (**Figure 175-4A**). Dry the mucosa overlying the peritonsillar abscess with a gauze square. Arm a 3 mL syringe with a 25 or 27 gauge needle. Inject 1 mL of local anesthetic solution containing epinephrine through the area of topical anesthesia and just under the mucosal surface (**Figure 175-4B**). Allow 3 to 5 minutes for the anesthetic to work.



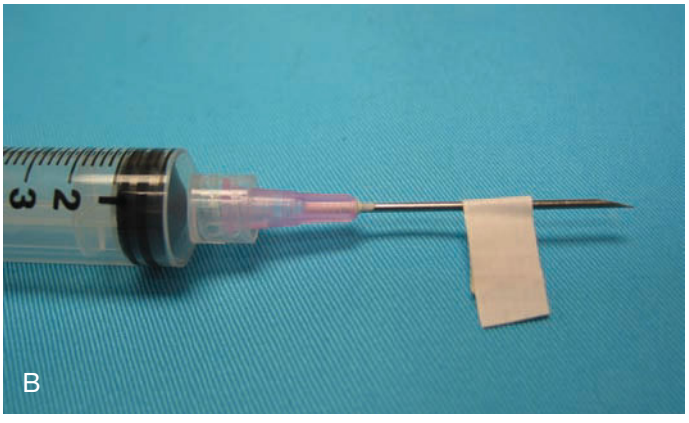


FIGURE 175-4. Anesthesia techniques. **A.** Topical spray anesthesia. **B.** Infiltrative anesthesia.

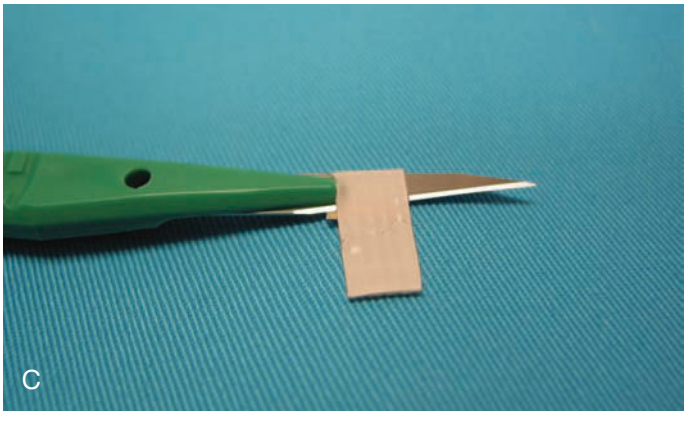

FIGURE 175-5. Safety techniques to prevent injury to the internal carotid artery. **A.** The needle cover is cut and placed over the needle as a guard. **B.** Tape applied to an 18 gauge needle. **C.** Tape applied to a #11 scalpel blade.

TECHNIQUES

ASPIRATION

Identify the area of maximal fluctuance at the upper pole of the abscess. Anesthetize the area as described previously. Prepare the equipment. Apply an 18 gauge needle onto a 10 mL syringe. **A smaller needle may not allow thick pus to be aspirated.** Break the seal of the syringe. Trim the needle cap and place it over the needle to act as a depth gauge (**Figure 175-5A**). The needle should project only 1 cm from the distal end of the needle cap. Alternatively, apply a piece of tape onto the needle to mark a point 1 cm from the tip of the needle (**Figure 175-5B**). The guard (cap or tape) serves as a marker for the maximum allowable depth to insert the needle during the procedure. **Limiting of the depth of insertion of the needle will prevent injury to the carotid artery that is located approximately 1.5 to 2 cm posterior and lateral to the tonsil.**

Depress the tongue with a tongue depressor held in the nondominant hand (**Figure 175-6A**). Insert the prepared needle attached to the syringe into the upper pole of the abscess, into the point of maximal fluctuance (**Figures 175-6A & B**).[14,17,20,21] Hold and advance the needle parallel to the floor and directly posterior.

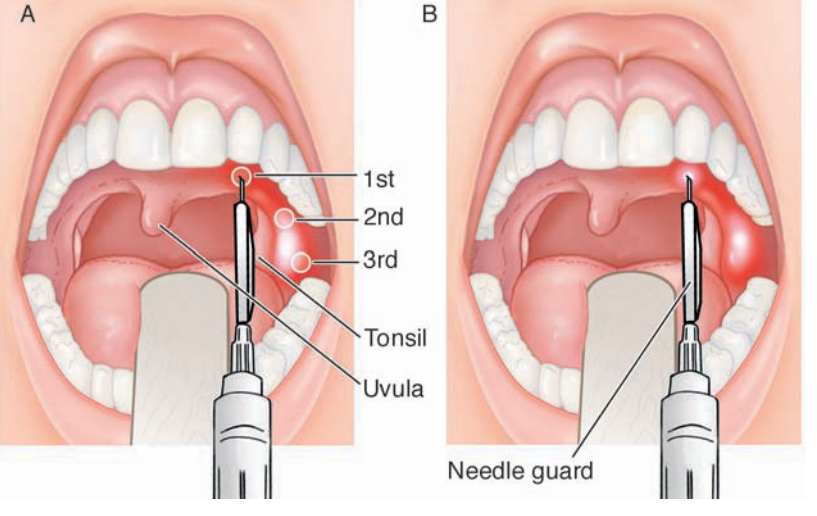

FIGURE 175-6. Needle aspiration of a peritonsillar abscess. **A.** Recommended sites for needle aspiration. **B.** Aspiration in the first area.

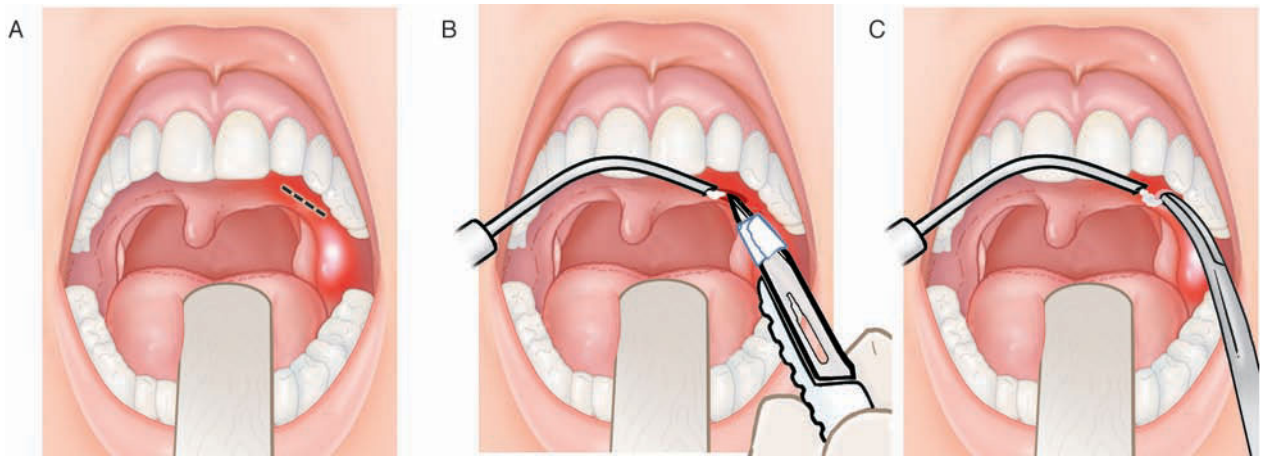

FIGURE 175-7. Incision and drainage of a peritonsillar abscess. **A.** The incision site is also the same site for the first aspiration. **B.** Incision with a #11 scalpel blade. Note the tape marking the maximum insertion depth of the scalpel blade. Suction any bloody or purulent fluid that escapes from the incision. **C.** Hemostat gently inserted to break any loculations.

Do not direct the needle laterally where it can injure the carotid artery. Aspirate while advancing the needle. Approximately 85% to 90% of abscesses occur in the upper pole of the tonsil.[14,17] If purulent fluid is obtained, continue to aspirate and remove as much purulent material as possible. Obtain a culture and sensitivity of the aspirated material. Allow the patient to rinse and spit several times with Peridex solution or half-strength hydrogen peroxide solution.

If the initial aspirate is negative, reattempt the procedure by inserting the needle into the middle pole and then the inferior pole of the abscessed tonsil until purulent material is obtained (**Figure 175-6A**). **A completely negative aspiration, while more consistent with a tonsillar cellulitis, does not rule out the existence of an abscess.** Gentle palpation will reveal fluctuance when an abscess if present.

INCISION AND DRAINAGE

It is recommended to always perform a needle aspiration prior to the incision and drainage technique. Aspiration will localize the collection of pus and allow a more accurate incision and drainage. **A negative aspiration at all three sites (Figure 175-6A) is a contraindication for an incision and drainage procedure.** It may be too early and an abscess has not yet formed. A negative aspiration at all three sites suggests that the patient has a tonsillar cellulitis requiring oral antibiotics, gargles with hydrogen peroxide, and follow-up in 24 hours for reevaluation.

Identify the area of maximal fluctuance at the upper pole of the abscess. Anesthetize the area as described previously. Prepare the equipment. Place a piece of tape on the #11 scalpel blade so that only 0.75 to 1 cm is exposed (**Figure 175-5C**). Place the Frazier suction catheter near the incision site. Insert the scalpel blade to make a horizontal stab wound to a maximum depth of 1 cm in the same area noted for the aspiration technique (**Figures 175-7A & B**). The Frazier suction catheter will remove any blood and purulent material to prevent the patient from aspirating. **The depth of the stab should be no more than 1 cm. Extend the length of the incision to a maximum of 1.0 to 1.5 cm.**

Insert a curved hemostat into the wound (**Figure 175-7C**). Gently spread apart the jaws of the hemostat to break up any loculations in the abscess. Continue to simultaneously suction the area during the procedure. Packing of the abscess cavity is not required. Obtain a culture and sensitivity of the purulent material. Allow the patient to rinse and spit several times with Peridex solution or half-strength hydrogen peroxide solution. Leave the suction in the patient's hand so they can use it as needed.

US GUIDANCE

Anesthetize the area as described previously. Prepare the equipment. Place sterile US gel on the transducer surface of the US probe. Apply the US probe cover. Take care to avoid trapping air bubbles between the cover and the US probe, as they can seriously degrade the image. Apply sterile US gel over the covered US probe transducer surface.

Gently insert the US probe into the patient's oral cavity. Direct the US probe to the peritonsillar area and until it rests lightly against the posterior pharynx (**Figure 175-8**). Maintain the US probe in a transverse orientation to maximize visualization of the posterior pharynx. Note the location of the palatine tonsil, a small oval structure with low-level echoes, and the internal carotid artery (**Figure 175-9**). A peritonsillar abscess can have variable appearances on US. They usually are heterogeneous, cystic, and

FIGURE 175-8. Placement of the endocavitary US probe inside the oral cavity and directed against the peritonsillar area.

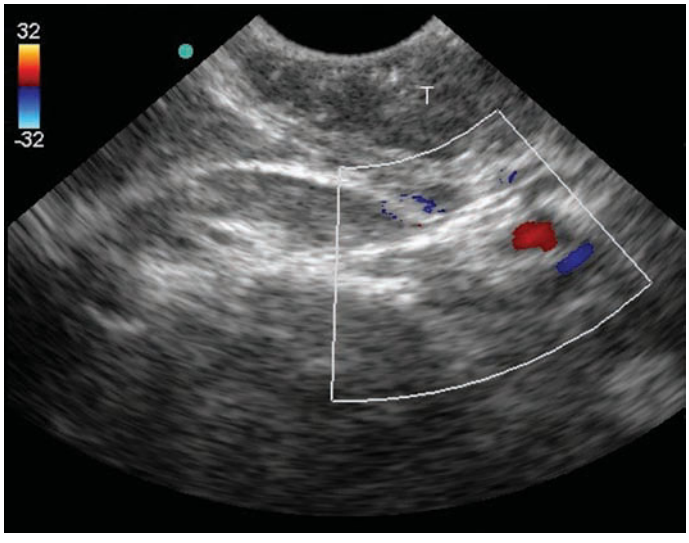

FIGURE 175-9. Transverse color Doppler scan of the normal posterior pharynx. The tonsil (T) is visible on the top of the image. The internal carotid artery is noted by its red color Doppler signal.

FIGURE 175-10. Intraoral ultrasound image. The needle (*arrows*) is inserted into the peritonsillar abscess (A). The tonsil (T) is visible on the top of the image. The internal carotid artery is not visualized in this image.

adjacent to the tonsil (**Figure 175-10**). The carotid artery usually lies 5 to 20 mm posterolateral to the tonsil. Note the depth and location of the abscess.

After the presence of a peritonsillar abscess is confirmed and its location mapped, proceed using the previously described techniques for aspiration or incision and drainage. Alternatively, perform a needle aspiration under real-time US guidance. Use the long axis approach to direct the needle into the peritonsillar abscess (**Figure 175-10**).

ASSESSMENT

Incision and drainage will result in significant relief of the patient's pain and trismus. Allow the patient to rinse and spit with either Peridex solution or half-strength peroxide solution. Observe the patient for any evidence of continued bleeding or upper airway symptomatology. Assess the patient's ability to tolerate oral fluids prior to discharge.

AFTERCARE

Discharge the patient with oral antibiotics and analgesics. Penicillin used to be the antibiotic of choice. The emergence of beta-lactamase-producing organisms has required a change in antibiotic choice.[10] Use clindamycin, or a second or third generation cephalosporin, to treat peritonsillar abscesses due to their polymicrobial coverage.[9,10] If penicillin is used, many Otolaryngologists will add either clindamycin or metronidazole due to the increasing incidence of penicillin-resistant organisms.[2,22] Nonsteroidal anti-inflammatory drugs will adequately control any pain and fever. Consider the administration of 3 mg/kg, to a maximum of 250 mg, of methylprednisolone to decrease pain and inflammation.[23]

Recommend to the patient to follow a soft diet and drink plenty of fluids during the first 48 hours after the intervention. Instruct the patient to gargle with half-strength hydrogen peroxide or Peridex after each meal, at a minimum, and several other times per day. Arrange follow-up within 48 hours, or sooner if they do not improve. Instruct the patient to return to the Emergency Department immediately if they develop bleeding, shortness of breath, difficulty swallowing, drooling, or have any concerns.

Admission is generally required for patients who appear toxic, pediatric patients, dehydrated patients, immunocompromised patients, recurrent abscesses, and for patients who are unable to tolerate oral fluids. These patients require observation for 23 hours and intravenous antibiotics.

COMPLICATIONS

There are few complications associated with the management of a peritonsillar abscess. Potential complications include aspiration pneumonitis, airway obstruction, hemorrhage, or extension of infection into deep tissue of the neck. Aspiration pneumonitis or lung abscess can occur secondary to abscess rupture.[9] Protect against aspiration of purulent material and subsequent pulmonic infection by having the patient sit upright during the procedure and using suction as the abscess is opened. Making an incision that is too large or too deep can injure the carotid artery (or a carotid artery aneurysm) which could result in prolonged bleeding or hemorrhage. Always limit the depth of the needle or scalpel insertion.

The use of US to locate and assist in the drainage of a peritonsillar abscess is associated with several pitfalls. Failure to recognize the internal carotid artery can be catastrophic for the patient. Always note the relationship of the tonsil and the peritonsillar abscess to the internal carotid artery.[24] The internal carotid artery lies posterolateral to the tonsil. The use of color Doppler can assist in the identification of the carotid artery and differentiate it from the peritonsillar abscess. US may fail to identify a peritonsillar abscess. Although fluid within a peritonsillar abscess is usually hypoechoic, it can appear isoechoic or hyperechoic.

SUMMARY

A peritonsillar abscess is commonly encountered in the Emergency Department. Diagnosis and treatment result in rapid symptom resolution in the majority of patients. Admission may be required in a few instances for observation and intravenous antibiotics. Appropriate antibiotics after the procedure can prevent a recurrence of the peritonsillar abscess.

176 Dental Anesthesia and Analgesia

Eric F. Reichman

INTRODUCTION

Dental anesthesia techniques are used by Emergency Physicians for a variety of intraoral and extraoral conditions. This includes dental caries, jaw fractures, dry sockets, intraoral hemorrhage, laceration repair, and tooth fractures. These techniques are simple to learn, easy to perform, and provide temporary pain relief for the patient. The Emergency Physician can provide pain-free intraoral manipulations, extraoral manipulations, facial manipulations, and simple pain control until the patient receives definitive evaluation and treatment by a Dentist or Oral Surgeon. The fundamental principles of dental anesthesia and anatomy will be discussed so that the Emergency Physician will feel knowledgeable and comfortable performing dental anesthetic techniques.

ANATOMY AND PATHOPHYSIOLOGY

An understanding of the anatomy of the fifth cranial nerve is essential to performing dental nerve blocks[1] (**Figure 176-1**). The fifth cranial nerve is also referred to as CN V or the trigeminal nerve. It is the largest cranial nerve. It is a mixed cranial nerve containing primarily sensory fibers to the skin of the face and scalp, the nasal cavity, and the oral cavity. The motor fibers innervate the muscles of mastication.

The trigeminal nerve originates in the brainstem as a small motor root and a large sensory root. These roots fuse as they leave the brainstem. The trigeminal nerve travels forward into the middle cranial fossa where it expands into a large and crescent-shaped trigeminal ganglion. The trigeminal ganglion divides to give rise to the three divisions of the trigeminal nerve: the ophthalmic nerve (V_1), the maxillary nerve (V_2), and the mandibular nerve (V_3) (**Figure 176-1**). Each of these nerves leaves the middle cranial fossa through its own foramen.

OPHTHALMIC NERVE

The ophthalmic nerve is the smallest branch of the trigeminal nerve. It travels forward in the lateral wall of the cavernous sinus and enters the orbit via the superior orbital fissure. It provides sensory innervation to the forehead, scalp, upper eyelid, cornea, nasal cavity, sinuses, and the orbit. This nerve is not discussed further because it does not innervate any oral or dental structures.

MAXILLARY NERVE

The maxillary nerve is purely sensory. It travels forward in the lateral wall of the cavernous sinus and exits the cranial vault via the foramen rotundum into the pterygopalatine fossa. It then enters the

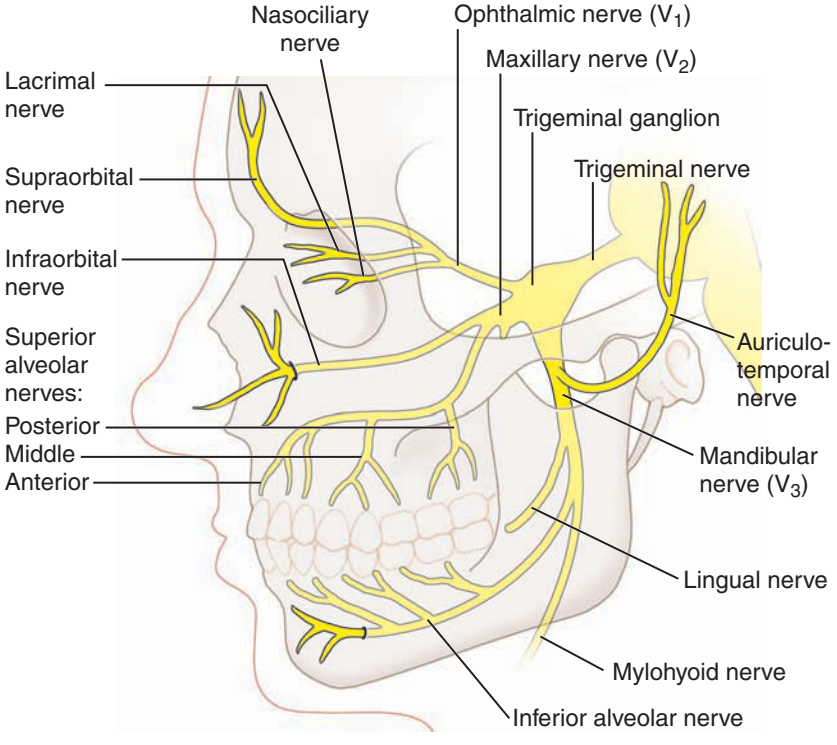

FIGURE 176-1. The anatomy of the trigeminal nerve.

orbit through the inferior orbital fissure to continue on as the infraorbital nerve and emerge on the face. The infraorbital nerve terminates as a sensory nerve to the lower eyelid, upper cheek, nose, and upper lip. The infraorbital nerve gives off the anterior superior alveolar nerves prior to its termination. These nerves supply the maxillary sinus, the maxillary incisors, the maxillary canine teeth, and the maxillary premolar teeth. The anterior superior alveolar nerve occasionally crosses the midline to supply the contralateral maxillary incisors.

The maxillary nerve forms numerous branches in the pterygopalatine fossa. The zygomaticofacial and zygomaticotemporal nerves are cutaneous to the face and temple. The nasal and nasopalatine nerves supply the nasal cavity and floor of the nasal cavity. The nasopalatine nerve exits the nasal canal through the midline incisive foramen, just posterior to the central incisors. It provides sensory innervation to the anterior hard palate and associated soft tissues. The greater palatine nerve exits the greater palatine foramen to provide sensory innervation to the posterior two-thirds of the hard palate. The lesser palatine nerve exits the lesser palatine foramen and provides sensory innervation to the soft palate. The greater and lesser palatine nerves exit 1 cm medial to the junction of the second and third molar on the hard palate. The middle superior alveolar nerve provides sensory innervation to the premolars, and occasionally the canine and the first molar teeth. The posterior superior alveolar nerve provides sensory innervation to the molars and, occasionally, the premolars.

MANDIBULAR NERVE

The mandibular nerve is the largest division of the trigeminal nerve. It is the only division of the trigeminal nerve to contain motor fibers. The mandibular nerve exits the middle cranial fossa via the foramen ovale. It provides branches to the meninges and the small muscles of the palate and the medial pterygoid muscle. It divides into a small anterior division and a large posterior division.

The anterior division of the mandibular nerve is primarily motor. It innervates the muscles of mastication (i.e., masseter, temporalis, and lateral pterygoid). The sensory portion of the anterior division is the buccal nerve. This nerve travels between the two heads of the lateral pterygoid muscle, under the masseter muscle, and emerges from the anterior border of the masseter muscle. It travels forward to innervate a small and variable portion of the skin of the cheek. It primarily innervates the mucous membranes of the cheek.

The posterior division of the mandibular nerve is purely sensory. It divides into the auriculotemporal, inferior alveolar, and lingual nerves. The auriculotemporal nerve supplies sensory innervation to the skin of the auricle, external auditory canal, scalp, and temporomandibular joint. It conveys postganglionic parasympathetic fibers to the parotid gland.

The lingual nerve descends into the mouth and travels along the lateral surface of the tongue. It supplies sensory innervation to the anterior two-thirds of the tongue and the floor of the mouth. The lingual nerve receives, near its origin, and conveys the chorda tympani from the facial nerve. The chorda tympani provides taste sensation to the anterior two-thirds of the tongue and preganglionic fibers to the submandibular ganglion for the submandibular and sublingual glands.

The inferior alveolar nerve descends immediately posterior and adjacent to the lingual nerve. It enters the upper one-third of the ramus of the mandible, posterior to the lingula, to enter the mandibular canal. It provides sensory innervation to the mandible, the mandibular teeth, and the adjacent mucous membranes. The inferior alveolar nerve gives origin to the mental nerve. The mental nerve exits the mental foramen located on the outer surface of the mandible between the first and second premolars. It supplies sensory innervation to the lower lip, the skin of the chin, and the mucous membrane of the chin.

INDICATIONS

Dental nerve blocks can be performed to provide temporary relief of pain. They are often used to provide relief from alveolar ridge fractures, dental caries, dry sockets, mandible fractures, and tooth fractures. Nerve blocks can be performed prior to painful intraoral procedures such as incision and drainage of dental abscesses and laceration repair to the cheek, lips, oral mucosa, and tongue. Nerve blocks do not distort the local anatomy, when compared to infiltration of the surrounding soft tissue with local anesthetic solution, and allow better approximation of the wound edges during suturing. Nerve blocks are an excellent alternative if narcotic analgesics are contraindicated or to be avoided. Local anesthetic solutions containing epinephrine can be utilized to provide longer pain relief and vasoconstriction along the nerve distribution (**Table 176-1**).

CONTRAINDICATIONS

The two absolute contraindications to dental anesthesia include a known hypersensitivity to the anesthetic agent and gross distortion of the anatomic landmarks required to perform the nerve

TABLE 176-1 Local Anesthetic Solutions Commonly used in Dental Anesthesia Procedures

Anesthetic solution	Proprietary name	Time of onset (minutes)	Pulpal duration of action (minutes)	Soft tissue duration of action (minutes)	Maximum dose (mg)*	Maximum adult or pediatric weight-based dose (mg/kg)
1% procaine	Novocaine™	6–10	10	15–90	500	7.0
1% procaine with epinephrine		6–10	15	15–120	600	9.0
2% lidocaine	Xylocaine™	2–5	10	30–45	300	4.5
2% lidocaine with epinephrine		2–5	60	180–300	500	7.0
3% mepivacaine	Carbocaine™	5	5–10	90–120	400	6.6
2% mepivacaine with epinephrine		5	45–60	120–140	400	6.6
4% prilocaine	Citanest™	3–5	10–60	60–240	400	6
4% prilocaine with epinephrine		3–5	60–90	180–480	400	6
4% articaine with epinephrine	Septocaine™	1–3	45–75	180–300	500	7
0.5% bupivacaine	Marcaine™	5	60–90	240–280	90	1.3
0.5% bupivacaine with epinephrine		5	90–120	240–720	90	1.3

*Do not exceed this quantity if the maximum weight-based dose is larger than this number.

block. Other relative contraindications include an uncooperative patient, such as an anxious adult, scared child, or any patient with altered mental status. These patients place themselves and the Emergency Physician at significant risk for injury. It may be most prudent to abort the procedure and perform procedural sedation and analgesia (or general anesthesia in the operating room) to ensure the safety of the patient and the Emergency Physician.

The needle used to inject local anesthetic solution should not traverse infected tissue. Injection of the local anesthetic solution into or through infected tissue is also a relative contraindication. These processes may result in spread of the infection into other adjacent tissues or tissue planes. It is possible to cause bacteremia when injecting into infected tissues. Local anesthetic solutions are less effective when injected into areas of infection or inflammation. An infection that tracks along a nerve and into a bone of the face and/or skull is extremely difficult to treat. Evaluate the risks and benefits of injecting through infected tissue and attempt an alternative method of anesthesia if possible.

EQUIPMENT

- Nonsterile gloves
- Antiseptic mouth rinse, any of the following:
  - Hydrogen peroxide
  - Ethanol (7%) with chlorhexidine (0.5%)
  - Povidone iodine solution
  - 0.12% chlorhexidine or Peridex solution
- 4 × 4 gauze squares
- Cotton-tipped applicators
- Aspirating dental syringe (**Figure 176-2**)
- Local anesthetic solution (**Table 176-1**)
- Syringes, 1 and 3 mL
- Suction source and tubing
- Yankauer suction catheter
- Topical anesthetic (e.g., viscous lidocaine, viscous benzocaine, or aerosolized benzocaine)
- Overhead light source or headlamp
- 22 to 27 gauge needles, 2 inches long

The above-listed supplies are required to provide dental anesthesia. They are contained in every Emergency Department. An aspirating dental syringe and anesthetic cartridges, if available, are ideal to perform the nerve blocks (**Figure 176-2**). Standard 1 to 3 mL syringes armed with a 25 or 27 gauge, 2 inch long needle will work as a substitute. The aspirating dental syringe allows better control of the syringe and the ability to simultaneously aspirate and insert the needle with one hand. This allows the nondominant hand to be used to identify landmarks, retract the cheek or tongue, adjust the light source, and/or use the suction catheter. Many local anesthetic solutions are available in 1.8 mL carpules that fit into the dental aspirating syringe. The carpules are available with the local anesthetic solution, and also with or without a vasoconstrictor (usually epinephrine). A dental or multipositional procedure chair would be preferred to the use of a standard cart or gurney.[2,3] Unfortunately, this may not be available in many Emergency Departments.

Numerous injectable agents are available to provide anesthesia (**Table 176-1**). The most commonly used agents are lidocaine and lidocaine without epinephrine (1:100,000). Longer acting agents are commonly available in the Emergency Department (e.g., bupivacaine and mepivacaine, with and without epinephrine) when a prolonged period of anesthesia is required. Avoid using long-acting

FIGURE 176-2. The aspirating dental syringe and local anesthetic cartridges.

local anesthetic agents if the tongue (i.e., inferior alveolar or lingual nerve blocks) or mucosa (i.e., buccal nerve block) is anesthetized, especially in children, to prevent the patient from biting the area and causing injury.

A relatively new device is the Accupal (Accupal, Little Rock, AR). It is an injection preparation tool that prepares the gums before the anesthetic needle is inserted. The Accupal vibrates and produces ultrasonic tissue stimulation to reduce pain sensation at the needle injection site. The Accupal is usually not available in the Emergency Department.

Numerous jet injectors for the delivery of local anesthetic agents are commercially available. These devices inject the local anesthetic solution under pressure and in a fine stream into the soft tissues without the use of a needle. The small volume of injected solution and its superficial penetration into the soft tissues only anesthetizes the soft tissues and not the teeth. Thus, jet injectors cannot be used to anesthetize teeth. They can be used to provide topical anesthesia.

PATIENT PREPARATION

Perform a thorough history and a directed physical examination, dependent on the clinical situation, in any patient undergoing dental anesthesia. Give special attention to the past medical history, past surgical history, current medications, and any history of allergic or adverse reactions to an anesthetic agent. A patient with severe systemic disease may be better served by rescheduling the procedure after appropriate consultation or referral. This will clarify functional reserve and treatment limitations.[2,3] Any patient with cardiac valvular disease, congenital heart anomalies, artificial heart valves, or other indications should receive antibiotic prophylaxis to help prevent bacterial endocarditis caused from transient bacteremia. Please refer to Chapter 177 for more complete details of antibiotic prophylaxis.

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent for the specific

technique to be performed. A formal consent may exist depending upon the institution in which one practices. Some physicians desire a formal signed and dated consent form. Other physicians choose to chart: "All the risks, benefits, and complications were described and discussed with the patient. They understood the procedure described and gave verbal consent for the procedure." This is physician and institution dependent. Place the patient in a well-lighted environment. Reassurance often alleviates a patient's anxiety regarding injections or manipulations and puts them at ease.[2]

Prepare the mucosa at the injection site. Completely dry the mucosa with gauze squares. Apply an antiseptic solution (e.g., 7% ethyl alcohol (ETOH) with 0.5% chlorhexidine solution, diluted povidone iodine, 0.12% chlorhexidine solution, or hydrogen peroxide) to the working area with a cotton ball or gauze square for 15 seconds. Alternatively, the patient can swish 0.12% chlorhexidine mouth rinse or hydrogen peroxide for 30 seconds and then spit it out.

Apply a topical anesthetic agent (e.g., viscous lidocaine or benzocaine with a cotton-tipped applicator, or 20% benzocaine spray) for added patient comfort. **It is not recommended to use TAC (tetracaine, adrenalin, and cocaine) or other topical anesthetic combinations that are used for cutaneous laceration repair on mucosal surfaces.** Their use may lead to significant absorption and systemic toxicity.

TECHNIQUES

The general procedure of a dental nerve block will be described. The specific details are contained within each nerve block described below. Identify the anatomic landmarks required to perform the nerve block. Clean the mucous membrane at the injection site with a gauze square. Apply an antiseptic solution. Apply a topical anesthetic and allow it to work for 2 to 3 minutes. Reidentify the anatomic landmarks. Insert a 25 or 27 gauge needle into the appropriate area to deliver the local anesthetic agent. **If the patient experiences paresthesias, do not inject the local anesthetic solution. Paresthesias signify that the tip of the needle is within the nerve bundle.** Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. This usually takes 5 to 20 seconds. Inject the local anesthetic solution. Allow up to 10 minutes for the local anesthetic solution to take effect. Some Dentists prefer to apply pressure to the area immediately next to the site of the anesthetic injection with a cotton-tipped applicator. This aids in distracting the patient from the pain of injection. Other Dentists "jiggle" the mucous membrane to and fro rapidly as they simultaneously introduce the needle.[2,3]

SUPRAPERIOSTEAL INFILTRATION (FIELD BLOCK)

This technique is commonly used in dentistry. Excellent anesthesia can be achieved with this technique when it is used to anesthetize a branch of the anterior or middle superior alveolar nerve.[3,4] This technique deposits local anesthetic agent against the periosteum of the alveolar ridge adjacent to a tooth (**Figure 176-3A**). The local anesthetic agent then infiltrates through the periosteum, the cortical plate of the maxilla, and the medullary bone to anesthetize the nerve root as it leaves the apex of the tooth. This technique works best for teeth with associated thin cortical bone. This includes the maxillary incisor, canine, and premolar teeth. The molars of the maxilla in an adult are less likely to be anesthetized with this technique as the cortical bone in which they lie is relatively thick and a poor conduit for the anesthetic. Supraperiosteal infiltration is also a poor technique for anesthesia of mandibular teeth in the adult patient for the same reasons. In children, the cortical bone of the maxillary molars and the mandible is thin and may allow this technique to be effectively utilized to anesthetize a tooth.

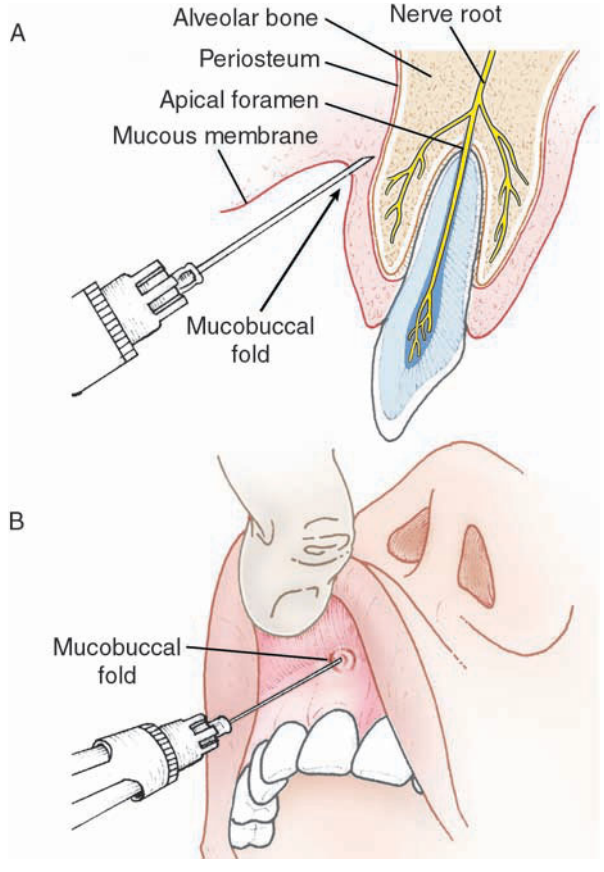

FIGURE 176-3. Supraperiosteal infiltration of local anesthetic solution. **A.** Illustration of the correct needle position. **B.** Elevate the upper lip and insert the needle through the mucobuccal fold.

Anatomy The anterior superior alveolar nerve provides sensory innervation to the ipsilateral medial and lateral incisors, canine, and sometimes the first premolar teeth. The middle superior alveolar nerve provides sensory innervation to the ipsilateral premolars, canine, and first molar teeth.

Patient Positioning Place the patient recumbent in a dental chair with their neck extended 45°. Alternatively, position the patient sitting upright with their back and head firmly set against an examination chair or table.

Landmarks Use the nondominant hand to grasp and pull the upper lip outward and upward (**Figure 176-3B**). Identify the mucobuccal fold above the tooth to be anesthetized.[3]

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the mucobuccal fold above the tooth to be anesthetized. Firmly grasp the upper lip. Pull it outward and upward to tighten the tissues and allow a clear identification of the maxillary mucobuccal fold (**Figure 176-3B**). Insert a 27 gauge needle through the mucobuccal fold over the center of the tooth to be anesthetized (**Figure 176-3B**). Aim the tip of the needle toward the maxilla. Advance the needle 1.0 to 1.5 cm until it contacts the maxilla (**Figure 176-3A**). Withdraw the needle 1 mm. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution.

Remarks The anesthetic will be deposited in a nonoptimal location if the needle is too deep or too shallow. It may take as long as 10 minutes to achieve anesthesia as the local anesthetic solution diffuses through the cortical bone and to the nerve root. **Be careful when using this technique for anesthesia of the incisor or canine**

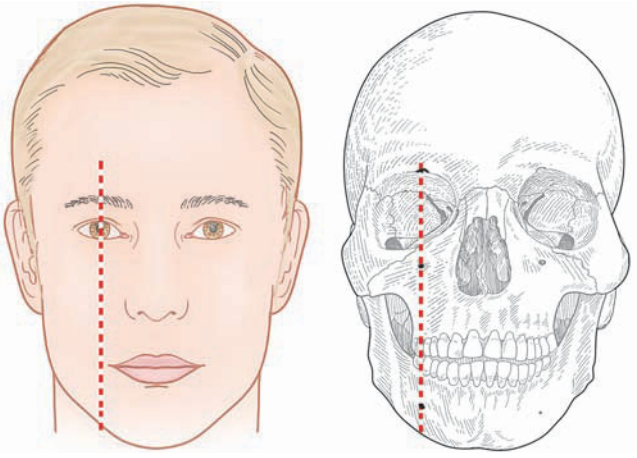

FIGURE 176-4. The supraorbital foramen, infraorbital foramen, and the mental foramen all lie along a straight line drawn through the pupil in the midposition.

teeth because advancing the needle too far may breach the nasal cavity or maxillary sinuses.

INFRAORBITAL NERVE BLOCK

Anatomy The infraorbital nerve is the terminal branch of the maxillary nerve. It exits the maxilla via the infraorbital foramina and supplies sensation to the ipsilateral upper lip, cheek, lateral nose, and lower eyelid. It may be blocked by either an extraoral or intraoral approach.

Patient Positioning Place the patient recumbent in a dental chair with their neck extended 30°. Alternatively, position the patient sitting upright with their head and back against an examination chair or table with their neck extended 30°. Instruct the patient to slightly open their mouth.

Landmarks Identify the infraorbital foramen by palpation. It is located below the infraorbital ridge in the midpupillary line (**Figure 176-4**). The midpupillary line is a line drawn in the sagittal plane (vertical) through the pupil while the patient is staring straight ahead.

Needle Insertion and Direction (Extraoral Approach) Identify the infraorbital foramen as above. Clean and prep the skin over the infraorbital foramen. Instruct the patient to close their eyes. Insert a 25 or 27 gauge needle through the skin overlying the infraorbital foramen (**Figure 176-5**). Advance the needle to just beneath the

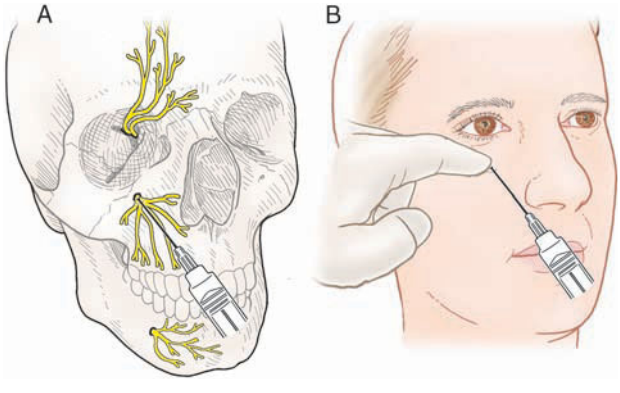

FIGURE 176-5. The extraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

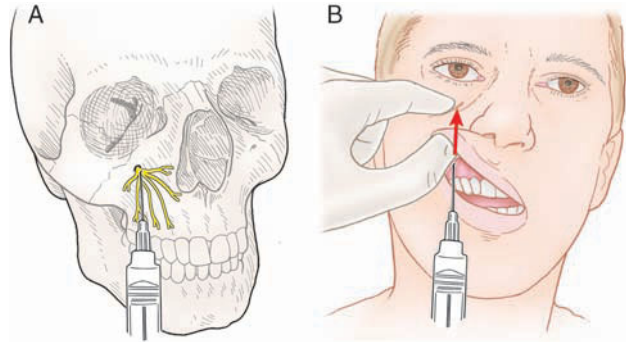

FIGURE 176-6. The intraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

subcutaneous tissue. **Do not enter the infraorbital canal as this may damage the nerve.** Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution. Massage the area over the infraorbital foramen for a few seconds to ensure optimal infiltration.

Needle Insertion and Direction (Intraoral Approach) Clean, prep, and apply a topical anesthetic agent to the mucosa opposite the first maxillary premolar. Place the nondominant index finger over the infraorbital foramen (**Figure 176-6**). Retract the upper lip using the nondominant thumb. Identify the mucobuccal fold above the first premolar. Insert a 25 or 27 gauge needle through the mucobuccal fold. Advance the needle toward the nondominant index finger situated over the infraorbital foramen (**Figure 176-6B**). Stop advancing the needle when the tip is felt beneath the index finger. The estimated depth of penetration of the needle tip is 1.0 to 1.5 cm in an older child or an adult and 0.5 to 1.0 cm in a younger child. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution.

Remarks **Be careful not to penetrate too deeply when performing the intraoral approach.** The infraorbital venous plexus may be disrupted and result in a hematoma. The globe may also be accidentally penetrated. Avoid these complications by positioning the nondominant index finger over the infraorbital foramen and using it to palpate and track the advancing needle tip. The intraoral approach is the preferred technique.

NASOPALATINE NERVE BLOCK

Anatomy The nasopalatine nerve provides sensory innervation to the anterior one-third of the hard palate (**Figure 176-7A**). It exits the maxilla via the incisive foramen in the midline and 0.5 cm posterior to the central incisors.

Patient Positioning Place the patient recumbent in a dental chair with their head extended 45°. Alternatively, place the patient supine with a rolled sheet beneath their shoulder blades to assist in neck extension. Instruct the patient to fully open their mouth.

Landmarks The incisive foramen lies in the midline and approximately 5 mm posterior to the central incisors of the maxilla. Overlying the incisive foramen is the incisive papilla, a soft tissue elevation.

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the mucosa on the anterior one-third of the hard palate. Identify the incisive foramen by first identifying the incisive papilla. Insert a 27 to 30 gauge needle, with the bevel facing the hard palate, from a position immediately lateral to the edge of the incisive papilla (**Figure 176-7B**). Advance the needle

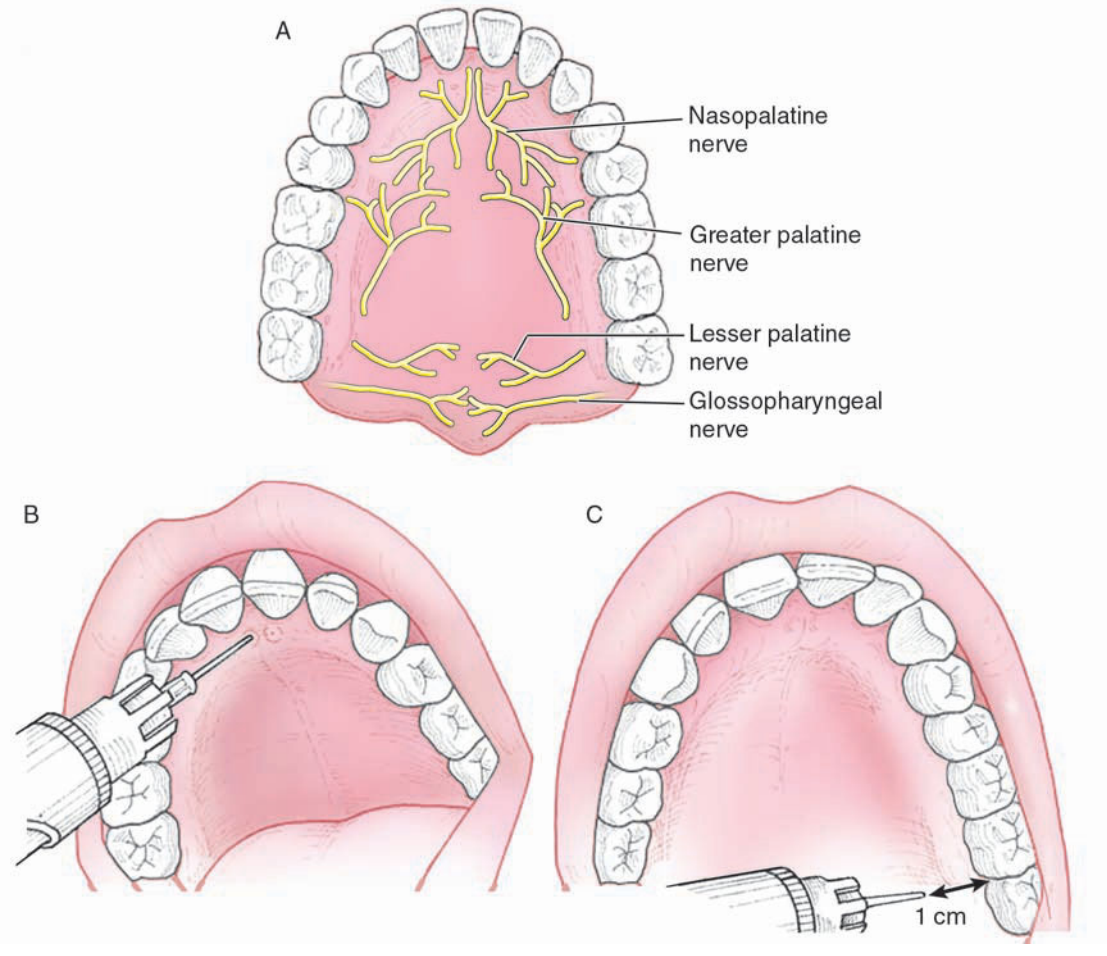

FIGURE 176-7. Anesthesia of the palate. **A.** Sensory innervation of the palate. **B.** Nasopalatine nerve block. **C.** Greater palatine nerve block.

3 to 4 mm toward the midline or until bone is identified. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 0.25 to 0.35 mL of local anesthetic solution. The area surrounding the injection site will blanch upon deposition of the local anesthetic solution.[2,3]

Remarks This is a particularly painful injection due to the adherent nature of the mucosa to the underlying hard palate. Topical anesthetics will provide adequate preinjection anesthesia. Some clinicians use a cotton-tipped applicator or a blunt instrument to put pressure on the incisive papilla for 30 seconds prior to and during the injection.[3] This seems to defer the attention of the patient and make the injection more bearable. **Be careful not to penetrate too deeply with the needle and enter the incisive foramen.** Insertion into the incisive foramen will cause severe pain. **Injection into the incisive foramen can result in permanent nerve damage.**[2,3] The mucosa of the hard palate receives its blood supply from the hard palate. Injection of more than 0.4 mL will elevate the mucosa from the hard palate and result in mucosal necrosis. This block may be performed to repair lacerations of the mucosa of the anterior hard palate.

GREATER PALATINE NERVE BLOCK

Anatomy The greater palatine nerve provides sensory innervation to the ipsilateral posterior two-thirds of the hard palate (**Figure 176-7A**). It enters the oral cavity via the greater palatine foramen. The greater palatine foramen lies between the second and third maxillary molar and approximately 1 cm onto the hard palate.

Patient Positioning Place the patient recumbent in a dental chair with their head extended 45°. Alternatively, place the patient supine with a rolled sheet beneath their shoulder blades to assist in neck extension. Instruct the patient to fully open their mouth.

Landmarks The greater palatine foramen lies 1 cm medial to the gingival junction of the second and third maxillary molar (**Figure 176-7C**).

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the hard palate adjacent to the second and third maxillary molars. Insert a 27 to 30 gauge needle 1 cm medial to the junction of the second and third maxillary molars (**Figure 176-7C**). Ensure that the tip of the needle is held at 90° to the curve of the palate. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 0.25 to 0.35 mL of local anesthetic solution. The area surrounding the injection site will blanch upon deposition of the local anesthetic solution.[2,3]

Remarks This block may be performed to repair lacerations of the mucosa of the hard palate. The mucosa of the hard palate receives its blood supply from the hard palate. Injection of more than 0.4 mL will elevate the mucosa from the hard palate and result in mucosal necrosis. The position of the lesser palatine foramen is 2 to 4 mm posterior to the greater palatine foramen. The lesser palatine nerve provides sensory innervation to the soft palate and uvula. If anesthetized, as it often is when blocking the greater

palatine nerve, the patient may experience a feeling of dysphagia or throat closure. Reassurance is usually adequate to alleviate the patient's anxiety until the anesthesia wears off.

POSTERIOR SUPERIOR ALVEOLAR NERVE BLOCK

Anatomy The maxillary nerve exits the skull via the foramen rotundum. It then courses anteriorly into the pterygopalatine fossa and divides into its constituent branches. The posterior superior alveolar nerve provides sensory innervation to the maxillary molar teeth and their associated mucosal tissues.

Patient Positioning Place the patient semirecumbent in a dental chair with their head extended 30°. Alternatively, place the patient sitting upright with their head and back firmly against the examination chair or table and their head extended 30° to 45°. Instruct the patient to fully open their mouth.

Landmarks Pull the buccal mucosa laterally and identify the inferior-most posterior portion of the zygoma. It lies posterior, lateral, and superior to the third maxillary molar. The pterygomaxillary fissure lies posterior, medial, and superior to the vestibule between the third maxillary molar and the posterior zygoma. The pterygopalatine fossa can be reached by following the pterygomaxillary fissure superiorly and medially.[2,3]

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the recess posterior and lateral to the maxilla. Insert the nondominant index finger between the maxillary molars and the cheek (**Figure 176-8A**). Palpate the zygomatic process of the maxilla with the index finger. Rotate the index finger 180° so that the pad is against the patient's cheek (**Figure 176-8B**). Apply outward pressure to move the cheek away from the teeth. Place the needle along the middle of the nail plate of the index finger. Aim the needle and syringe along the index finger (**Figure 176-8B**). The needle and syringe should be aimed posteriorly, superiorly, and medially (**Figure 176-8C**). Insert and advance the needle 2.5 cm along the index finger. If the needle contacts bone, withdraw the needle completely and direct it more laterally.[2,3] Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 3 mL of local anesthetic solution.

Remarks Bend the needle 30° at the hub to assist in achieving a medial direction of the needle. **Do not bend the needle more than 30° as the needle may fracture. It is extremely important to never change the direction of a needle once it is inserted.** This is associated with an increased risk of needle breakage requiring an operative procedure to recover the needle segment. **Never force the needle.** The needle is inappropriately positioned if it is meeting resistance. Abort the procedure, reidentify the landmarks, and reattempt the procedure.[2,3] Occasionally, the first molar is only partially anesthetized by this block. Consider supplementation of this block with a supraperiosteal infiltration of the first molar.

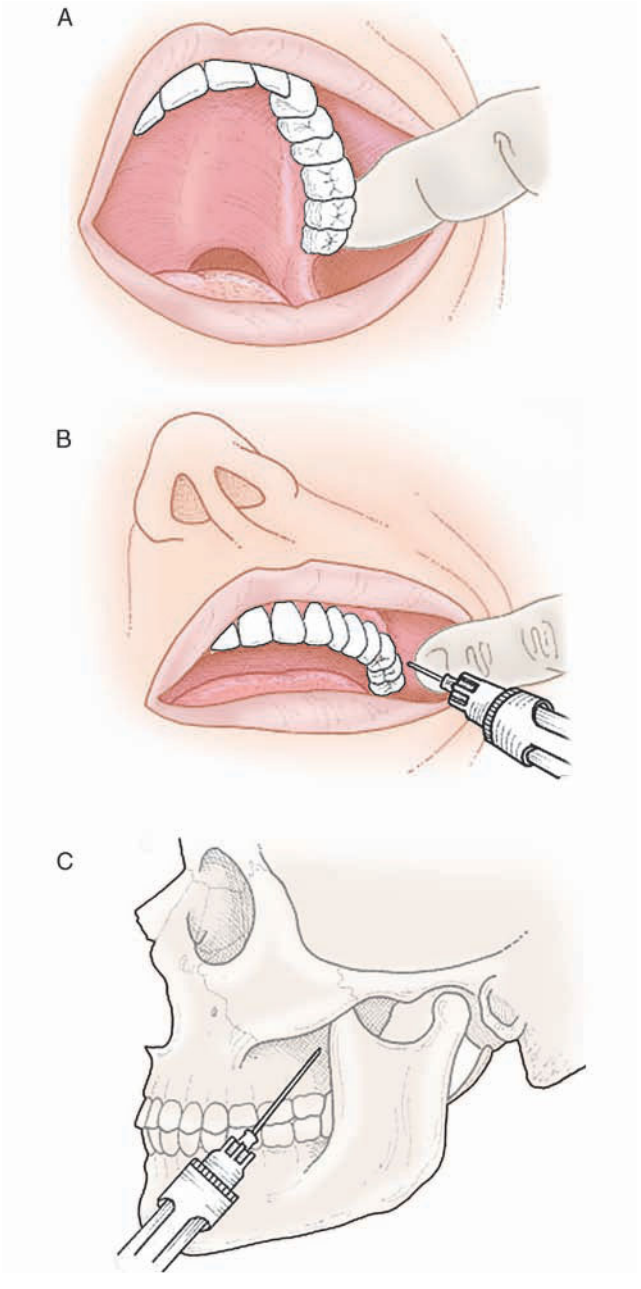

FIGURE 176-8. The posterior superior alveolar nerve block. **A.** The nondominant index finger is inserted and positioned. **B.** The cheek is retracted. **C.** The proper direction for insertion and advancement of the needle.

MENTAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy The mental nerve is one of the two terminal divisions of the inferior alveolar nerve. It provides sensory innervation to the ipsilateral skin and mucosa of the lower lip and chin. It exits the bony mandible at the mental foramen.

Patient Positioning Place the patient recumbent in a dental chair. Alternatively, place the patient sitting upright or supine with their head against the examination table and in the neutral position. Instruct the patient to slightly open their mouth.

Landmarks The mental foramen lies in the same plane as the infraorbital foramen and the midpupillary line (**Figure 176-4**). The mental foramen is located approximately 1 cm beneath the gum line, between the first and second premolar.

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the oral mucosa overlying the mental foramen. Grasp the lower lip with the nondominant hand. Pull it outward and downward (**Figure 176-9**). Insert a 27 gauge needle into the mucobuccal fold between the first and second premolar (**Figure 176-9**). Advance the needle medially until it contacts the mandible. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1.5 to 2.0 mL of local anesthetic solution.

Remarks The mental nerve block, as the infraorbital nerve block, has an intraoral and an extraoral approach. The extraoral approach will not be discussed as it is more painful and there is no benefit to its use over the intraoral approach. A description of the extraoral

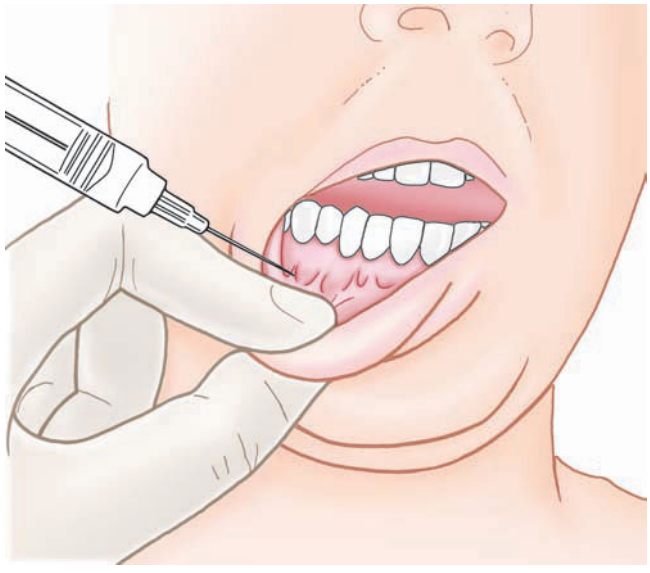

FIGURE 176-9. The intraoral approach to the mental nerve block.

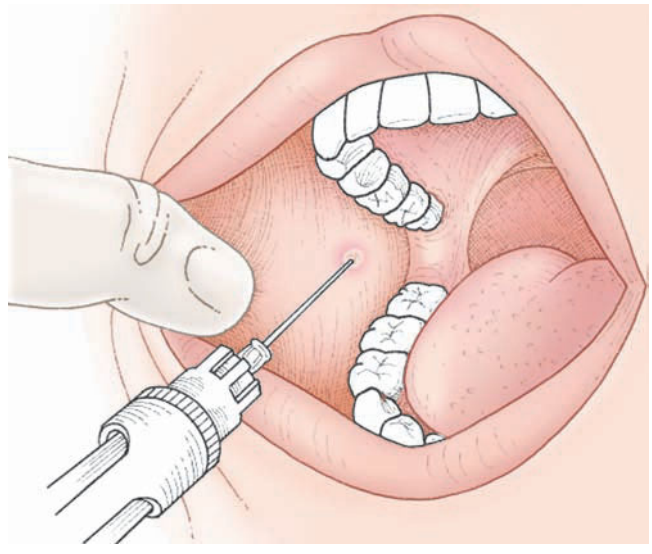

FIGURE 176-10. The buccal nerve block.

approach to the mental nerve block is found in Chapter 126. A near midline lower lip or chin injury may necessitate bilateral mental nerve blockade due to the midline crossover from each of the mental nerves.[2]

BUCCAL NERVE BLOCK

Anatomy The buccal nerve is one of the main branches of the mandibular nerve. It travels down the medial aspect of the ramus of the mandible, anterior to the inferior alveolar neurovascular bundle. It crosses from the medial mandible into the soft tissue of the cheek at the level of the occlusive plane. It supplies the sensory innervation to the mucous membrane of the cheek and vestibule.[1] It innervates, to a variable degree, a small patch of skin over the cheek.

Patient Positioning Place the patient recumbent in a dental chair with their head extended 30°. Alternatively, place the patient sitting with their head and back firmly against an examination chair or upright table with their head extended 30° to 45°. Instruct the patient to fully open their mouth.

Landmarks Visually identify the third mandibular molar. Palpate the anterior border of the ramus of the mandible. The buccal nerve traverses the anterior border of the ramus of the mandible, posterior and slightly lateral to the third molar at the level of the occlusive plane.

Needle Insertion and Direction Clean, prep, and apply a topical anesthetic agent to the oral mucosa over the anterolateral border of the ramus of the mandible. Place the thumb of the nondominant hand on the inner surface of the cheek. Pull the cheek outward. Insert a 27 gauge needle 1 mm lateral to the anterior border of the ramus of the mandible and at the level of the occlusal plane (**Figure 176-10**). Advance the needle 3 to 4 mm into the soft tissues. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

Remarks Buccal nerve blocks are used when extensive intraoral manipulation is anticipated, when buccal manipulation or repair is required, or for the incision and drainage of an abscess. It provides additional patient comfort. The block is nearly always performed as an adjunct to an inferior alveolar, maxillary, or posterior superior alveolar nerve block.[3]

INFERIOR ALVEOLAR NERVE BLOCK

Anatomy The lingual and inferior alveolar nerves are two of four branches of the mandibular nerve. The nerves initially travel together and inferiorly on the medial side of the mandibular ramus (**Figure 176-11A**). The lingula is a palpable bony landmark immediately anterior to the mandibular foramen. The inferior alveolar nerve courses posterior to the lingula and enters the mandibular canal via the mandibular foramen. It continues to travel anteriorly within the mandible to provide sensory innervation to the body of the mandible, the mandibular teeth, and the overlying oral mucosa. One of the terminal branches of the inferior alveolar nerve is the mental nerve. The inferior alveolar nerve may be blocked by the classic, open-mouth approach or the closed-mouth approach.

Patient Positioning Place the patient in a dental chair with their head neutral, such that the occlusive surface is parallel to the floor. Alternatively, place the patient sitting upright in an examination chair or on a gurney with their head positioned firmly against the back of the gurney or chair. Instruct the patient to fully open their mouth. Perform the open-mouth approach if the patient can fully open their mouth. Perform the closed-mouth approach if the patient has trismus or cannot fully open their mouth.

Landmarks Identify by palpation the anterior border of the ramus of the mandible within the mouth, the coronoid notch within the mouth, and the posterior border of the ramus of the mandible externally (**Figure 176-11B**). Approximately equidistant from these two points lie the lingual and the inferior alveolar nerves. Palpate the lingula of the ramus of the mandible. It is a bony projection on the medial surface of the ramus of the mandible and 1 cm above the occlusive plane.

Needle Insertion and Direction (Open-Mouth Approach) Clean, prep, and apply a topical anesthetic agent to the inner surface of the ramus of the mandible. Stand opposite the side to be blocked. Place the thumb of the nondominant hand on the anterior border of the ramus of the mandible. Move the thumb posteromedially to identify the lingula. Place the index finger of the nondominant hand against the extraoral border of the mandibular ramus, just above the angle of the mandible. Grasp the ramus between the thumb and

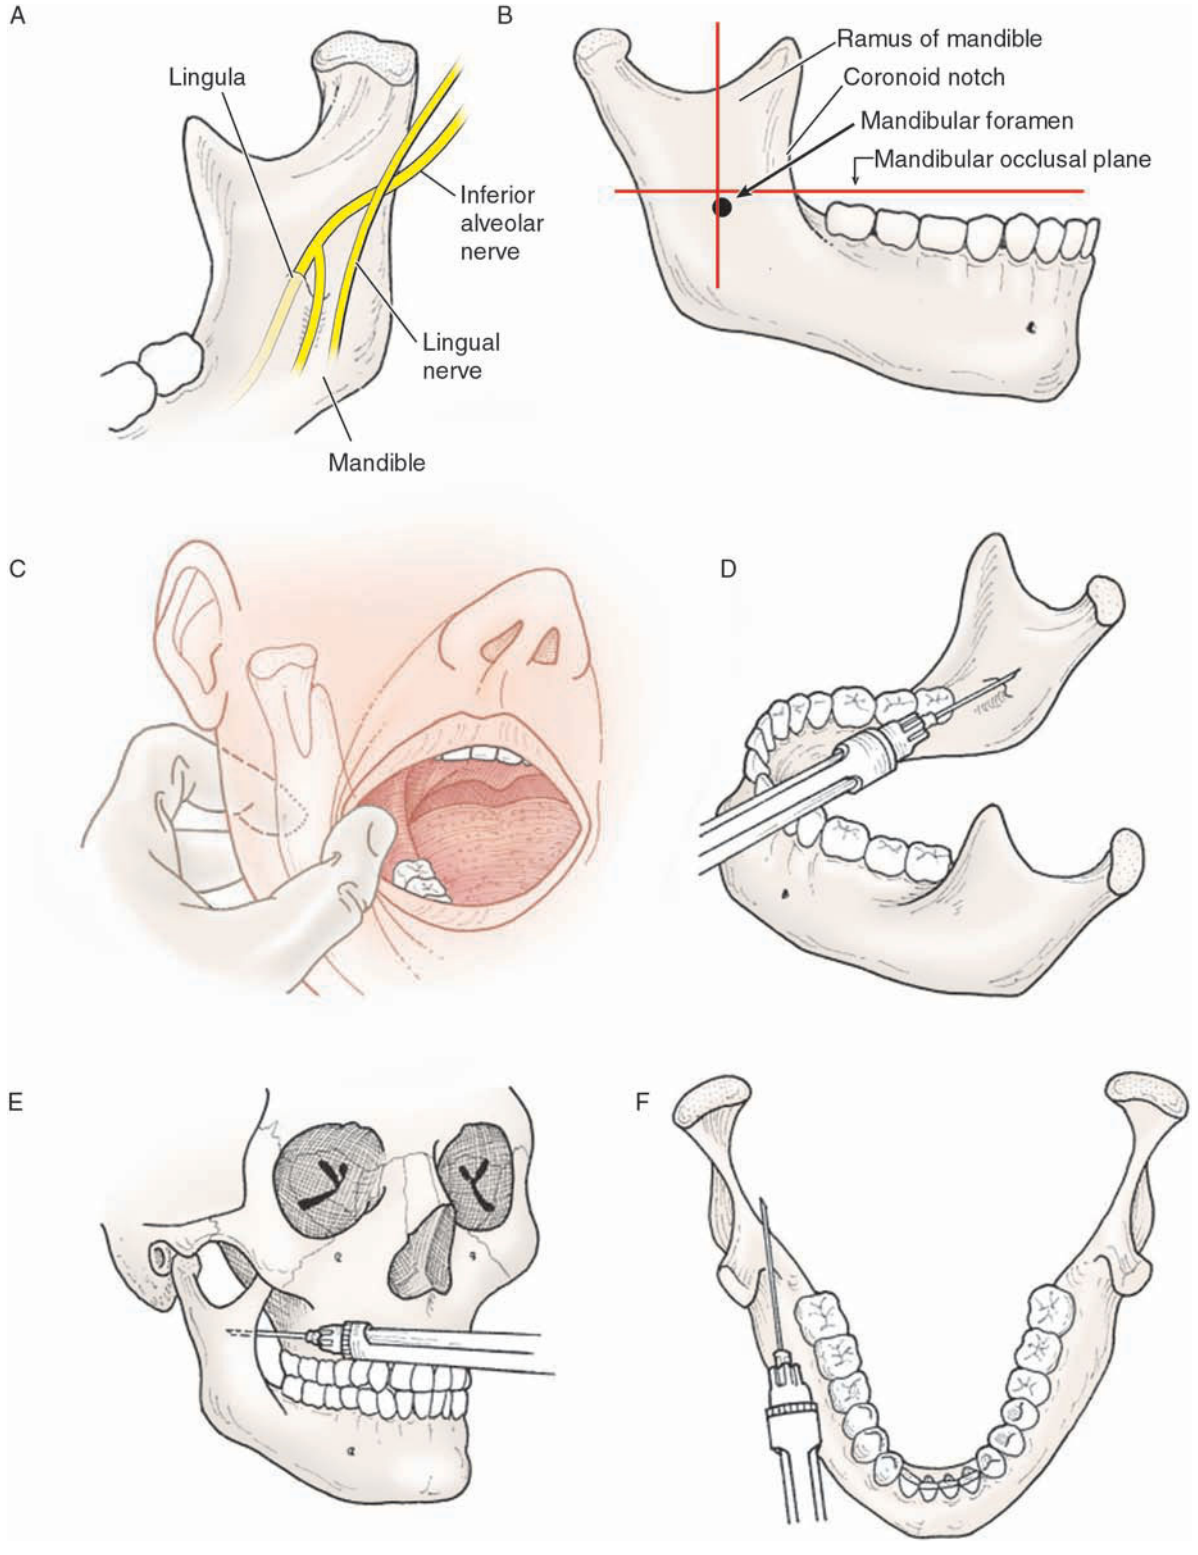

FIGURE 176-11. The inferior alveolar nerve block. **A.** The course of the inferior alveolar nerve and the lingual nerve along the ramus of the mandible. **B.** The anatomy of the external surface of the mandible. **C.** Positioning for the open-mouth approach. **D.** Proper needle insertion and direction for the open-mouth approach. **E.** The closed-mouth approach. **F.** Superior view of the closed-mouth approach demonstrating the proper needle direction.

the forefinger (**Figure 176-11C**). Pull the cheek outward using the nondominant thumb as a lever. Place a 27 gauge, 2 inch needle on a 3 mL syringe that contains local anesthetic solution. A 5 mL syringe is too large for this approach. A syringe smaller than 3 mL will not carry enough anesthetic.

Introduce the needle from the opposite side (**Figure 176-11D**). Align the tip of the needle toward the lingula with the barrel of the syringe between the contralateral first and second premolars (**Figure 176-11D**). Hold the syringe parallel to the occlusal plane and 3 to 4 mm above the premolars. Insert the needle into the oral

mucosa just superior and posterior to the lingula. Advance the needle until the tip contacts the ramus of the mandible. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

The above technique is optimal if the operator is right-handed and a right-sided inferior alveolar block is attempted. If the operator is right-handed and attempting a left-sided inferior alveolar nerve block, it is still necessary to stand opposite the side to be anesthetized with the syringe in the dominant hand. Place the nondominant arm over and around the patient's head so that the thumb of the nondominant hand can contact the anterior border of the mandibular ramus and the index finger can grasp the posterior border above the angle of the mandible. The remainder of the technique is the same.

Needle Insertion and Direction (Closed-Mouth Approach) This method can be used when the patient cannot fully open their mouth due to an abscess, edema, mandible fractures, trismus, or if the mandible is wired-closed to the maxilla. This approach deposits the local anesthetic solution superior to the site of the classic, open-mouth approach. The local anesthetic solution will descend, due to gravity, to bathe the inferior alveolar nerve and provide adequate anesthesia.

Place the nondominant thumb on the inner surface of the cheek. Pull the cheek outward. Place a 27 gauge needle on a 3 mL syringe that contains local anesthetic solution. Place the needle and syringe parallel to the occlusal plane and aligned along the junction of the maxillary molars and their gingiva (**Figure 176-11E**). Direct the needle just medial to the ramus of the mandible (**Figures 176-11E & F**). Advance the needle 3 cm through the mucosa. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

Remarks **It is crucial that the tip of the needle contacts the mandible in the open-mouth approach.** The needle is usually advanced 0.5 to 1 cm before the mandible is encountered. The needle is most likely inappropriately placed and deposition of anesthesia will not produce the desired results if the mandible is not encountered. Remove the needle, reidentify the appropriate anatomic landmarks, and reattempt the procedure if the mandible is not encountered. The buccal, inferior alveolar, and lingual nerves must be blocked on one side to achieve complete anesthesia of the hemimandible. Facial nerve paralysis can occur if the needle is inserted too far posterior and enters the capsule of the parotid gland. This paralysis is usually transient and resolves as the anesthetic wears off.

LINGUAL NERVE BLOCK

Anatomy The lingual nerve is a branch of the mandibular division of the trigeminal nerve. It travels with the inferior alveolar nerve until the inferior alveolar nerve enters the mandible. The lingual nerve leaves the medial aspect of the mandibular ramus and penetrates the posterior tongue at the level of the occlusive plane, just medial to the third mandibular premolar. It courses anteriorly to provide sensory innervation to the anterior two-thirds of the tongue, the floor of the mouth, and the lingual mucous membrane.[1]

Patient Positioning Place the patient in a dental chair with their head neutral, such that the occlusive surface is parallel to the floor. Alternatively, place the patient sitting upright in an examination chair or on a gurney with their head firmly against the back of the gurney or chair. Instruct the patient to fully open their mouth.

Landmarks Identify the lingual side of the second mandibular molar. The injection site is 1 cm medial to the second mandibular molar.

Needle Insertion and Direction Approach the patient from the contralateral side. Move the tongue upward or toward the contralateral side with a tongue blade. Insert a 27 gauge, 2 inch needle into the mucosa 1 cm medial to the second mandibular premolar (**Figure 176-12**). Advance the needle posteriorly 1 cm. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1.0 to 1.5 mL of local anesthetic solution.

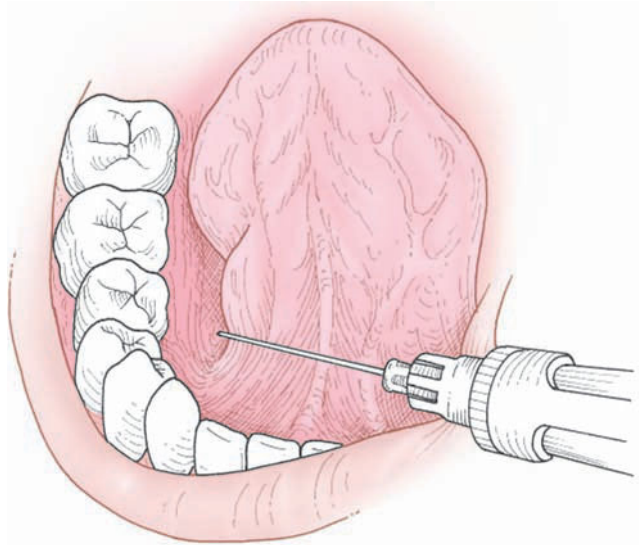

FIGURE 176-12. The lingual nerve block.

Remarks The inferior alveolar nerve and the lingual nerve can be, and usually are, blocked simultaneously during an inferior alveolar nerve block. The lingual nerve, however, can be blocked in an isolated fashion. Perform an isolated lingual nerve block only when the initial combined block has failed or for isolated tongue lacerations.[1,3] This is an optimal block for tongue laceration repair. However, bilateral lingual nerve blocks may be necessary.

ASSESSMENT

Anesthesia is usually achieved within 5 minutes of the injection. However, depending upon the particular injection and the local anesthetic used, anesthesia can be achieved anywhere from 20 seconds to 10 minutes. The block was properly performed if the patient experiences anesthesia. Repeat the block if anesthesia is not achieved by 10 minutes.

AFTERCARE

The aftercare of dental anesthesia is minimal. Reexamine the area of the local anesthetic injection before the patient is discharged to ensure that a hematoma has not developed. **Instruct the patient to use caution as there is no sensation in the area anesthetized.** Encourage them to refrain from meals, chewing gum, hot beverages, aggravated scratching, placing foreign bodies in the mouth, or anything that may cause injury to the anesthetized area. Parents must be informed to discourage children from testing the anesthetized area by biting or chewing. Many Dentists and Physicians place a cotton roll, or rolled 2 × 2 gauze, between the area anesthetized and the teeth to provide added protection from a self-inflicted bite injury.[2,3]

COMPLICATIONS

Any patient receiving dental anesthesia has the potential to develop complications. The key is to have knowledge of these complications and be prepared to deal with them should they occur. Most severe complications will declare themselves in a rapid fashion. These severe complications include intravascular injection of local

anesthetic, allergic reactions to the local anesthetic, cardiovascular toxicity, neurologic toxicity, seizures, and unintentional overdosage. Allergic reactions can occur from the latex vial/carpule seal or the preservative in the local anesthetic.[5] These complications can be avoided by aspiration before injection, obtaining an appropriate history of prior anesthesia, and cautious calculation of anesthetic dosages, respectively.[2–4]

Late complications of dental anesthesia include hematomas, neuropathy, infection, and trismus.[2,3] Hematomas after dental anesthesia occur after the inadvertent puncture of an artery or vein. Arterial hematomas enlarge more rapidly and are usually more painful than venous hematomas. They can cause a significant facial deformity. Hematomas following dental anesthesia are usually of little significance, require no intervention, and resolve spontaneously with time. A proper preprocedural history should determine if the patient is using anticoagulants or blood thinners, has a real or potential bleeding disorder, or had adverse bleeding complications from previous procedures. Treatment initially involves applying cold packs. Heat in the form of an externally placed heating pad should be used to help disintegrate the clot after 24 hours.[2,3]

A peripheral neuropathy can occur in the form of prolonged anesthesia, paresthesias (burning or itching sensation), hyperesthesias (increased sensitivity to noxious stimuli), and dysesthesias (painful sensation to non-noxious stimuli). This may be a result of direct damage to the nerve from traumatic needle insertion, hemorrhage or hematoma within the nerve sheath, deposition of local anesthetic into a foramen or canal causing pressure injury to the nerve, or chemical injury to the nerve.[6,7] Reduce the risk of causing a neuropathy by avoiding injections into a foramen, using a small gauge needle, and withdrawing the needle slightly before injection if the patient should feel a shock or paresthesias with needle insertion.[2,3] While many nerve injuries are temporary and will resolve with time, some can be permanent.[7]

Infection due to dental anesthesia is rare, but does exist. Follow several simple measures to minimize potential infections. Never inject through an infected area. Doing so may carry bacteria through facial planes into deeper compartments. Refrain from multiple injections (needle misadventures) as this increases the risk of iatrogenic infection. This is easily resolved by appropriately identifying the anatomic landmarks prior to needle insertion.

Needle breakage can occur as a result of manufacturing defects or operator imprudence. **To prevent needle breakage, never exert force against resistance.** Resistance signifies that the tip of the needle is against bone or a tooth. Withdraw the needle and reattempt insertion if this occurs. **Never advance the needle to the hub.** The greatest percentage of needle breaks occur when the needle is inserted to the hub.[2,3] **Never redirect the needle after it is inserted through the skin or mucosa.** This puts abnormal force on the needle and potentiates breakage. The needle may inadvertently be in an undesired anatomic location. Withdraw the needle completely, identify the appropriate anatomic landmarks, and reinsert the needle. Do not bend the needle as this can weaken it and make it more prone to breakage. If a needle breaks, grasp the fragment with a forceps or hemostat and remove it from the soft tissue. If the needle fragment is not palpable with an instrument, consult a Dentist or Oral Surgeon for possible removal. The consultant may choose to see the patient in the Emergency Department, see the patient in their office within 24 to 48 hours, or leave the needle fragment in place and not remove it.

SUMMARY

Dental anesthetic techniques are easy to learn, simple to perform, and effective in providing temporary pain relief. The required equipment is readily available in every Emergency Department. Consider using local anesthetic agents that contain epinephrine because they provide significantly longer analgesia than those without epinephrine. A rapidly performed local anesthetic injection goes a long way toward patient satisfaction.

177 Dental Abscess Incision and Drainage

Daniel J. Ross

INTRODUCTION

Patients frequently present to the Emergency Department complaining of a "toothache". The common causes of toothache pain are multiple.[1] Similarly, there are multiple etiologies for a dental abscess (**Table 177-1**). Distinguishing the type of dental abscess can have an impact upon treatment decisions, prognosis, and patient morbidity.[2–5] The accurate diagnosis and proper treatment of these maladies require that the Emergency Physician has a basic understanding of dental anatomy, pathophysiology, and simple dental treatment protocols. Many of these conditions can be managed initially through the Emergency Department. The prudent Emergency Physician must have a clear understanding that these infections can rapidly become complicated and may require timely consultation or referral.

ANATOMY AND PATHOPHYSIOLOGY

Teeth are essentially composed of three layers (**Figure 177-1**). These layers, from the outside working inward, are the enamel, the dentin, and the pulp. The dentin and pulp are living tissues that are sensitive to noxious stimuli. The crown is covered with enamel, while the root is covered with a substance known as cementum. Cementum helps attach the tooth to the surrounding alveolar bone via the periodontal ligament (PDL). The neurovascular supply enters the pulp through the apical foramen at the root apex. The pulp contains only pain transmitting neuronal fibers, while the PDL contains both pain-sensitive and pressure-sensitive fibers.[7] Dental abscesses arise when bacteria penetrate the normal anatomic and physiologic barriers of the tooth and surrounding structures. This can lead to a localized collection of purulence contained within the tooth (pulpal abscess), or around the apex of the tooth (periapical abscess) (**Figure 177-2**). Alternatively a dental abscess may localize to the supporting structures of the tooth (periodontal abscess) or strictly to the adjacent soft tissues (pericoronitis) (**Figure 177-2**).

PULPAL OR PERIAPICAL ABSCESSES

Dental abscesses often arise from pulpal necrosis secondary to dental caries or a defective restoration.[1,3,4,6,7] Dental caries is commonly known as dental decay or "cavities". This is the direct destruction

TABLE 177-1 Common Etiologies for a Dental Abscess

of the tooth substance by the acidic bacterial products of normal oral flora. A carious tooth may not initially be painful. The products of inflammation eventually reach the dental pulp as the disease process progresses and the tooth will become sensitive.[1–3,7–9] This is known as pulpitis. Patients will report nonlocalizable and intermittent symptoms. This process may initially be reversible by routine dental treatment (e.g., a filling), but the pulp will rapidly necrose and die if it becomes infected. If the infectious process is allowed to continue, products from the necrotic pulp may escape the confines of the tooth via the apical foramen and begin to involve the PDL and surrounding alveolar bone. This is known as a periapical abscess, and makes the infected tooth easily localizable by patient complaints of spontaneous or constant sensitivity, and/or tenderness to gentle percussion.[1–3,5–7,9] The infection could likely be halted at this stage of the pathophysiologic process with a "root canal," which is essentially an incision and drainage procedure performed on the inside of a tooth by an Endodontist.[6,7]

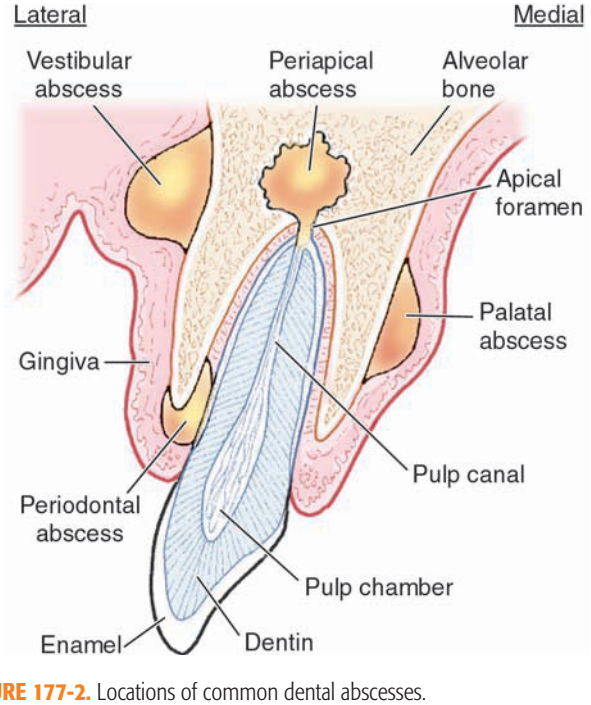

FIGURE 177-2. Locations of common dental abscesses.

If left unchecked, however, the bacterial products of a periapical infection and the host's immune response to it can lead to a progressive destruction of the dental supporting tissues, including the alveolar bone. At this point the tooth will become increasingly mobile. The infection will follow the path of least resistance as it penetrates through the alveolar bone into the surrounding soft tissues.[6,7] It may perforate laterally to form a vestibular abscess (**Figure 177-3A**). Alternatively, it may perforate medially to form a palatal or lingual abscess (**Figure 177-3B**). Further spread will be dictated by the proximity of the muscle attachments and fascial planes.[3,5–7,9–11] The appropriate treatment for an abscessed tooth depends on the extent of infection. It may include endodontic treatment, incision and drainage, extraction, or a combination of these.[6,7] An incision and drainage procedure is warranted if the infectious process extends outside the alveolar bone and involves the soft tissues.[5,6,7,9,10]

The extension of infectious products outside the root apex can lead to a multitude of clinical signs throughout the head and neck. Swelling, erythema, warmth, fluctuance, and spontaneous drainage of purulence via a sinus tract or fistula may be seen intraorally or extraorally. A localized or generalized cellulitis may be present. There is often a foul breath odor.[1,5,6,10] One or more of the numerous named fascial spaces of the head and neck may become involved via direct extension.[3,5–8,10–16] Systemic symptoms may become involved including fever, malaise, anorexia, and leukocytosis.[5,6,8,10,12] Structures immediately adjacent to the oral cavity may become involved. This can result in trismus, reactive sinusitis, lymphadenopathy, osteomyelitis, cavernous sinus thrombosis, airway compromise, and/or a brain abscess.[3,11–16]

Dental infections extending into any of the fascial compartments of the head and neck are dangerous, can rapidly progress, and are

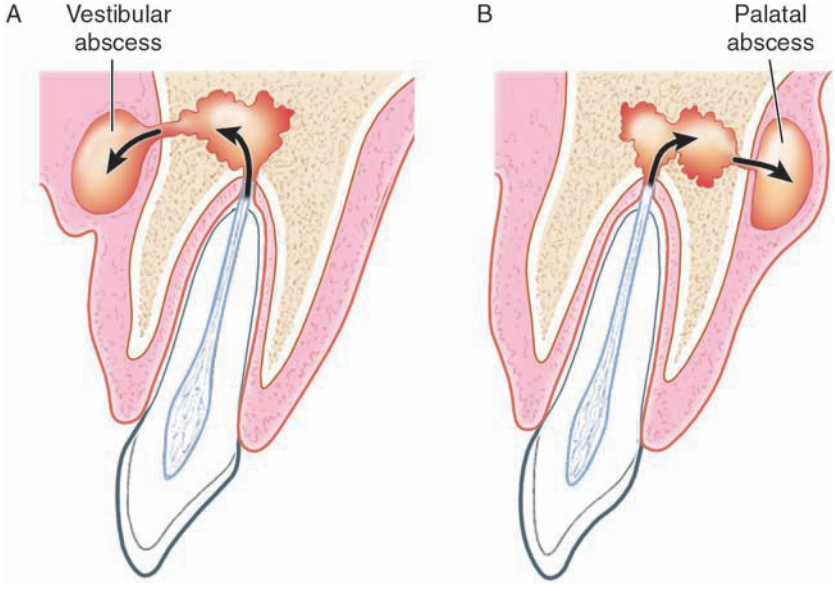

FIGURE 177-3. The spread of a dental abscess. A pulpal abscess progresses to a periapical abscess that perforates the alveolar plate. **A.** Labial or buccal perforation leads to a vestibular abscess. **B.** Palatal or lingual perforation leads to a palatal or lingual abscess, respectively.

considered complicated infections.[3,5–7,10,12–16] Patients typically have a toxic appearance with systemic signs and symptoms. They often present with dysphagia, dysphonia, or dyspnea. The classic example is Ludwig's angina or a concurrent bilateral involvement of the sublingual, submental, and submandibular spaces. This represents an immediate threat to the airway.[11,13,15,16] Infectious extensions into the lateral pharyngeal, retropharyngeal, and prevertebral spaces are rare and can lead to disastrous complications such as aspiration, mediastinitis, and airway compromise. A retropharyngeal space measuring greater than 3 to 5 mm on lateral soft tissue neck radiographs or CT scans is indicative of airway compromise.[10] **Consider rapid and aggressive management with prompt surgical consultation, broad-spectrum antibiotics, and early airway intervention in patients who are suspected of manifesting any of these processes.[3,8,10–15]**

PERIODONTAL ABSCESSES

Poor dental hygiene and poor nutrition lead to local inflammation of the tissues surrounding and attaching the tooth to its socket, allowing bacterial penetration. Early periodontal disease is isolated to the gingiva and known as gingivitis.[5,17] Alveolar bone may be destroyed as the disease progresses, leading to gingival pockets and tooth mobility.[1,5,18] Food debris or plaque may become trapped within these pockets and create a localized infection known as a periodontal abscess.[4,5,17] Periodontal disease is very common in pregnant women.

Patients may complain of bleeding, foul odor, bad taste, loose teeth, pain, or swelling. The physical examination reveals gingival tissue that may be erythematous or necrotic and bleed easily. Heavy accretions of dental plaque and calculous may be present. An abscess may present as a focal swelling, tooth mobility, pain on percussion, and purulence that is expressible from the gingival sulcus.[1,5,17,18] It may be impossible, with current dental caries, to differentiate a periapical abscess from a periodontal abscess without radiographs.[3,5] In fact, both lesions may occur together.[18] A periodontally diseased tooth may be so mobile that it cannot be salvaged and requires extraction.[5]

True periodontal abscesses rarely spread beyond the local dentoalveolar structure and rarely require an urgent referral.[3,4] Treat an isolated periodontal abscess with dental anesthesia, incision and drainage, and dilute peroxide (1:5 solution or 5%) or chlorhexidine rinses. Prescribe oral antibiotics for evidence of spread, if there is a delay to definitive care, or for systemic manifestations.[1,3–5,18] Appropriate antibiotics include penicillin, clindamycin, or erythromycin. Refer patients with these lesions to a Dentist within 24 to 48 hours for definitive follow-up care to avoid recurrence.[1,3,5]

PERICORONITIS

Inflammation can occur around the crown of any erupting tooth and is common around impacted teeth, especially the third molars.[1,3,4,19] This condition is known as pericoronitis. It is often exacerbated by the impaction of food under the soft tissue. Progression of the primary process or overzealous treatment can easily lead to extension of the infection posteriorly to multiple contiguous spaces, including the retropharyngeal space.[1,3,19,20] Simple cases are easily managed in the Emergency Department. Always maintain a very low threshold for consultation and referral of patients with complicated presentations.

Treatment of pericoronitis may include dental anesthesia, direct saline irrigation, warm saltwater rinses, dilute peroxide or chlorhexidine rinses, and oral analgesics. The presence of swelling, trismus, and inflammation may be severe enough to warrant a course of oral antibiotics.[1] Some authors advocate antibiotic coverage in essentially all cases.[1,10,19,21] Definitive treatment requires the completed eruption or extraction of the tooth. Refer the patient to a Dentist or Oral Surgeon for follow-up and definitive care within 24 to 48 hours.

INDICATIONS

The indications for dental abscess incision and drainage include a periapical or periodontal abscess with clinical evidence of alveolar penetration and soft tissue spread.[9,10] Some authors recommend incision and drainage for purely cellulitic processes.[4,5,11] **Extraoral incision and drainage is indicated only for dental infections progressing toward inevitable spontaneous extraoral drainage.[3,10] Drain all other dental abscesses intraorally.**

CONTRAINDICATIONS

A review of the current literature reveals no direct contraindications to the incision and drainage of a dental abscess. Maintain a low threshold for consultation and referral to a surgical specialist for

TABLE 177-2 Prophylactic Regimens for Endocarditis in Patients Undergoing Dental or Oral Surgical Procedures[23,*]

Situation	Antibiotic choice	Adult dose	Pediatric dose[†]
Standard general prophylaxis and able to take oral medications	Amoxicillin	2000 mg PO	50 mg/kg PO
Standard general prophylaxis and unable to take oral medications	Ampicillin	2000 mg IV or IM	50 mg/kg IV or IM
	or		
	Cefazolin	1000 mg IV or IM	50 mg/kg IV or IM
	or		
	Ceftriaxone	1000 mg IV or IM	50 mg/kg IV or IM
Penicillin allergic patient able to take oral medications	Clindamycin	600 mg PO	20 mg/kg PO
	or		
	Cephalexin or Cefadroxil[‡]	2000 mg PO	50 mg/kg PO
	or		
	Azithromycin or Clarithromycin	500 mg PO	15 mg/kg PO
Penicillin allergic patient unable to take oral medications	Clindamycin	600 mg IV or IM	20 mg/kg IV or IM
	or

	or		
	Ceftriaxone[‡]	1000 mg IV or IM	50 mg/kg IV or IM

*Administer the antibiotics 30 to 60 minutes prior to the procedure.
[†]The pediatric, weight-based dose should not exceed the adult dose.
[‡]Do not use cephalosporins in a patient with a history of a penicillin allergy and any of the following: anaphylaxis, angioedema, respiratory difficulties, urticaria, or unknown reactions.

any patient with rapidly progressing infections, difficulty breathing, difficulty swallowing, fascial space involvement, temperature greater than 101 °F (38.3 °C), white blood cell count greater than 10,000, severe trismus (manifested by mandibular opening less than 10 mm or inability to adequately visualize the hypopharynx), a toxic appearance, compromised host defenses, or who are children.[3,6,10,22]

EQUIPMENT

- #15 scalpel blade on a handle
- #11 scalpel blade on a handle
- Povidine iodine or chlorhexidine solution
- Minnesota retractor
- Wieder tongue retractor
- Frazier suction catheter
- Suction source and tubing
- Needle driver
- Hemostat
- Suture, 4-0 and 5-0 silk
- Gelfoam
- 0.25 inch wide Penrose drain
- Light source, overhead or headlamp

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain dental radiographs if the infection is from a dental source.[5,6,10] Obtain an informed consent for the procedure. Provide adequate anesthesia; ideally in the form of a dental block. Obtain a separate informed consent for the dental block. **Direct infiltration into the area of purulence does not achieve adequate anesthesia and risks spreading the infection by inoculation.**[3,5] Dental blocks may require augmentation with direct infiltration anterior and posterior to the abscess. Anesthetize the areas adjacent to the abscess last to avoid seeding. Refer to Chapter 176 for a complete discussion of dental analgesia and anesthesia. The application of procedural sedation may be required if adequate local anesthesia is not possible.[10] Refer to Chapter 129 for the complete details regarding procedural sedation and analgesia.

Prophylaxis to prevent infective bacterial endocarditis should be addressed in the appropriate patients prior to incision and drainage of a dental abscess in accordance with the policy put forth by the American Dental Association. Further information and specific antibiotic regimens can readily be found at the website of either the American Heart Association or the American Dental Association (**Table 177-2**).[23,24]

TECHNIQUES

SIMPLE INTRAORAL INCISION AND DRAINAGE

There are two techniques for intraoral incision and drainage. The first technique is to make a simple stab incision with a #11 scalpel blade in the area of greatest fluctuance and in the area that best facilitates dependent drainage (**Figure 177-4A**). **Do not make the incision more than 1 cm in length.** Gently insert a closed, curved hemostat into the incision (**Figure 177-4B**). Gently spread the jaws of the hemostat in several different directions to break up any loculations (**Figure 177-4C**). Express and suction any remaining purulence. Insert a sterile rubber drain cut from a 0.25 inch wide Penrose drain or from a sterile surgical glove (**Figure 177-4D**). Place one to two silk sutures through the drain and the oral soft tissues. This will ensure that the drain does not fall out and result in premature closure of the incision or aspiration of the drain.

The second technique for simple intraoral incision and drainage differs only in the location of the incision. Make an incision with a #15 scalpel blade at the alveolar crest within the gingival sulcus, scalloping around the teeth. Extend the incision one tooth medial and distal to the tooth in question or the area of the abscess. Gently elevate the attached gingiva from the bone with a blunt instrument. Continue the blunt dissection until the abscess cavity is penetrated. This typically occurs just within the level of unattached gingiva. The remainder of the procedure is as described above. This technique affords some mechanical advantages to the operator and is well tolerated by the patient postoperatively. It can be performed in both arches, buccally, palatally, and lingually. It is often useful for draining a periodontal abscess.

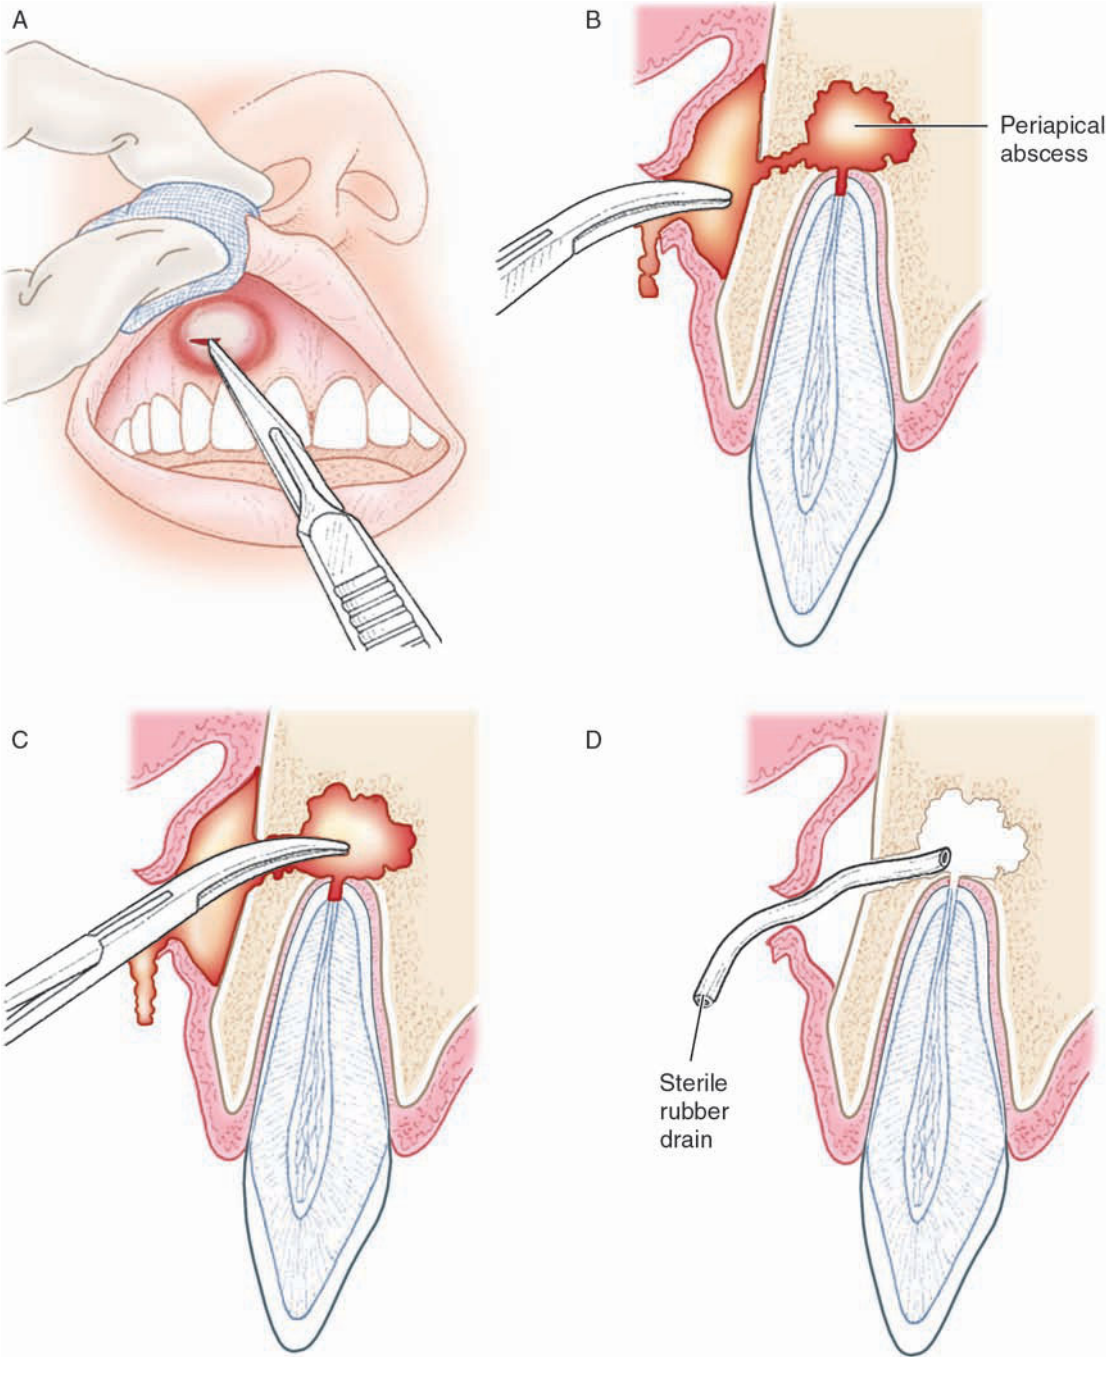

FIGURE 177-4. Incision and drainage of a periapical abscess that has extended into a vestibular abscess. **A.** Make a stab incision with a #11 scalpel blade. **B.** Insert a hemostat into the incision. **C.** Advance the hemostat into the abscess cavity to lyse any adhesions. **D.** Place a sterile drain into the abscess cavity.

EXTRAORAL INCISION AND DRAINAGE

Extraoral incision and drainage is indicated when a dental infection appears to be progressing toward inevitable spontaneous extraoral drainage.[10] This procedure requires more attention and skill because of the numerous underlying vital structures and the possible cosmetic consequences.[3,10] Make every effort to avoid extraoral incision and drainage.[3] Consider consulting a Dentist or Oral Surgeon before performing an extraoral incision and drainage.

Extraoral incision and drainage differs from the intraoral approach.[3,10,11] **Advise the patient that they will almost certainly have a visible scar after the incision heals.[3,10]** Extraoral incision and drainage requires the use of aseptic technique. Prepare the area with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a field. Perform local subcutaneous infiltrative anesthesia of the skin. Use a separate needle and syringe for any intraoral anesthetic techniques.

Make a 1.0 to 1.5 cm long incision with a #15 scalpel blade in an area of healthy skin, proximal to the site of expected breakdown and in a location that facilitates dependent drainage (**Figure 177-5**). Extend the incision into the subcutaneous tissues. This is another critical difference from the intraoral technique. Insert a hemostat to penetrate and drain the abscess cavity. Spread the hemostat in several directions to break up any loculations. The remainder of the procedure is performed as described as above. Scarring with extraoral incisions is virtually universal.

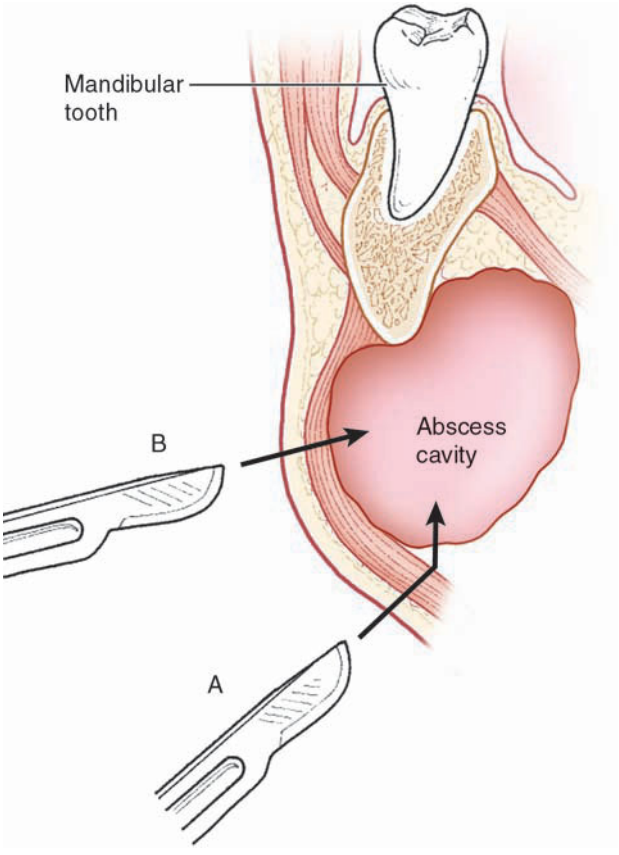

FIGURE 177-5. Extraoral drainage of a dental abscess. Choose a location that has healthy skin and that will allow dependent drainage.

PEDIATRIC CONSIDERATIONS

Facial infections in children tend to develop and progress more rapidly. They are more likely to present with systemic signs and symptoms.[25] Facial infections in children are also more likely to be associated with complications, such as dehydration or bacteremia.[25] Unlike adults, the anatomic location of a facial infection in a child can be a more useful guide in determining its source and management.[25] In general, upper face infections tend to be more common in children less than 5 years of age and frequently have no identifiable source. Children older than 5 years of age more commonly have lower face infections and typically have an odontogenic or wound-related source.[25] According to the American Academy of Pediatric Dentistry, a child presenting with a facial swelling secondary to a dental infection should receive immediate dental attention.[26] Lastly, in sharp contrast to adults, children with facial infections in either location more frequently respond to antibiotics alone and may not require an incision and drainage procedure.[25]

ASSESSMENT

Basic postoperative assessment includes inspecting the operative site for the minor complications described below. **Assess adequate drain retention. A loose intraoral drain may represent an aspiration risk.** Observe the patient for postprocedural bleeding. It can be controlled with the application of pressure, injection of a local anesthetic agent containing epinephrine, or topical Gelfoam. Wound cultures are not indicated unless the patient is immunocompromised or the infection is recurrent. The wound cultures usually demonstrate mixed oral flora with no predominate organism.

AFTERCARE

The application of warm moist compresses, oral fluids, rest, and good nutrition are mainstays in the treatment of any inflammatory process. Patients may benefit from a soft, bland diet and frequent oral rinses with a warm saltwater solution. All patients require postoperative oral analgesics.[3,5,10,11] Patients with an extraoral incision require dressing changes.[3,5,10,11] Provide the patient with adequate supplies and teaching. Instruct the patient on the application of pressure if postprocedural bleeding occurs.

The use of antibiotics in light of adequate drainage is somewhat controversial. Clear-cut indications for oral antibiotics in orofacial infections include cellulitis, extraoral incision, systemic symptoms, persistent infection, pericoronitis, fascial space involvement, and immunocompromised patients.[4,7,10,16] The prudent Emergency Physician is advised to err on the side of caution while the academics quarrel over antibiotic indications. Penicillin is the drug of choice for the empiric treatment of dental-related infections. Alternatives to penicillin include erythromycin, clindamycin, or a cephalosporin. Clindamycin is the first alternate choice. It is especially useful when anaerobes are suspected or in recalcitrant infections where sensitivities are lacking.[3,5,6,10]

Allow the intraoral drain to remain in place until the swelling has resolved and purulent drainage has ceased. Evaluate the patient for drain removal or advancement in 24 to 48 hours. Prescribe oral antibiotics and analgesics during this time. Refer the patient to a Dentist within 24 hours.

COMPLICATIONS

Minor postoperative pain, swelling, bleeding, drainage, and possibly bruising can be expected following the incision and drainage of a dental abscess. Significant postprocedural bleeding can be controlled with pressure, a vasoconstricting local anesthetic agent, or topical Gelfoam.[5,6,17,18] An incision and drainage tract that communicates freely between the oral cavity and the external face represents a significant complication. Refer these patients to a Plastic or Oral Surgeon.

SUMMARY

The recognition of common dental-related infections such as pericoronitis, periodontal abscesses, and dental abscesses can impact patient prognosis and morbidity. The diagnosis and treatment of these maladies, and their complications, requires knowledge of dental anatomy and pathophysiology. The Emergency Department management of these infections is quick and simple. Refer all patients to a Dentist or Oral Surgeon for definitive care of their teeth.

178 Post-Extraction Pain and Dry Socket (Alveolar Osteitis) Management

Eric F. Reichman

INTRODUCTION

Post-extraction pain, or periosteitis, begins as the local anesthetic agent wears off. The pain begins to diminish, most of the time, within 12 hours. The prescription of nonsteroidal anti-inflammatory drugs will provide analgesia and comfort while the

pain subsides over 1 to 2 days. Narcotic analgesics may occasionally be required for the first 24 to 48 hours.

Pain that develops 2 to 4 days after the tooth extraction most likely indicates a localized alveolar osteitis or a dry socket. A dry socket occurs most commonly with the extraction of the third mandibular molar, but can be associated with any tooth that has been extracted. The pain is quite severe in nature and is localized to the area of the extraction site. The extraction site may emit a foul odor and the patient often complains of a bad taste in their mouth.[1,2] Physical examination may reveal the socket is missing a clot, but this is sometimes difficult to identify. The signs of an infection are absent.

ANATOMY AND PATHOPHYSIOLOGY

The exact etiology or the pathogenesis of a dry socket is not clear.[1–6] It may be multifactorial due to smoking, a localized infection, a poor blood supply, traumatic extractions, a foreign body in the socket, and certain medications. These factors result in an increased level of fibrinolysis of the blood clot in the socket before the clot has had the time to be replaced by granulation tissue. The clot falls out of the socket and exposes the bony surface of the socket to the oral cavity. The exposed bone is extremely sensitive to air, resulting in severe pain.[1–4]

INDICATIONS

The single and utmost therapeutic goal of alveolar osteitis is to relieve the patient's pain during the healing process. This procedure should be performed on all patients with a dry socket.

CONTRAINDICATIONS

There are no contraindications to the management of a dry socket.

EQUIPMENT

- Dental mirror
- 2 × 2 gauze squares
- Scissors
- Dry socket paste or Dressol-X
- Gelfoam
- Irrigating syringe
- Normal saline solution
- Frazier suction catheter
- Suction source and tubing
- Forceps
- Iodoform ribbon gauze
- Eugenol-impregnated ribbon gauze
- Oil of cloves

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare to the patient and/or their representative. A signed consent is not required for this procedure. Place the patient sitting upright or reclining. A multipositional dental chair is ideal and allows for a variety of positions to visualize the affected tooth. This procedure may be accomplished with no anesthesia. Some may consider performing a dental block to temporarily alleviate the patient's pain and allow the procedure to be accomplished with minimal discomfort, and increase the level of patient satisfaction. If performed, use lidocaine without epinephrine because the procedure is quickly performed and the anesthesia wears off while the patient is still in the Emergency Department. Refer to Chapter 176 for the complete details regarding dental anesthesia and analgesia. Consider obtaining a plain radiograph or panorex to rule out a retained root tip or foreign material in the socket.

TECHNIQUES

Identify the defective tooth. Gently and thoroughly irrigate the socket with warm normal saline and low-level suction to remove any debris. Use a forceps to pack dry socket paste into the socket. Dry socket paste is composed of balsa wood fragments saturated with eucalyptol and looks like chewing tobacco. Completely fill the socket with the dry socket paste. The patient will experience almost instant pain relief if a dental block was not performed. Place a piece of Gelfoam on top of the dry socket paste. Compress the Gelfoam and dry socket paste into the socket. Instruct the patient to bite down against a 2 × 2 gauze square placed over the socket for 5 to 10 minutes. Dressol-X may be used instead of dry socket paste if available.

Unfortunately, few Emergency Departments stock dry socket paste or Dressol-X. An alternative is ribbon gauze or Gelfoam impregnated with eugenol, iodine, or oil of cloves. Ribbon gauze tends to dry out and fall out sooner than commercially available dry socket paste. Use a forceps to pack the socket completely with the impregnated ribbon gauze (**Figures 178-1A to C**) or Gelfoam. Place a piece of plain Gelfoam on top of the socket (**Figure 178-1D**). Compress the plain Gelfoam and the underlying impregnated ribbon gauze or impregnated Gelfoam into the socket. Instruct the patient to bite down against a 2 × 2 gauze square placed over the socket for 5 to 10 minutes.

ASSESSMENT

The patient should experience almost immediate pain relief after the socket is packed. If a dental block was performed, allow the local anesthetic to wear off to ensure the patient's pain truly has resolved.

AFTERCARE

The patient may be discharged immediately after the procedure, or after the local anesthetic has worn off. Nonsteroidal anti-inflammatory drugs are usually adequate to provide analgesia. Narcotic analgesics are not needed nor required. Arrange follow-up as soon as possible with the Dentist or Oral Surgeon who performed the extraction procedure. The dressing must be replaced daily, or as needed, until the patient is pain free. Instruct the patient to begin a soft diet, to not ingest extremely hot or cold substances, and to not play with the packing with their tongue. **Instruct the patient to also not suck anything, use a straw, gargle, spit, or smoke.** All these activities will produce negative pressure within the oral cavity and remove the clot from the extraction site.

The decision to prescribe antibiotics to cover the oral flora is physician dependent. There is no literature to support or refute this practice. Consult the Dentist or Oral surgeon who extracted the tooth. Oral penicillin VK (500 mg QID) is the preferred antibiotic if they are prescribed. Clindamycin (300 mg QID) is an alternative for patients allergic or intolerant to penicillin.

COMPLICATIONS

There are no complications associated with this procedure. A potential complication is the aspiration of the material used to pack the socket. This has never been reported in the literature. The packing may fall out and result in the patient's pain recurring. Instruct the

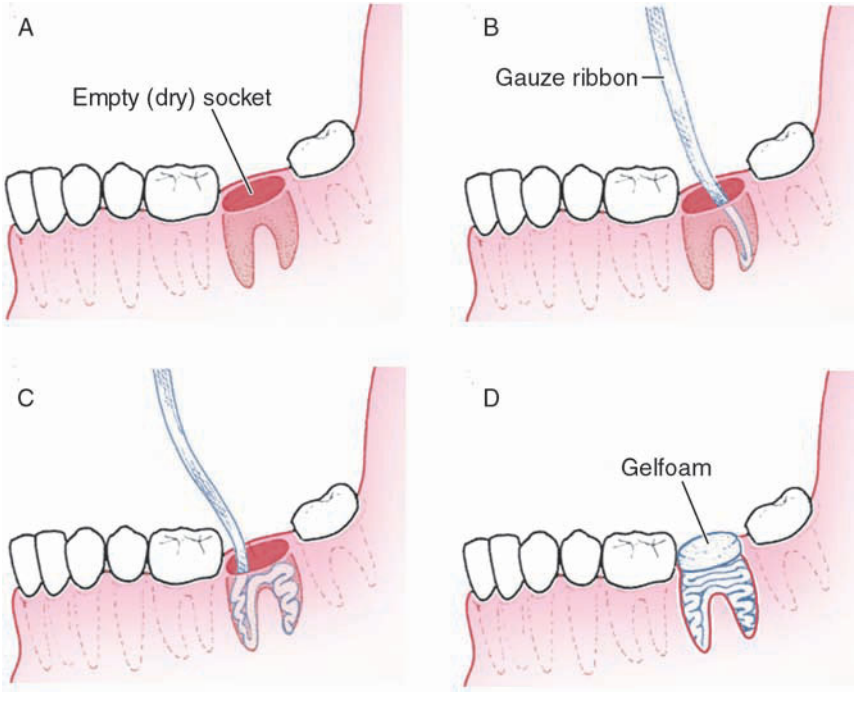

FIGURE 178-1. Packing a dry socket with ribbon gauze. **A.** The empty socket. **B.** Pack the socket starting inferiorly and working upward. **C.** Completely fill the socket. **D.** Apply Gelfoam over the socket and the ribbon gauze.

patient to return to the Emergency Department if the packing falls out prior to their follow-up appointment.

SUMMARY

A dry socket can be extremely painful. Packing an empty socket is easy, quick, simple, and provides the patient with significant relief. The packing needs to be changed daily for several days and then less frequently after that, until the patient is free of pain. Prescribe antibiotics to cover oral flora and analgesics to manage pain.

179 Post-Extraction Bleeding Management

Eric F. Reichman

INTRODUCTION

Post-extraction bleeding is a common problem after the removal or extraction of a tooth. It is often seen in the Emergency Department in the late evening or night when the patient is unable to contact their Dentist. Bleeding that occurs within a few hours of the extraction is often due to the wearing off of the vasoconstrictor effect of the local anesthetic solution used for anesthesia. The application of direct pressure over the bleeding site by having the patient bite down on a folded piece of moist gauze almost always controls post-extraction bleeding. Many patients, however, will report that they have been doing this prior to coming to the Emergency Department and require additional assistance.

ANATOMY AND PATHOPHYSIOLOGY

A careful history may reveal that the patient inadvertently caused the extraction site to bleed by drinking through a straw, spitting, gargling, or smoking. All these activities will produce negative pressure within the oral cavity and remove the clot from the extraction site. Ask the patient if they are touching the extraction site with their tongue, causing a mechanical disruption of the clot. Obtain information about any significant medical history, any history of bleeding, and current medications. This includes use of aspirin products, anticoagulants, broad-spectrum antibiotics, alcohol, and antineoplastic medications. These all may contribute to prolonged bleeding. Ask about the symptoms and examine for the signs of liver disease, hypertension, or hematologic disorders.[1,2] Post-extraction bleeding may be a sign of an underlying and undiagnosed coagulopathy.

INDICATIONS

All post-extraction bleeding must be managed carefully and methodically. The techniques are easy to perform, simple, and straightforward.

CONTRAINDICATIONS

There are no contraindications to the management of post-extraction bleeding.

EQUIPMENT

- 2 × 2 gauze squares
- Irrigating syringe
- Dental mirror, optional
- Local anesthetic solution containing 1:100,000 epinephrine
- 23 to 25 gauge, 1.5 inch needle
- 5 mL syringe
- Silk or plain gut sutures, 4-0 or 5-0
- Absorbable gelatin sponge (Gelfoam)
- Oxidized regenerated cellulose (Surgicel)
- Topical thrombin

- Suture set
- Dental forceps
- Tea bag
- Bone rongeur
- Bone wax
- Headlamp
- Yankauer suction catheter
- Suction source and tubing
- Silver nitrate matchsticks
- Electrocautery unit

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare to the patient and/or their representative. Document this discussion in the medical record. A signed consent form is usually not required for these procedures. Consider obtaining a radiograph of the affected area to rule out a retained root or a bony spur.

Position the patient to visualize the extraction site. Place the patient in a multipositional dental chair, if available, or on a gurney. Do not place the patient in a chair as they may become presyncopal and require being placed supine to prevent injury. An overhead light source or a headlamp is ideal to illuminate the field. Suction any blood and oral secretions from the mouth. Visualize the extraction site for any signs of bleeding. Thoroughly irrigate the site with warm saline and remove all clots with the aid of suction. It may be necessary to perform a dental block if the patient complains of pain upon irrigation. Refer to Chapter 176 for the complete details regarding dental anesthesia and analgesia.

TECHNIQUES

The management of post-extraction bleeding is simple. Numerous methods to control the bleeding have been described and tested (**Table 179-1**). These techniques are often performed in a sequential manner as described below. The techniques may, of course, be performed in any order, depending on the physical examination and physician preference.

MECHANICAL PRESSURE

Place saline-moistened 2 × 2 gauze squares over the socket. Instruct the patient to apply firm pressure by biting down on the gauze for 20 minutes. Instruct the patient to maintain pressure for 20 minutes despite initial bleeding. Place the suction catheter, intermittently, into the vestibule of the mouth to remove any blood and secretions. The application of pressure will control most post-extraction bleeding. It may be necessary to perform a dental block, if not performed during the irrigation phase, if the patient cannot bite down due to pain.

TABLE 179-1 Methods to Control Post-Extraction Bleeding

Absorbable dressing into socket and mechanical pressure with gauze squares
Absorbable dressing into socket and stitch gingival tissue closed
Cauterize bleeding granulation tissue
Cauterize or stitch bleeding blood vessels
Gingival infiltration with local anesthetic containing epinephrine
Mechanical pressure with gauze squares
Moist tea bag and pressure
Rongeur or apply bone wax to bone spurs
Stitch gingival tears

TEA BAG APPLICATION

Place a saline-moistened tea bag in the socket if mechanical pressure does not control the bleeding. The tannins in the tea leaves will assist with the coagulation process. Instruct the patient to bite down on the tea bag for 15 minutes.

ABSORBABLE DRESSINGS

The two most commonly used absorbable dressings are Gelfoam and Surgicel. Gelfoam is an absorbable gelatin sponge that is readily available and inexpensive. It forms a scaffold for the formation of a blood clot. Surgicel is composed of oxidized and regenerated cellulose. It promotes coagulation better than Gelfoam and can be packed into the socket under pressure. Unfortunately, Surgicel results in delayed healing of the socket and its use should be reserved for persistent bleeding or when Gelfoam is not available.

Place an absorbable dressing (Gelfoam or Surgicel) in the socket if the extraction site continues to bleed.[1–3] The author prefers to use Gelfoam because it is easier to manipulate and it is absorbed more rapidly than Surgicel. Work the Gelfoam in your fingers until it resembles the shape of the socket. Insert the Gelfoam into the socket and compact it with a dental forceps. Insert additional pieces of Gelfoam into the socket, as necessary, to obtain a solid mass of Gelfoam filling the socket. An alternative is to pack the socket with Surgicel. Once the socket is packed, apply a 2 × 2 gauze square over the socket. Instruct the patient to bite down for approximately 20 to 30 minutes. The author prefers to place a figure-of-eight stitch using 4-0 or 5-0 silk suture or plain gut suture over the socket (**Figure 179-1**). The suture applies pressure over the socket and ensures that the Gelfoam or Surgicel will not prematurely fall out of the socket. This technique will usually stop most post-extraction bleeding.

Two additional absorbable dressings are topical thrombin and collagen. They are expensive, not usually available in the Emergency Department, and their use should be limited to circumstances where other hemostasis methods have failed. Topical thrombin is made from bovine thrombin. Place a piece of Gelfoam or Surgicel saturated with thrombin into the socket. Thrombin converts fibrinogen to fibrin, bypassing the coagulation cascade, to form a clot within the socket. Collagen is available in multiple forms from a variety of sources. It promotes platelet aggregation and forms a scaffold for the formation of a clot. Pack the socket with collagen and cover it with a piece of Gelfoam. Place a figure-of-eight suture over the thrombin or collagen-filled socket to secure it in place.

The use of chitosan bandages to control battlefield and prehospital hemorrhage has crossed over into the dental realm. Chitosan dental bandages (HemCon Medical Technologies, Portland, OR) have

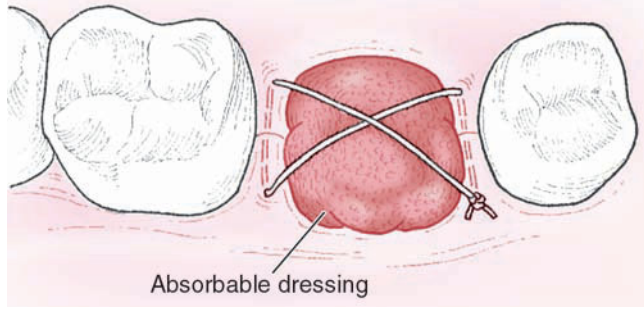

FIGURE 179-1. Pack the socket with Gelfoam followed by a figure-of-eight stitch to control the bleeding.

been designed to control post-extraction hemorrhage. Chitosan is a naturally occurring polysaccharide derived from shellfish. It attracts red blood cells. When placed over the bleeding extraction site, the red blood cells attach to the bandage to form a clot and tamponade the bleeding.

LOCAL ANESTHETIC INFILTRATION

Infiltrate the soft tissue surrounding the socket with local anesthetic solution containing epinephrine if the bleeding is not controlled by the above methods. The most commonly used local anesthetic solutions are lidocaine and bupivacaine. Infiltrate the soft tissues surrounding the socket with the local anesthetic solution until the tissue blanches. This usually requires 2 to 3 mL of the local anesthetic solution. Irrigate the socket. Apply a piece of moist gauze over the socket. Instruct the patient to bite down and to exert pressure on the socket. The patient is often able to bite down much harder on the tissues after the infiltration of the local anesthetic solution.

The effect of mechanical pressure combined with the vasoconstrictive effects of epinephrine control the bleeding. Occasionally, after the vasoconstrictive effect of epinephrine wears off, there is a rebound effect and the persistence of bleeding. This may be prevented by routinely placing Gelfoam or Surgicel into the socket after the bleeding is controlled.

MISCELLANEOUS TECHNIQUES

Reexamine the extraction site if the bleeding is not controlled by the above methods. The source of bleeding may be new granulation tissue, gingival tears, a bone spur, or a partially transected vessel. Cauterization of granulation tissue with silver nitrate or electrocautery will control the bleeding. Handheld, disposable, single-patient use electrocautery units work well but require the patient to be anesthetized. Use a blunt instrument to feel for the presence of a bone spur. This may be a source of significant bleeding. Remove the bone spur with a rongeur or cover it with bone wax to control the bleeding. An exposed and bleeding arteriole or venule can be controlled with cauterization (silver nitrate or electrocautery) or the application of a plain gut suture through the vessel. Suture any tears in the gingiva.

ASSESSMENT

Observe the patient for 30 to 60 minutes after the bleeding has terminated. Do not give the patient anything by mouth (NPO). Reevaluate the socket for signs of bleeding. Continued bleeding requires further attempts at termination.

AFTERCARE

Discharge the patient home after the bleeding has been terminated and a brief observation period. Instruct the patient to avoid any liquids or solids for 2 hours. Stress the importance of not spitting, gargling, drinking through a straw, smoking, using aspirin-containing products, or playing with the site with their tongue. Instruct the patient to apply gauze squares and bite down for 20 minutes if the bleeding returns. They should return promptly to the Emergency Department if the bleeding continues after 20 minutes. Additional instructions should include a soft diet, avoidance of extremely hot or cold substances, avoidance of chewing gum, and avoidance of other such "sticky" foods. Arrange follow-up as soon as possible with the Dentist or Oral Surgeon who performed the extraction.

COMPLICATIONS

There are no documented complications associated with the termination of post-extraction bleeding. The complications are associated with the bleeding itself. Obtain screening labs (e.g., PT, PTT, platelet count, and bleeding times) if hemostasis is not achieved by any of the aforementioned methods. Early consultation with a Dentist or Oral Surgeon and a Hematologist should be considered if the patient is coagulopathic or has a bleeding disorder.

SUMMARY

A careful history and physical examination will often provide the reasons for most post-extraction bleeding that presents to the Emergency Department. Most patients without complicating medical conditions will be easily managed in a simple and systematic manner with a minimal amount of equipment. All patients should follow-up with their Dentist or Oral Surgeon after the bleeding is terminated.

180 Defective Dental Restoration Management

Daniel J. Ross

INTRODUCTION

The field of restorative dentistry is a complex specialty that derives from many disciplines. Patients have often invested considerable time, money, and quite possibly "blood, sweat, and tears" in their dental work. This may be particularly true with the advent of both cosmetic and implant dentistry, which involve long and complicated treatment plans that are often not covered by insurance. A patient's investment in their dental work and the technical complexity of today's dental appliances should not be taken lightly. In fact, the treatment of common dental emergencies was published in the Emergency Medicine Clinics of North America under the heading "Difficult and Advanced Procedures".[1]

The urgent management of an acutely problematic dental restoration can be as simple as relieving discomfort, treating injury and infection, and employing temporizing measures until definitive treatment can be rendered by the appropriate specialist. This requires a basic understanding of dental anatomy, the pathophysiology of various dental states, and their typical treatment modalities.[1,2] It goes without saying that one should also recognize the inherent and all too frequent limitation of treating these problems in the Emergency Department. **The key to the successful emergent or urgent management of an acutely problematic defective dental restoration is stabilization and timely referral with great care to "first, do no harm".**

A few basic principles serve as a useful guide in treating patients with defective dental restorations. First, know your limitations. Dental pain in general, and a defective dental restoration in particular, is rarely if ever, a true emergency.[2–4] Chronic problems should be treated with equal measures of conservatism and reluctance. Refer the patient to a Dentist if you are hesitant to treat or are unfamiliar with an appliance or a presentation. Always consider a secondary or comorbid process. Consider the utility of dental radiographs when in doubt. Never remove a fixed appliance without first discussing it with a specialist, preferably the one who placed it. Save anything

and everything that belongs to the patient, whether it be appliance or tissue, as it may have utility for the definitive treatment.[5,6] Treat pain, inflammation, and evidence of infection. Consider a reversible or temporary solution over all others. Remember to treat a tooth for dental trauma if a restoration is determined to be defective secondary to trauma. Always consider ingestion or aspiration when dealing with a multiply fragmented tooth or appliance. Consider facial, neck, chest, and abdominal radiographs if all fragments cannot be accounted for.[5,7–10] Whenever a patient is actively involved in an ongoing treatment process, it is probably best to do as little as possible. Always use caution and tact when discussing the possibility of a defective dental restoration with a patient. Remember that you are not an expert. The treating specialist may have insight into the patient's current condition that you are unaware of. Attempt to consult before treating. Always arrange follow-up within 24 to 48 hours.

ANATOMY AND PATHOPHYSIOLOGY

Patients frequently present to the Emergency Department with some sort of dental complaint and their primary concern is typically pain related.[1,2,11,12] The perioral tissues are exceptionally sensitive to noxious stimuli. This is particularly true for the oral mucosa, periodontal ligament, dentin, and pulp. This concept is paramount to the effective management of any dental-related complaint. Although a patient's chief complaint may be directed at a particular tooth, be diligent in searching the entire mouth for alternative primary, comorbid, or secondary problems.

A meaningful discussion of the management of defective dental restorations requires a brief outline of the available types of dental appliances. In general, dental appliances are either fixed or removable. Fixed dental appliances are considered permanently attached to the teeth. They include crowns, bridges, implants, some forms of dentures, orthodontic bands and brackets, interdental wiring, and any type of filling (e.g., silver amalgam, gold, porcelain, or tooth-colored composite material). Removable dental appliances are those that are not permanently attached to the teeth and include partial dentures, complete dentures, space-maintenance devices, and other orthodontic devices.

Understanding whether a defective dental device is permanent or removable is often the first step in managing an acutely problematic appliance. Removing a broken or defective removable appliance is a simple and easy solution if it can be done safely and without significantly damaging the appliance. If removal would significantly alter or damage an appliance and there is no other reasonable option but to remove it, document the discussion with the patient and their consent to proceed. This is true whether the appliance is permanent or removable.

Removable dental appliances can predispose patients to several easily treatable mucosal conditions such as ulcerations, abrasions, or mucosal infections.[13,15] Compromised cellular immunity, broad-spectrum antibiotics, low salivary flow, poor oral hygiene, and trauma from poorly fitting dentures can all contribute to oral candidal overgrowth.[13,16] Patients often complain of burning pain. Treat the oral cavity with nystatin or clotrimazole troches. The appliance itself may harbor the organism and must be treated. Instruct the patient to take the appliance out of their mouth for 24 to 48 hours and soak it overnight in a nystatin suspension [5 mL nystatin in 250 mL (8 ounces) of tap water]. Instruct the patient to scrub the denture daily with an approved product to clean it.[13–15]

Oral candidiasis must be differentiated from other mucosal ulcerating conditions such as simple traumatic ulcers, aphthous ulcers, and oral herpes. Herpetic lesions occur on attached mucosa only, whereas aphthous ulcers occur on unattached mucosa.[13–16] Traumatic ulcers, minor aphthae, and major aphthae can be treated with topical corticosteroid ointment, such as triamcinolone, applied with a cotton-tipped applicator. The symptoms associated with herpetic outbreaks can be diminished if treated with acyclovir or a similar antiviral agent.[13–15] Orthodontic or interdental wiring that is impinging upon the oral mucosa may lead to traumatic ulcerations. Apply soft dental wax directly to the irritating appliance to relieve the impingement. This can be easily removed or replaced and is available over the counter at many local pharmacies.

In general, all patients with painful mucosal conditions may benefit from soft and bland diets, frequent use of ice chips for discomfort, and frequent warm saltwater rinses to avoid superinfection.[13,14] A stomatitis cocktail or BMX solution may be helpful for patients with severe mucosal pain. Mix equal amounts of Benadryl (12.5 mg/5 mL), Maalox, and Xylocaine (2% viscous lidocaine). Instruct the patient to swish 30 mL in their mouth for 1 minute and then spit it out.

The repair of broken or defective removable appliances in the Emergency Department is not recommended even though multiple over-the-counter products are available for home use (Figure 180-1).[16] Under the best of circumstances these procedures

FIGURE 180-1. Commercially available home repair kits for the fractured denture.

can be tedious, time consuming, and fraught with complications—even for the trained dental professional.[3] Most importantly, a botched repair attempt can result in patient discomfort, morbidity, and irreversible damage to an otherwise salvageable appliance. **In this light, it seems best to simply recommend removal and a dental referral to the patient seeking care for a broken removable appliance.**[16] Although far less than ideal, a home repair kit may be a viable option for some patients under certain circumstances.

The temporary urgent repair of defective fixed dental restorations by nondental personnel is advocated throughout the literature.[2,3,11,12,14,17–19] Use caution, however, when evaluating a new or recently placed fixed restoration because sensitivity from recent dental procedures can occur due to pulpal or periodontal ligament (PDL) irritation.[20] This may be a normal and expected sequelae of the dental procedure and not necessarily an indication that the restoration is defective.[1,20,21] Trauma from occlusion can result if a new dental restoration is left "too high" and does not fit properly with the opposing dentition.[3,14,18–20] These patients complain of pain with mastication and are sensitive to percussion secondary to PDL irritation. **Do not alter a fixed restoration if it is firmly in place.** Simple temporizing measures include dental blocks (Chapter 176), oral analgesics, a soft diet, and possibly removing the tooth from occlusion by placing a small amount of soft dental wax (or something similar) between the teeth on the opposite side.[3]

Long-standing fixed dental restorations may be defective secondary to microleakage or recurrent decay around the margins of the restoration.[1,20] Estimates suggest that approximately one in three restorations in existence may be defective in some fashion.[20,21] A faulty restoration that sits within or upon a tooth can lead to dentinal exposure regardless of the etiology. Exposed dentin is highly sensitive and prone to further decay. Dentinal sensitivity (also known as reversible pulpitis) is typically nonspontaneous and fleeting.[1,16,18,22] Patients who complain of spontaneous and lasting sensitivity have an irreversible pulpitis that is most likely due to recurrent decay. Sensitivity to percussion is indicative of periapical involvement and suggests the possibility of a periapical periodontitis or an abscess.[1,14,16,18,22]

Evaluate the tooth and its restoration for recurrent decay or a possible dentinal exposure if a patient present complaining of sensitivity associated with a tooth that has a long-standing restoration. **A temporary restoration can easily be fabricated in the Emergency Department if the restoration in question is missing, broken, or easily removed.**

Consideration should be given to a possible pulpal pathology, as outlined above, if a restoration is firmly in place. Provide dental anesthesia, oral analgesics, antibiotics as necessary, and a referral to a Dentist. Refer to Chapter 177 for the details regarding the management of dental abscesses.

INDICATIONS

Replace any previously fixed, permanent or temporary, dental restoration that has completely or partially fallen out or that is easily removed with a dental explorer. Replace any previously fixed, permanent or temporary, crown that has fallen out or is easily removed with a dental explorer and is in the patient's possession.

CONTRAINDICATIONS

Relative contraindications for the placement of a temporary dental filling, or temporarily recementing a crown, include patients who are involved with an extensive ongoing dental treatment plan, have a consulting specialist readily available, are at a significant aspiration risk, or have obvious extensive comorbid or secondary processes including antecedent trauma.

EQUIPMENT

- 10 mL syringe
- 18 gauge angiocatheter
- Normal saline solution
- Local anesthetic solution containing epinephrine
- Dental mirror
- Dental explorer
- 2 × 2 gauze squares
- Sterile cotton rolls
- Dental floss
- Clear nail polish
- Cavit-G
- IRM (zinc oxide and eugenol)
- Dycal (calcium hydroxide paste)
- Copalite (cavity varnish) or clear acrylic nail polish
- Tin foil
- Cotton-tipped applicators
- Discoid-cleoid dental carver
- Articulating paper
- Frazier suction catheters
- Suction source and tubing
- Petrolatum-based lubricant (Vaseline)
- Good overhead lighting or a headlamp

PATIENT PREPARATION

Explain the procedure, its risks, complications, and aftercare to the patient and/or their representative. Obtain an informed consent for the procedure. The simple placement of a temporary filling does not usually require local anesthesia. However, consider the use of a dental block if the patient is uncomfortable. Refer to Chapter 176 for the complete details regarding dental anesthesia and analgesia.

Prepare the patient. Seat the patient in a multipositional procedure chair. Gently irrigate the area with a syringe that contains warm normal saline and is armed with an 18 gauge angiocatheter to remove any food debris. Warm saline is usually less sensitive to the exposed dentin.[1] Gently remove any debris that does not irrigate away with a dental explorer. **Do not attempt to remove any decay because doing so may lead to a complicating pulpal exposure.**[1] Remove the loose portion of the restoration. **Do not remove any firmly fixed portion of the restoration.**

It is mandatory to have a dry field when performing this procedure. Dry the area to be filled with sterile cotton pellets or compressed air. Remember that the tooth may be sensitive.

TECHNIQUES

REPLACING A TEMPORARY OR PERMANENT FILLING

Treatment of defective fillings depends upon the relative size of the defect. There are no specific guidelines of what size (i.e., how many millimeters) the defect must be to perform each of these techniques. Paint small dentinal exposures with calcium hydroxide paste followed by cavity varnish or clear acrylic nail polish to relieve sensitivity.[1,10,14,19] Alternatively, place a simple tin foil dressing over the tooth to act as a bandage following placement of the calcium hydroxide paste.[10,14,19]

FIGURE 180-2. Commercially available home use products for temporary dental filling and crown restoration.

Larger defects require a filling to avoid food impaction and other sequelae. Cavit-G is an excellent choice for temporary filling material, especially in inexperienced hands.[1,10,12,23] This material is premixed, nonirritating, and sets quickly (approximately 30 minutes) upon contact with saliva. IRM, or a mixture of zinc oxide and eugenol, is similar material with the benefit of pulpal sedative properties. The use of IRM is operator dependent and requires a longer setting time.[23] Oddly enough, multiple mixtures of zinc oxide and eugenol are available over-the-counter for home use (Dentemp, Tempanol, Thin Set; **Figure 180-2**).

Cavit-G is recommended for Emergency Department use. Determine whether the missing filling exposes an open endodontically treated root (i.e., root canal). Place a small sterile cotton pellet into the canal prior to placing the filling material if the pulp cavity is exposed.[23] Express a small amount of Cavit-G from the container. Apply it onto the cavity and condense it into the cavity with the moistened end of a cotton-tipped applicator or a dental explorer (**Figure 180-3A**). **A temporary restoration placed by nondental personnel is always better "short" and out of occlusion with the opposing tooth for patient comfort. Work quickly because Cavit-G can set rapidly and it may be difficult to remove once it sets.** Remove any excess Cavit-G with the stick end of the cotton-tipped applicator. Instruct the patient to fully occlude on the new restoration and grind their teeth back and forth in all directions for 5 to 10 minutes. This will form the occlusal aspect of the filling to fit the opposing teeth if it is not made "short".

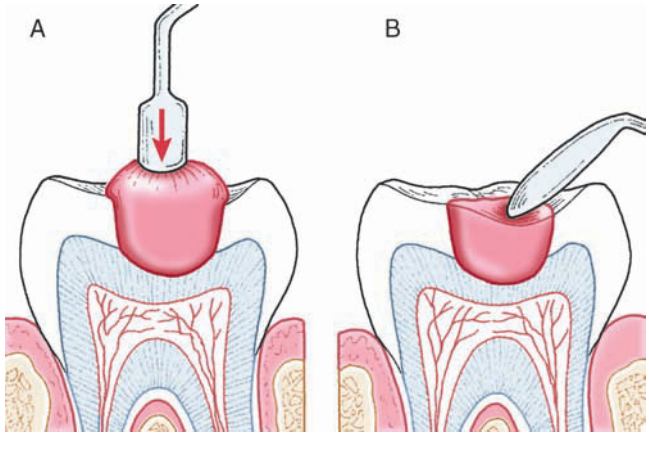

FIGURE 180-3. Application of temporary restorative material. **A.** Pack the material into the defect and condense it with a dental explorer (or a cotton-tipped applicator). **B.** Remove any excess material.

Remove any excess material with the stick end of the cotton-tipped applicator. Use the discoid-cleoid dental carver to remove excess material once it begins to harden (**Figure 180-3B**). Use dental floss to contour a proper embrasure and clear excess material from the gingival tissues. **Use the dental floss in a downward direction only. Never bring the dental floss back up toward the occlusal surface because doing so risks dislodging the new restoration.** Simply pull the dental floss through after one downward pass around the tooth.

REPLACING A TEMPORARY OR PERMANENT CROWN

The patient preparation required for this procedure is essentially the same as that for replacing a temporary filling. However, avoid dental anesthesia if possible to allow better patient proprioception. This will provide the Emergency Physician with a crucial aid in assessing the orientation and occlusion of the final restoration.[1] The same over-the-counter mixtures for repairing a filling may be used to temporarily replace a crown (**Figure 180-2**).

Reapply the crown to ensure that it fits properly. It is often necessary to remove a small amount of the existing cement from within the patient's existing restoration in order to provide an adequate seal and a proper occlusion.[1] This may or may not be possible to do with the discoid-cleoid dental carver. Do not use rotary instruments as these may irreversibly damage the inside of the coping. Reinsert the patient's crown after removing some of the cement to assure a proper fit and proper occlusion. Make an attempt using the alternative technique described below if sufficient preexisting cement cannot be removed and the crown seats properly. Treat dentinal sensitivity as outlined above (i.e., as replacing a filling) if the appliance does not seat at all.

Proceed with this technique if the restoration appears to fit and a small amount of the preexisting cement can be removed from the inside. Prepare the area. Apply a thin layer of petrolatum-based lubricant (i.e., Vaseline) to the mucosal tissues surrounding the tooth to aid in the cleanup. **Do not contaminate the prepared tooth with the lubricant.**

Prepare or mix a thin consistency of zinc oxide and eugenol cement. Place a very small amount of the mixture into the preexisting crown with a cotton-tipped applicator.[3,14,18] Place the crown on the tooth and in the proper orientation. Firmly and fully seat the crown with firm finger pressure. Remove any excess cement material from around the margin of the newly cemented restoration. This may be easier once the material has hardened. Instruct the patient to gently and fully occlude on the restoration. **Ensure proper occlusion.** Ask the patient to provide a subjective report if their occlusion feels like baseline (i.e., does their bite feel funny). Confirm this using articulating paper to ensure that the contact marks are light or minimal. Wipe the petrolatum-based lubricant from the mucosal tissues.

A simpler, alternative, and far more temporary method of replacing a crown involves using Vaseline as the cementing agent.[1] Apply a thin layer of Vaseline to the inside of the coping. It may be necessary to remove a small amount of the preexisting cement. Seat the crown on the tooth in the proper orientation. Ensure proper occlusion. Warn the patient that the crown may come off again and about the risk of aspiration. Instructions may be given to the patient for repeating the procedure at home.

ASSESSMENT

Check the patient's occlusion. It may be necessary to use articulating paper to ensure minimal or no contact with the opposing teeth with the temporary filling. The newly cemented crown restoration must primarily be assessed for proper occlusion. The patient's subjective opinion is invaluable in this regard.

AFTERCARE

Instruct the patient not to eat or chew on their new restoration for at least 1 hour. Additional instructions should include a soft diet, avoidance of extremely hot or cold substances, avoidance of chewing gum, and avoidance of other such "sticky" foodstuffs. They may brush their teeth normally, but should not floss adjacent to the new restoration. Warn them that they may experience some continued sensitivity. Nonsteroidal anti-inflammatory drugs will provide any needed analgesia. Arrange follow-up within 24 to 48 hours.

COMPLICATIONS

Typical complications of replacing a filling include improper occlusion and poor retention of the restoration. The solution for both problems is replacing the restoration. Adjust the occlusion with the discoid-cleoid dental carver. Treat the restoration as a dental restoration that is "too high" if using the discoid-cleoid dental carver is not effective. Treat the tooth as a simple dentinal exposure if a temporary restoration is continually falling out. An unlikely complication would be a pulpal exposure, manifested as minimal bleeding from within the tooth defect.[1,10,12] Manage this as a dental trauma or fractured tooth.

Typical complications for replacing a crown are similar to those listed in replacing a temporary filling. These restorations are often easily removed with a slight twisting motion. A restoration that is seated "too high" should be replaced. Treat the tooth as a simple dentinal exposure if a restoration is consistently "too high".

SUMMARY

Management of the patient with a dental complaint may initially seem intimidating to the Emergency Physician. The recognition and treatment of dental pain, minor defective dental restorations, and painful mucosal conditions can be relatively simple provided a minimal understanding of basic dentistry. Emergency Physicians must be cognizant of the inherent limitations involved in treating these patients in the Emergency Department. Have a low threshold for referral. Pain, inflammation, and infection should always be treated. Refer patients to the appropriate specialist within 24 to 48 hours.

181 Subluxed and Avulsed Tooth Management

Daniel J. Ross

INTRODUCTION

Traumatic dental injuries are a common presentation to the Emergency Department. They can have significant lasting cosmetic, functional, and psychological consequences for the patient. Recent estimates indicate over three quarters of a million annual Emergency Department visits in the United States for dental-related complaints.[1] Nearly 12% of these are related to some form of trauma.[1] Approximately 50% of children will sustain traumatic dental injuries, the majority of these to the permanent dentition.[2–4] Violence of a suspicious nature, such as domestic or child abuse, must always be considered when evaluating dental injuries.

The appropriate Emergency Department management of dental trauma depends heavily upon the type of tooth (permanent vs. primary), the age of the tooth, the time elapsed since the incident, and the extent of the damage. Successful treatment of dental injuries requires a basic understanding of dental anatomy, terminology, and pathophysiology. **The goals of the emergent treatment of dental trauma are to maintain patient comfort and tooth vitality, while ensuring prompt dental follow-up for definitive care.**

ANATOMY AND PATHOPHYSIOLOGY

TOOTH ANATOMY

There are significant differences in the adult and pediatric dentitions that impact their treatment in the Emergency Department (**Figure 181-1**). The pediatric dentition is known as the primary or deciduous dentition and consists of 20 teeth. These include eight incisors, four canines, and eight molars. The adult dentition consists of 32 teeth and is composed of 8 incisors, 4 canines, 8 premolars, and 12 molars. The variable absence of a tooth or the addition of an extra tooth is common in either dentition. The teeth in both the pediatric and adult dentitions erupt in a predictable sequence, albeit with considerable individual variation (**Figure 181-1**). Treatment strategies differ for permanent versus deciduous (primary) teeth as well as by the age of the adult tooth. **Exercise great care when evaluating patients with a "mixed" dentition, roughly between the ages of 6 and 12 years.**

The anatomy of a tooth is rather simple (**Figure 181-2**). The tooth itself consists of a neurovascular pulp surrounded by supportive dentin, which is surrounded by a hard thick crown of enamel. The crown portion lies above the gum line or gingiva. The root portion lies embedded within the alveolar bone of the jaw, anchored by a thin layer of cementum, and the periodontal ligament. The alveolar bone, periodontal ligament fibers, and fragile cementum cell layer taken together are considered a functional unit known as the attachment apparatus. A complete attachment apparatus requires

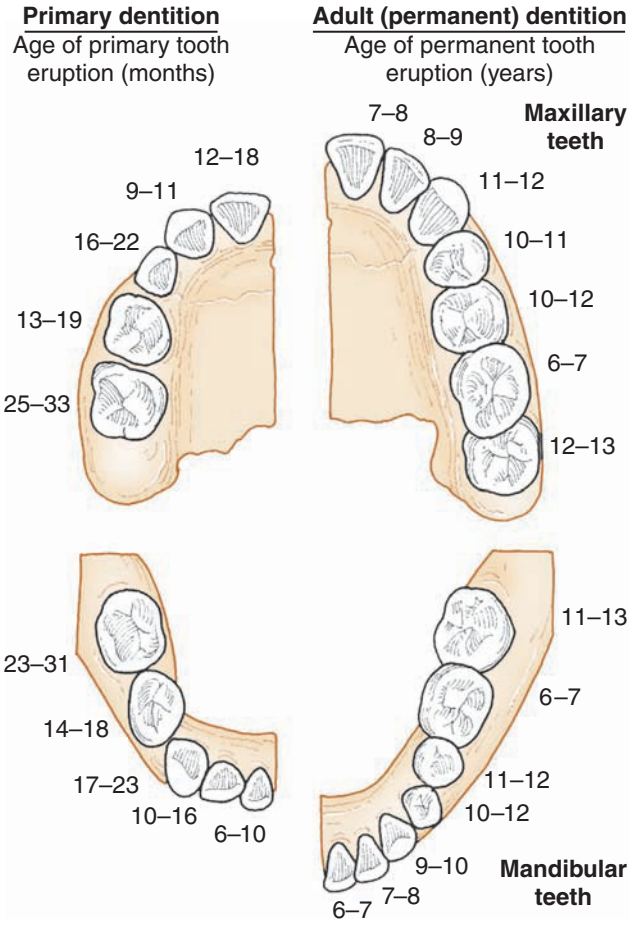

FIGURE 181-1. The normal eruptive patterns of the pediatric and adult dentition.

an intact cementum cellular layer and a fully formed root apex. Immature adult teeth do not have a fully formed apex and necessitate special attention to maintain pulpal viability.[3,5–9]

TOOTH INJURY

Mechanisms of tooth injury include direct trauma (i.e., a blow) or occlusive trauma (i.e., biting on a hard object or a seizure). These mechanisms can result in a spectrum of injury patterns that vary from simple sensitivity to complete tooth avulsion. Crown and root fractures are discussed in Chapter 182. This chapter focuses on the diagnosis and management of dental subluxations and avulsions.

Appropriate treatment of dental injuries requires a thorough history and meticulous examination of the oral cavity, including subsequent radiographs after ruling out more serious injuries. Historically, important points include the age of the patient, the time of the trauma, the mechanism of injury, the location of teeth or tooth fragments, subjective disturbance of bite, and treatments provided since the time of the incident. The physical examination must include an assessment of the extraoral and intraoral soft tissues, bony displacement, missing teeth, crown fractures, pulp exposures, tooth sensitivity, and tooth mobility.

The need for radiographs with dental trauma is worth emphasizing. A tooth that is missing, both by history and physical examination, may be found completely intruded below the gum line, embedded in the perioral soft tissues, floating within the maxillary sinus or stomach, or even aspirated.[10–14] **Obtain facial films if a tooth, or a portion of the tooth, cannot be unequivocally located by history or physical examination. Strongly consider obtaining chest and abdominal radiographs if the tooth, or the portion in question, is not visualized on the facial films.**

CONCUSSED AND SUBLUXED TEETH

Mild injuries to teeth are common and cause concussions and subluxations. Concussed teeth are essentially injured, nonmobile, and nonfractured teeth. These teeth have suffered a direct blow and are sensitive, with no concrete clinical or radiographic

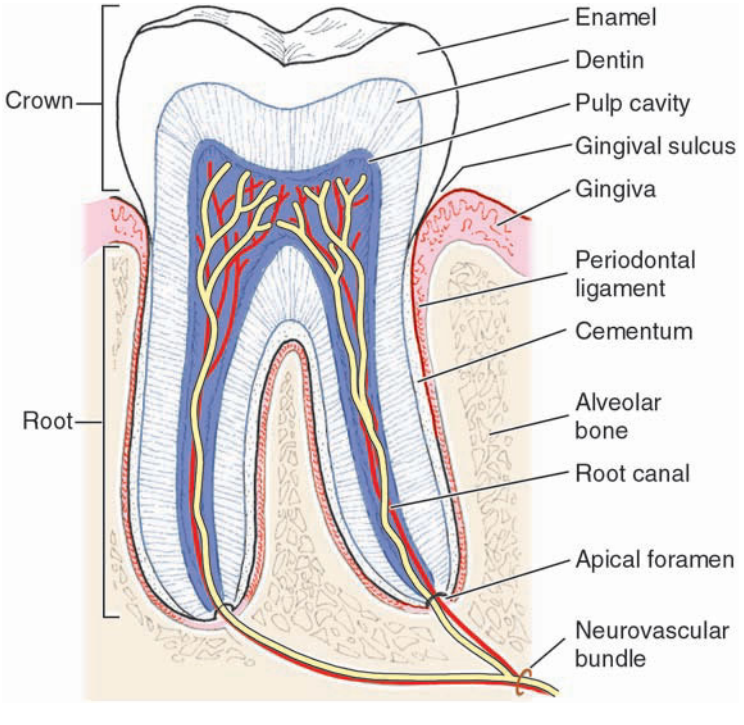

FIGURE 181-2. The dental anatomic unit (i.e., the tooth) and its supporting structures.

evidence of injury. Concussions are often mild injuries to the periodontal ligament with associated inflammation. Subluxed teeth may or may not be sensitive, are not displaced, but are perceptively mobile when manipulated between two cotton applicators or other instruments. Subluxations have definite damage to the periodontal ligament with associated inflammation. Mild gingival bleeding may be present. Both concussion and subluxation imply an injury to the attachment apparatus. Pain control, soft diet instructions, and follow-up with a Dentist are all that is required in the management of most of these injuries. Concussed and subluxed primary and permanent teeth are generally treated in the same manner.[2,7–9,16]

Excessive mobility from a severe subluxation may be irritating, painful, and damaging. These injuries require a temporary splint for relief.[2,3,5–9] Definitive treatment for severely subluxed permanent teeth requires splinting for 2 weeks or more.[9,16] Definitive treatment for severely subluxed primary teeth is extraction.[9,16]

LUXATED TEETH

Luxated teeth are displaced or dislocated from their usual position within the alveolar bone. The periodontal ligament is torn. Luxated teeth are commonly associated with other injuries such as alveolar fractures, root fractures, and gingival lacerations.[2,17] Subcategories of injury within this class are described by the direction of the dislocation. Luxated teeth may be displaced laterally, intruded, or extruded (**Figure 181-3**). Lateral luxations may be mesial, distal, buccal, or lingual in direction. An alveolar fracture is self-evident when several teeth are luxated as a solid segment.

Laterally luxated permanent teeth should be repositioned and temporarily splinted.[7–9] Laterally luxated primary teeth can be treated in the same fashion.[16] A general word of caution regarding primary teeth is warranted. **The apices of the primary teeth are in close anatomic proximately to the developing permanent tooth buds within the alveolus.** This close relationship can lead to numerous developmental disturbances in the permanent dentition whenever there is trauma to a primary tooth.[18] **Therefore, it is recommended that the Emergency Physician defer any manipulation of a primary tooth to the care of a Dentist, or at least consult them first.**

Extruded teeth represent a partial avulsion from the alveolar socket and a damaged attachment apparatus. They typically appear clinically longer than the surrounding teeth (**Figure 181-3B**). Patients may complain of occlusal prematurity. There may be associated gingival bleeding. A hematoma surrounding the apex may preclude complete repositioning. Extruded permanent teeth are treated with repositioning and temporary splinting.[2,3,5,7–9] Treatment decisions for extruded primary teeth are complex and best left to a Dentist. The majority of these teeth will likely require extraction.[16]

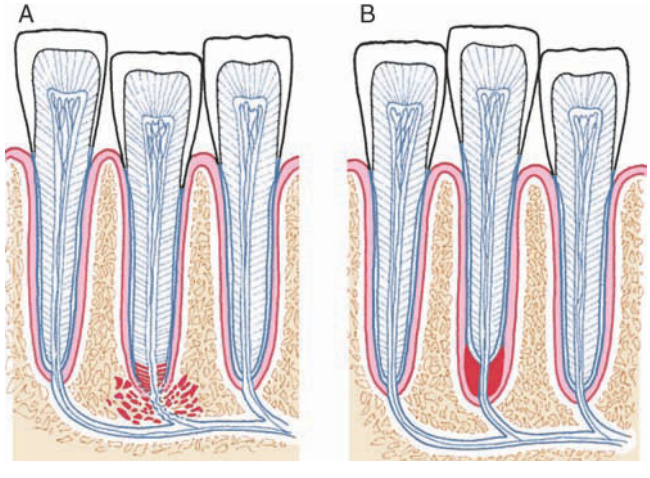

FIGURE 181-3. Luxation injuries with neurovascular damage to the apex. **A.** Intrusive luxation injury. **B.** Extrusive luxation injury.

Intrusion is a severe form of luxation injury with the tooth driven inward in an axial direction. These injuries are manifested by displacement of the tooth into the alveolar socket with a corresponding fracture of the alveolar bone surrounding the apex (**Figure 181-3A**). Adjacent structures, such as the floor of the nose or maxillary sinus, may be involved or damaged.[13,14] These injuries may be so profound that the tooth is not visible within the oral cavity and believed to be avulsed. **It is worth reiterating that a tooth that cannot be unequivocally located on physical examination requires radiographic localization.** Immature adult teeth suffering intrusion injuries generally have the best prognosis. They are often left alone and allowed to re-erupt. Mature adult teeth often require surgical or orthodontically assisted re-eruption and root canal therapy. The intrusion of primary teeth frequently leads to damage of the developing permanent tooth buds and requires close dental follow-up. Rule out more serious injuries, arrange an expedited appointment for definitive care, prescribe appropriate analgesics, and give strong consideration to the prescription of antibiotics.[2,3,5,7–9,19]

AVULSED TEETH

Avulsed teeth are teeth that have been completely torn from their alveolar sockets. **The teeth have suffered profound attachment and neurovascular damage that progresses in a time-dependent fashion.** There is a high likelihood of associated injuries with this type of trauma. Perform a thorough evaluation of the entire oral cavity after any dried blood, clots, and debris have been removed. Bleeding can generally be controlled with firm digital pressure or local infiltration of an epinephrine-containing local anesthetic solution. Patients may present with the tooth in hand or may not be aware of the location of the tooth. **The onus is on the Emergency Physician to determine the exact whereabouts of the tooth. Treat the patient for pain, control the bleeding, and provide tetanus prophylaxis.** Prescribe antibiotics for these patients if there are significant concomitant injuries or as the situation warrants. Arrange follow-up with a Dentist at their convenience. If available, a permanent tooth can be treated with replantation. **As a rule, avulsed primary teeth are not replanted to avoid damage to the developing permanent teeth and possible growth disturbances.**[5,7,8,16] Exercise great care in evaluating patients in the mixed dentition stage, roughly between the ages of 6 and 12 years.[2,3,5]

An attempt can be made at replantation in order to preserve patient comfort, cosmesis, and function when a permanent avulsed tooth is available. **The objective for the emergency treatment of these injuries is to maintain viability of the torn periodontal ligament fibers on the external root surface as pulpal necrosis is inevitable for the majority of these teeth.**[2] A successfully replanted tooth may be fully functional with little or no cosmetic impact following root canal therapy. **Periodontal ligament fibers are extremely sensitive to desiccation. The most critical factor in the successful replantation of avulsed teeth is the speed with which the tooth is replanted.**[2,3,17,20] Patients, parents, or Emergency Medical Service (EMS) personnel can be instructed to replant an avulsed tooth in the field in order to improve the prognosis.[2,3]

Take great care in the handling of an avulsed tooth. They should be handled minimally and only by the crown. The root

surface should not be manipulated in any way other than gentle cleansing with sterile saline, or tap water as a substitute. This will prevent further damage to the cementum and periodontal ligament. Treat the socket in a similar fashion (i.e., cleansed of any obstructing clots or debris with gentle irrigation and suction only) following anesthesia.[3,20]

When it is not possible to immediately replant an avulsed tooth, it can be transported or stored in such a way as to prevent desiccation of the fragile periodontal ligament fibers and to improve salvage rates.[2,5,7–9] The best possible transport and storage solutions are Hank's balanced salt solution (HBSS) and Viaspan, a special cell culture medium (SCCM) used to preserve transplant tissues. The SCCM seems to show some benefit over HBSS.[22] Several commercial products are readily available and specifically designed for tooth transportation and storage. They include EMT Tooth Saver (SmartPractice, Phoenix, AZ) and Dentosafe (Medice, Iserlohn, Germany) which utilize SCCM, or Save-a-Tooth (Phoenix-Lazerus, Pottstown, PA) which utilizes HBSS.[22] These products have great utility in the field and the Emergency Department. They should be considered standard and essential equipment for the Emergency Department. This is particularly true where definitive dental care is not readily available. Simply providing a patient with one of these products may allow successful replantation by a dental specialist hours or even days later.[2,23] Fresh pasteurized whole milk and sterile normal saline are alternatives, but carry diminishing returns for tooth salvageability. Saliva can be employed as a transport medium (by placing the tooth in the buccal vestibule of a conscious and cooperative adult) for very brief periods, again with diminishing hopes for salvage. Tap water or plastic wrap may prevent desiccation for a brief period if all else fails.[3,5,7–9,23]

The literature indicates that irreversible periodontal ligament cell damage occurs within minutes following total tooth avulsion.[3,5,20] Common clinical practice is typically to abandon attempts at salvageability if the tooth has been out of the socket for more than an hour. **However, the notion that replantation is not possible for extraoral times beyond 1 hour is a myth.** The dental trauma literature is replete with case reports with successful outcomes following very long extraoral times (up to a week) and under extremely suboptimal storage conditions such as being kept completely dry.[23,24] An esthetic and functional, albeit less than ideal, result may be possible for avulsed teeth with extraoral times over an hour through a process known as ankylosis if appropriately and aggressively treated by a skilled Dentist. **Therefore, it is never acceptable to discard an avulsed tooth.** Avulsed teeth with extraoral times greater than 1 hour require special treatment with topical fluoride and antibiotic soaks that are typically beyond the scope of care in the Emergency Department.[9,20] Consult a Dentist prior to considering these techniques. At the very least, always give the patient their tooth back in a suitable storage/transport device and advise them on their options for definitive care.

REDUCTION OF SEVERELY SUBLUXED, LATERALLY LUXATED, AND EXTRUDED TEETH

The emergent treatment of a severely subluxed tooth, a laterally luxated tooth, or an extruded tooth involves obtaining adequate anesthesia, reduction of the tooth, and a temporary splint for stabilization.

INDICATIONS

Any severely subluxed, laterally luxated, or extruded tooth is a candidate for reduction.

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a subluxed, laterally luxated, or extruded permanent tooth. Laterally luxated and primary teeth can be repositioned and splinted. However, their manipulation may damage the permanent tooth bud growing beneath the primary tooth root. Therefore, all subluxed, luxated, or extruded primary teeth should be considered for extraction in consultation with a Dentist or Oral Surgeon.[5,7,8,16,17,21] Consult a Dentist or Oral Surgeon if there is a significant alveolar bone fracture. Do not attempt to reduce teeth that are fractured or grossly carious.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 to 27 gauge needle
- Sterile saline
- Sterile 2 × 2 gauze squares
- Suction source and tubing
- Frazier suction catheter
- Cotton-tipped applicators
- Overhead lighting or headlight

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia. Refer to Chapter 176 regarding the details of dental anesthesia and analgesia. Cleanse the oral cavity with warm saline or tap water and gentle suction. Thoroughly examine the entire oral cavity. Obtain radiographs as indicated. Provide tetanus prophylaxis if required.

TECHNIQUES

SEVERELY SUBLUXED TOOTH REDUCTION

A severely subluxed tooth is not displaced from its socket but is excessively mobile. Ensure that the tooth is in its proper anatomic location. Apply a temporary dental splint, as described below.

LATERALLY LUXATED TOOTH REDUCTION

A laterally luxated tooth has its roots displaced laterally and out of the socket (**Figure 181-4**). It is often associated with a fracture of the surrounding alveolar bone. Place the dominant thumb over the medial surface of the tooth and the index finger overlying the root end of the tooth (**Figure 181-4**). Apply downward and inward pressure with the index finger (**Figure 181-4A**) followed by application of outward pressure with the thumb (**Figure 181-4B**) to reduce the tooth. Apply a temporary dental splint, as described below.

EXTRUDED TOOTH REDUCTION

An extruded tooth is a partially avulsed tooth that protrudes above the adjacent teeth. Apply gentle pressure to the crown of the tooth to reduce the tooth. **Do not force the tooth into the socket** to avoid an iatrogenic fracture at its base. Consult a Dentist if the tooth will not reduce. A hematoma in the base of the socket often prevents reduction. Insert a piece of gauze over the tooth and instruct the patient to gently bite down.

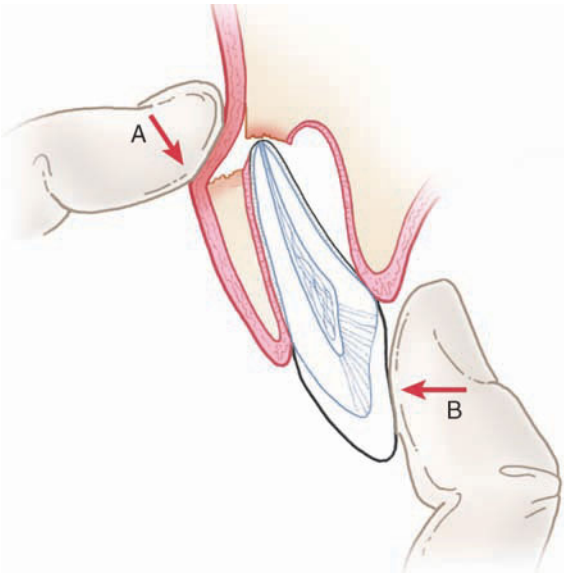

FIGURE 181-4. Manually repositioning a laterally luxated tooth. Apply downward and inward pressure with index finger (**A**) followed by outward pressure with the thumb (**B**).

ASSESSMENT

Obtain postreduction radiographs to verify the correct tooth position. Radiographs may be delayed until after splinting. Reassess the patient for pain, occlusal discrepancies, and stability of the reduction. Manage any soft tissue injuries.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesic will provide adequate analgesia. Prescribe empiric antibiotics (penicillin or clindamycin). Twice daily rinses with chlorhexidine may also be useful. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care as discussed below. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.[2,3,19]

COMPLICATIONS

Immediate complications of any dental trauma include pain and cosmetic deformity. Additionally, instability may be an issue following the application of a temporary splint. Delayed complications can be variable and include tooth mobility, root resorption, pulpal necrosis, infections, and abscess formation. Extension of untreated infections into alveolar bones can cause osteomyelitis and/or systemic infectious complications. A permanent tooth may develop abnormally in a younger child if injured. Bleeding is minimal and often self-limited. Refer to Chapter 179 for the details of post-extraction bleeding management. Ensuring prompt dental follow-up, adequate outpatient analgesics, and empiric antibiotics can limit most of these complications.

REPLANTATION OF AN AVULSED TOOTH

Permanent teeth that have been avulsed should be handled gently and only by the crown. Time is a critical factor in the successful treatment of these injuries and every effort should be made to expedite the care of these patients. Replantation consists of gently reinserting the tooth in the proper orientation and fully seating it with gentle pressure.

INDICATIONS

Any intact and avulsed permanent tooth is a candidate for replantation.

CONTRAINDICATIONS

There are no absolute contraindications to the replanting of permanent teeth by nondental personnel. Concerns for the ABC's (airway, breathing, and circulation), concomitant major morbidity, and aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth replantation. Primary teeth are never replanted. Do not attempt to replant teeth that are fractured or grossly carious.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 to 27 gauge needle
- Sterile saline
- Hank's balanced salt solution
- Sterile 2 × 2 gauze squares
- Sterile cotton rolls
- Suction source and tubing
- Frazier suction catheter
- Cotton-tipped applicators
- Overhead lighting or headlight

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia. Refer to Chapter 176 regarding the details of dental anesthesia and analgesia. Cleanse the oral cavity with warm saline or tap water. Use gentle suction, but never near the injured tooth. Thoroughly examine the entire oral cavity. Obtain radiographs as indicated. Provide tetanus prophylaxis if required. Gently irrigate the avulsed tooth and socket with warm sterile saline or Hank's solution. Remove and clots and debris using a Frazier suction catheter. **Take great care to avoid touching or contaminating the tooth root.** Soak the tooth in Hank's solution for 30 minutes prior to replantation if the extraoral dry time exceeds 30 minutes. Consult a Dentist skilled in dental trauma care prior to replanting if the extraoral time exceeds 1 hour.

TECHNIQUE

Grasp the avulsed tooth gently and only by the crown. Replace the avulsed tooth into the socket in an anatomically correct position. Seat the tooth fully with gentle but firm digital pressure. **Never force the tooth into the socket.** Evaluate the patient's occlusion. Instruct the patient to gently bite together several times while observing for any prematurity. Occasionally, a tooth cannot be completely seated or its position is uncertain. Instruct the patient to temporarily bite on a gauze roll until the dental specialist arrives or store the tooth in a storage/transport media until definitive dental

care can be rendered.[3,19] Address any soft tissue injuries once the tooth's position has been verified. Insert a piece of gauze over the tooth and instruct the patient to gently bite down. Apply a temporary dental splint, as described below.

ASSESSMENT

Obtain post-replantation radiographs to verify the correct tooth position. Radiographs may be delayed until after splinting. Reassess the patient for pain, occlusal discrepancies, and stability of the replanted tooth prior to discharge. Manage any soft tissue injuries.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesic will provide adequate analgesia. Prescribe empiric antibiotics. Doxycycline is recommended as the drug of choice in patients over 12 years of age. Penicillin or clindamycin are useful substitutes. Twice daily rinses with chlorhexidine are useful, but not required. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care as discussed below. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.[2,3,19]

COMPLICATIONS

Immediate complications of any dental trauma include pain and cosmetic deformity. Additionally, instability may be an issue following the application of a temporary splint. Delayed complications can be variable and include tooth mobility, root resorption, pulpal necrosis, infections, and abscess formation. Extension of untreated infections into alveolar bones can cause osteomyelitis and/or systemic infectious complications. A permanent tooth may develop abnormally in a younger child if injured. Bleeding is minimal and often self-limited. Refer to Chapter 179 for the details of post-extraction bleeding management. Ensuring prompt dental follow-up, adequate outpatient analgesics, and empiric antibiotics can limit most of these complications.

PREPARING A TEMPORARY DENTAL SPLINT

Concussed teeth, subluxed primary teeth, and subluxed permanent teeth usually do not require splinting. A temporary splint may prevent further damage and improve patient comfort if severe mobility, or subluxation, is present. Manually reposition laterally luxated and extruded permanent teeth using gentle and firm digital manipulation following adequate anesthesia. A Dentist or Oral Surgeon will typically extract laterally luxated or extruded primary teeth. Intruded teeth, both primary and adult, are associated with considerable comorbidity and complications. These injuries require consultation with a Dentist or Oral Surgeon after defining the extent of the injuries with appropriate radiographs.

INDICATIONS

Any severely traumatized and grossly mobile, luxated, repositioned, or replanted tooth requires temporary splinting. This will prevent further damage, promote patient comfort, preserve form, and preserve function.

CONTRAINDICATIONS

There are no absolute contraindications to the temporary splinting of mobile teeth. The aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth splinting.

GENERAL SPLINTING EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 to 27 gauge needle
- Sterile saline
- Coe-Pak or Perio-Pak
- Dental utility wax or beeswax
- Sterile 2 × 2 gauze squares
- Sterile cotton rolls
- Applicator sticks; tongue depressors or the wooden end of cotton swabs will substitute
- Frazier suction catheter
- Suction source and tubing
- Overhead lighting or headlight

ADVANCED SPLINTING EQUIPMENT

- General splinting equipment as described above
- Wire cutters
- Tooth etching gel
- Composite resin material (e.g., Centrix Tempit Ultra-F, Centrix Inc., Shelton, CT)
- Single-component adhesive (e.g., Optibond Solo Plus kit, Kerr Corp., Orange, CA)
- Bondable reinforcement ribbon (e.g., Ribbond, Ribbond Inc., Seattle, WA)
- Orthodontic wire, 0.025 inch
- Tubing and regulator to attach to wall air supply
- Visible curing light

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia. Refer to Chapter 176 regarding the details of dental anesthesia and analgesia. Cleanse and thoroughly examine the entire oral cavity. Obtain radiographs as indicated. Provide tetanus prophylaxis if required. Manually reposition any luxated and avulsed teeth. **Manage any soft tissue injuries prior to splint placement to avoid wound contamination by the splint material.**

TECHNIQUES

Cold-curing periodontal packing material (i.e., Coe-Pak or Perio-Pak) is an ideal splinting material for practitioners without dental experience. Measure out equal amounts (i.e., lengths) of the catalyst and the epoxy onto a paper pad (**Figure 181-5A**). Usually a 2- to 3-inch ribbon of each substance is adequate. Thoroughly mix the catalyst and epoxy compounds together with a tongue depressor to form a putty-like consistency (**Figure 181-5B**). Using tap water- or saline-wetted gloved hands, roll the material into a log (**Figure 181-5C**). Apply the material to frame both aspects, medial

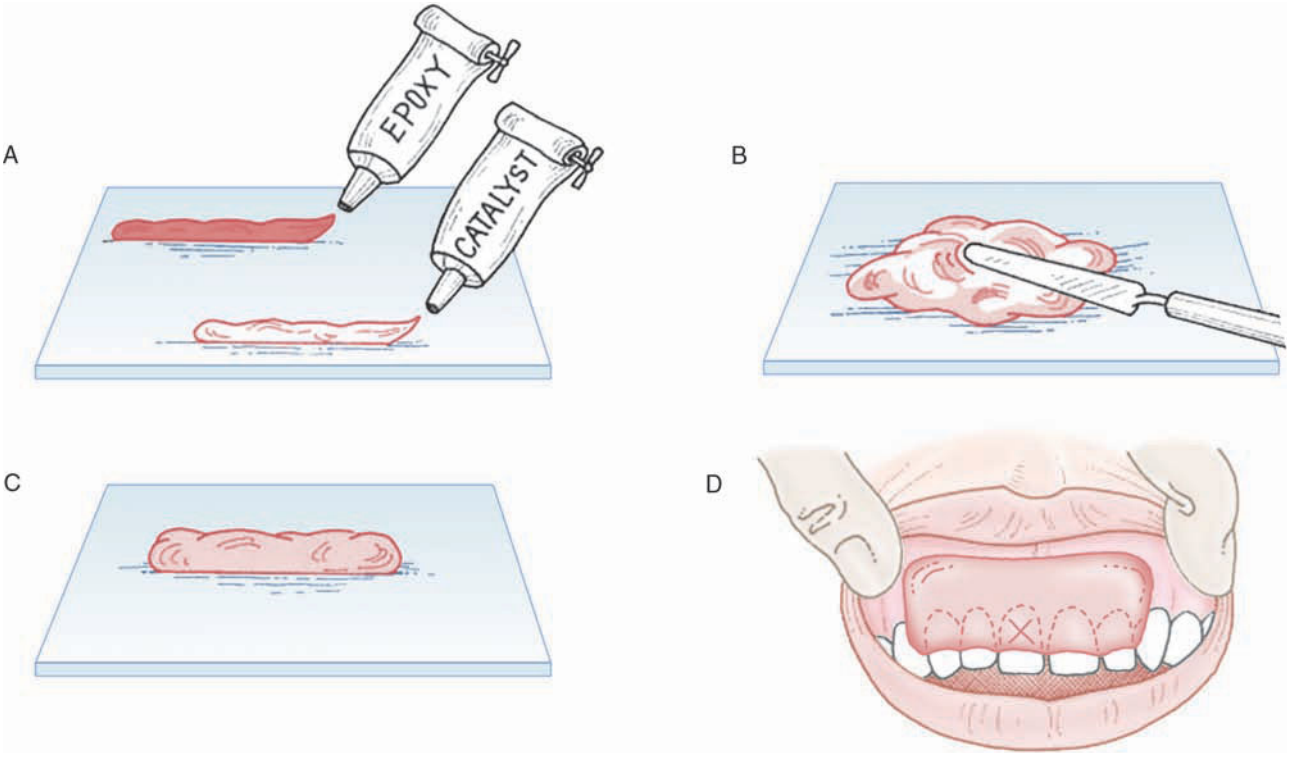

FIGURE 181-5. Preparation of the dental bonding resin and repair of the injured tooth. **A.** Equal amounts of the epoxy and catalyst are measured. **B.** The epoxy and catalyst are mixed together. **C.** The hardening dental paste is molded into a supportive bridge. **D.** The dental bridge is applied over the injured tooth and adjacent two uninjured teeth (both sides) for support while hardening.

and lateral, of the injured tooth and two to three adjacent stable teeth on either side of the injured tooth (**Figure 181-5D**). Use finger pressure to squeeze the material between the teeth medially and laterally to create a single splint unit. **To allow proper occlusion, do not place the packing material on the masticatory surfaces of the teeth. The material must be kept dry and uncontaminated to cure, which is achieved within minutes.**

ALTERNATIVE TECHNIQUES

Numerous alternative techniques have also been used to temporarily splint a tooth. A simpler technique employs softened dental utility wax or beeswax in a similar fashion as described above. The wax splint is not nearly as stable as the cold-curing periodontal packing. Both the medial and lateral surfaces of the teeth can be splinted in this fashion. Ligature splinting with suture material has been described, but rarely provides any significant stability.

Advanced techniques include bondable reinforcement ribbon, acid-etched composite resin, direct interdental wiring, resin-wire combinations, arch bars, and stabilization with a figure-of-eight stitch to the adjacent tooth. These are excellent materials in experienced hands. Unfortunately, they are difficult to use, fraught with complications, and cost prohibitive for routine Emergency Department use.[2,3,5,6,15,17,19,21] Two of these methods, which can be performed by the Emergency Physician if supplies are available, are described below. In an emergency with no immediate dental supplies or a Dentist, skin wound glue (2-octyl cyanoacrylate) and a metal nasal bridge from a face mask have been used to splint a tooth.[25]

A tooth may be splinted using bondable reinforcement ribbon. Open the Ribbond kit. Use the included scissors to cut a piece of the splinting fabric long enough to span the length of the injured tooth and one tooth on each side of the injured tooth. Apply a small drop of the acid etching solution onto all three teeth (the injured tooth, the one behind it, and the one in front of it). Allow the acid etching solution to remain on the teeth for 20 seconds. Thoroughly and gently rinse the acid etching solution using warm tap water or warm sterile saline in a syringe while using suction to capture the liquid. It is often easier to etch and rinse one tooth at a time instead of all three simultaneously. Thoroughly dry the teeth with compressed air. Remove the Optibond Solo Plus container from its packaging. Twist and remove the tip from the Optibond Solo Plus container. Apply a layer of the Optibond Solo Plus to the etched surface of all three teeth using the kits microbrush. Apply the curing light to the three teeth for 20 seconds each. Apply the Optibond Solo Plus onto the previously cut splinting fabric until it is saturated. Apply the tip onto the syringe containing the composite resin. Apply the composite resin to each of the three teeth. Apply and embed the splinting fabric into the composite resin on each tooth. Use a wooden stick (e.g., tongue depressor or cotton-tipped applicator) to ensure that the fabric is embedded in the resin as well as covered by the resin. Apply the curing light onto the three teeth for 40 seconds each. The procedure is the same if multiple adjacent teeth require splinting.

A tooth may be splinted using wire and composite resin. Use a wire cutter to cut a piece of orthodontic wire long enough to span the length of the injured tooth and one tooth on each side of the injured tooth. The remainder of the procedure is exactly as described above except the orthodontic wire is substituted for the splinting fabric.

ASSESSMENT

Allow the patient to wait in the Emergency Department until the splinting material has hardened. The splint material should impinge minimally on the soft tissues. The patient must be able to

open and close their mouth and lips freely, without any obstruction. Reassess the patient for pain, occlusal discrepancies, and stability of the replanted or subluxed tooth prior to discharge. Obtain post-splinting radiographs to verify the proper tooth position.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesic will provide adequate analgesia. Prescribe empiric antibiotics. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.[2,3,19]

COMPLICATIONS

The complications of temporary dental splinting are minimal. The splint material may not stabilize the tooth. A tooth allowed to move within the socket may result in damage to the cementum or the periodontal ligament. An improperly splinted tooth may fall out and result in an aspiration risk. To prevent irritation and bleeding, do not apply splinting materials over the soft tissues. Do not leave the etching acid on longer than 20 seconds or it can penetrate too deep and damage the tooth.

SUMMARY

Traumatic dental injuries are a common presentation to the Emergency Department, especially in pediatric patients during the mixed dentition stage. These injuries may have significant cosmetic, functional, and psychological consequences for the rest of the patient's life. The appropriate Emergency Department management of dental trauma depends heavily upon the type of tooth involved (primary vs. permanent), the time elapsed since the incident, and the extent of the damage. A basic understanding of dental anatomy, terminology, pathophysiology, and treatment protocols will facilitate an accurate description of the extent of the injuries to the dental consultant and be of great aid in providing temporizing emergent dental care when no specialist is readily available.

182 Fractured Tooth Management

Daniel J. Ross

INTRODUCTION

Traumatic dental injuries are common and can have significant lasting consequences for the patient. Recent estimates indicate over three quarters of a million annual Emergency Department visits in the United States for dental-related complaints.[1] Nearly 12% of these are related to some form of trauma.[1] It has been estimated that approximately 50% of children will sustain traumatic dental injuries, and the majority of these are to the permanent dentition.[2–4] Violence of a suspicious nature, such as domestic or child abuse, must always be considered when evaluating dental injuries. **The goals of the emergent treatment of dental trauma are to maintain patient comfort and tooth vitality, while ensuring prompt dental follow-up for definitive care.**

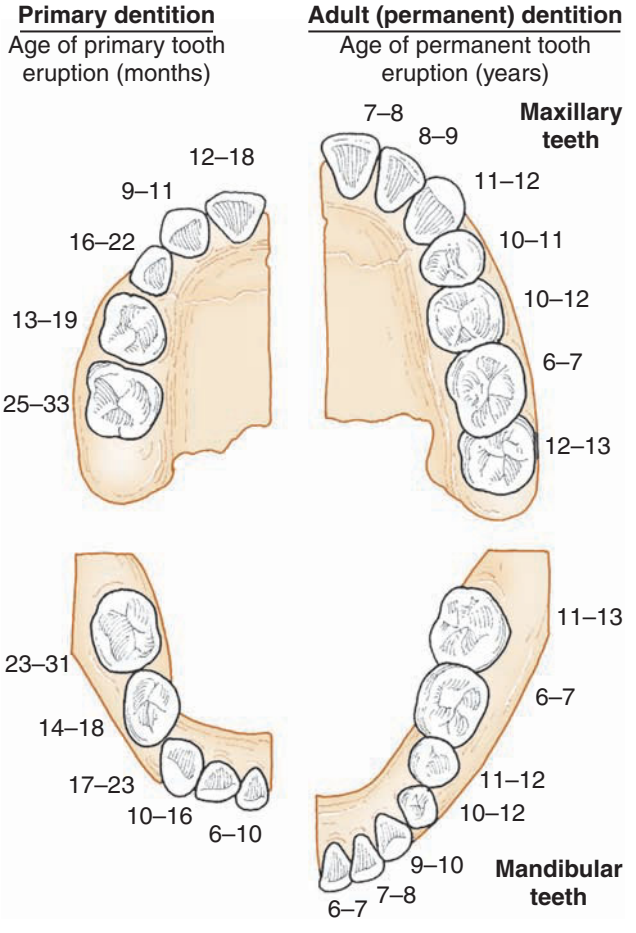

FIGURE 182-1. The normal eruptive patterns of the pediatric and adult dentition.

ANATOMY AND PATHOPHYSIOLOGY

TOOTH ANATOMY

There are significant differences in the adult and pediatric dentitions that impact their treatment in the Emergency Department (**Figure 182-1**). The pediatric dentition is known as the primary or deciduous dentition and consists of 20 teeth, which includes 8 incisors, 4 canines, and 8 molars. The adult dentition consists of 32 teeth and is composed of 8 incisors, 4 canines, 8 premolars, and 12 molars. The variable absence of a tooth or the addition of an extra tooth is common in either dentition. The teeth in both the pediatric and adult dentitions erupt in a predictable sequence, albeit with considerable individual variation (**Figure 182-1**). Treatment strategies differ for permanent versus deciduous (primary) teeth as well as by the age of the adult tooth. **Exercise great care when evaluating patients with a "mixed" dentition, roughly between the ages of 6 and 12 years.**

The anatomy of a tooth is rather simple (**Figure 182-2**). The tooth itself consists of a neurovascular pulp surrounded by supportive dentin, which is surrounded by a hard thick crown of enamel. The crown portion lies above the gum line or gingiva. The root portion lies embedded within the alveolar bone of the jaw, anchored by a thin layer of cementum and the periodontal ligament. The alveolar bone, periodontal ligament fibers, and fragile cementum cell layer taken together are considered a functional unit known as the attachment apparatus. A complete attachment apparatus requires a fully

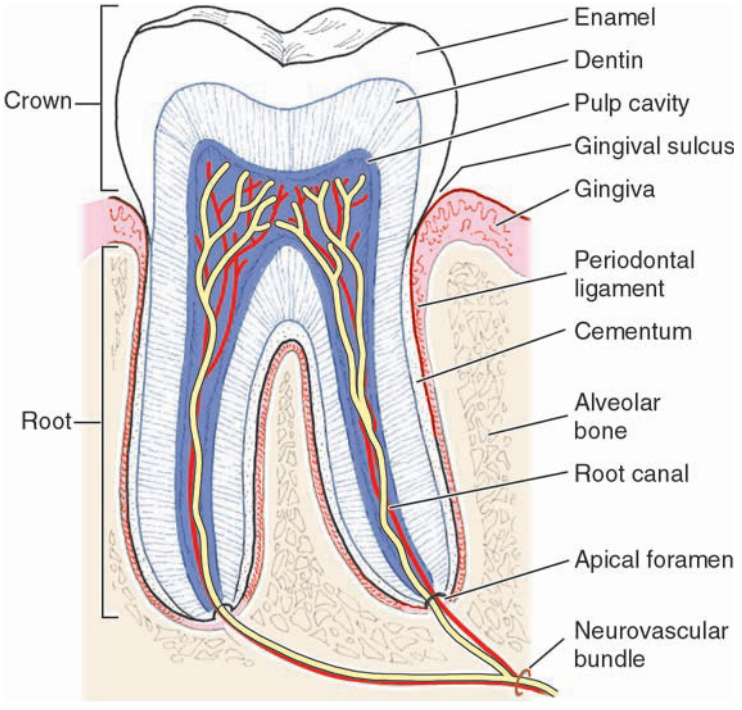

FIGURE 182-2. The dental anatomic unit (i.e., the tooth) and its supporting structures.

formed root apex. Immature adult teeth do not have a fully formed apex and necessitate special attention to maintain pulpal viability.[2,4,5]

TOOTH INJURY

Mechanisms of tooth injury include direct trauma (i.e., a blow) or occlusive trauma (i.e., biting on a hard object or a seizure). These mechanisms can result in a spectrum of injury patterns that vary from simple sensitivity to complete tooth avulsion. The fracture of any portion of the tooth, whether the crown or the root, falls in the middle of this spectrum and is frequently seen in the Emergency Department.[4]

Appropriate treatment of dental injuries requires a thorough history and meticulous examination of the oral cavity, including subsequent radiographs after ruling out more serious injuries. Historically, important points include the age of the patient, the time of the trauma, the mechanism of injury, teeth or tooth pieces at the scene, subjective disturbance of bite, and treatments provided since the time of the incident. The physical examination must include an assessment of the extraoral and intraoral soft tissues, bony displacement, missing teeth, crown fractures, pulp exposures, tooth sensitivity, and tooth mobility. This chapter focuses primarily on tooth fractures, while luxation and avulsion injuries are dealt with in Chapter 181.

The need for radiographs with dental trauma is worth emphasizing. A tooth that is missing, both by history and physical examination, may be found completely intruded below the gum line, impacted within the perioral soft tissues, floating within the maxillary sinus or stomach, or even aspirated. **Obtain facial films if a tooth, or a portion of a tooth, cannot be unequivocally located by history or physical examination.** Strongly consider obtaining chest and abdominal radiographs if the tooth, or portion in question, is not visualized on the facial films.[6–11] Any available tooth fragments, whether retrieved from the scene, the patient's perioral soft tissues, or the patient's pocket should be saved and stored for potential use during the definitive care process by the Dentist.[9,12–14] Bonding techniques in the Emergency Department are not prudent due to multiple potential complications including bond failure and tooth fragment aspiration.

TOOTH FRACTURES

Fractures involving the crown of the tooth are commonly described in the emergency literature using the Ellis classification system (**Figure 182-3**).[2,4–6,15,16] **An Ellis I fracture involves only the enamel portion of the tooth.** These injuries typically are not sensitive or

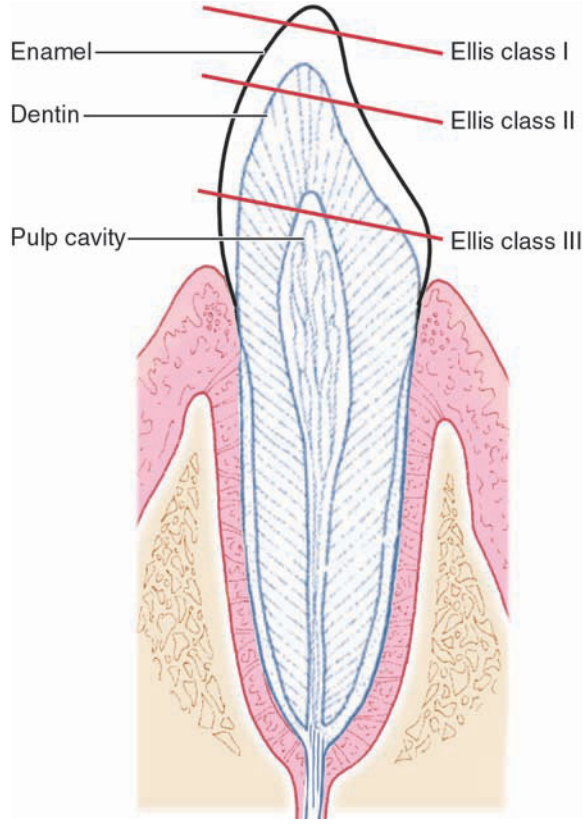

FIGURE 182-3. The Ellis classification scheme of dental fractures through the crown.

painful. They can result in a sharp edge of enamel that may irritate the tongue and other adjacent soft tissues. Emergency treatment may be as simple as smoothing the rough edge with an emery board or similar instrument.[2,4,14,17] These injuries frequently involve the prominent anterior teeth and may be cosmetically unappealing. Reassure patients with these concerns that aesthetic restorations are possible by their Dentist.[4–6,15,18] **Forewarn patients with even minor trauma and sensitivity that unseen or undiagnosed trauma at the apex of any traumatized tooth, even with an appropriately treated crown fracture, can compromise the blood flow to the pulp and obviate the need for root canal therapy.[4,18] Both primary and permanent teeth with these fractures can be treated in a similar fashion.[14,19]**

The Ellis II fracture involves the dentin. It can be recognized by the yellow to pink hue of the dentin in contrast to the white of enamel. This fracture allows for potential contamination of the dentin microtubular networks by oral bacteria that may eventually compromise the pulp if not treated. Dentin is alive and formed by the pulp. It is sensitive to temperature, osmotic gradients, and mechanical forces. Dentin is laid down concentrically from within the pulp chamber as the tooth ages. Therefore, children have less dentin than pulp (as compared to adults) and their pulp is less insulated against trauma and subsequent infection. Children under the age of 12 years with Ellis II fractures have a higher risk of complications and require more expeditious follow-up.[2,5,14,18] **Refer these patients to a General or Pediatric Dentist as soon as possible.**

Emergency treatment for Ellis II fractures consists of applying a protective dressing which is also sedative to the pulp. Examples include Dycal (L.D. Caulk Co., Milford, DE) and IRM (L.D. Caulk Co., Milford, DE). These materials need to cover the entirety of exposed dentin (and therefore the dentinal tubules) in order to protect the pulp from contamination. These materials are then often covered with a sealant such as Copalite (Cooley & Cooley, Houston, TX), clear acrylic nail polish, or a dental bonding resin.[2,3,5,6,14,15,18,20] Some authors have suggested that a non-light cured glass ionomer cement replace the long held standard of Dycal.[3] While these materials may offer some advantages, they can be expensive and tricky to use.[18]

Tissue adhesives such as Dermabond (Ethicon, Inc., Somerville, NJ) have been suggested as alternative dressings in the treatment of Ellis II dental fractures.[21–23] This should be discouraged as its effects on pulpal tissues via exposed dentinal tubules have not been studied and are unknown. Physicians may actually be causing harm by using this material on exposed dentin.

Both primary and permanent teeth with Ellis II fractured can be treated in a similar fashion. However, like immature permanent teeth, primary teeth with Ellis II fractured require special care and more expeditious follow-up.[14,19]

The Ellis III fracture involves exposure of both the dentin and the pulp. This is identified as a reddish tinge or subtle bleeding from the exposed dentin. Frank pulpal exposures are obvious. The pulp is highly vascular and exquisitely sensitive due to exposed nerve endings. The pulp is exceedingly vulnerable to bacterial infection if exposed. **These fractures constitute a true dental emergency and should be evaluated immediately by a Dentist for possible emergent root canal therapy or extraction.** Although less than ideal, minimal pulp exposures (less than 1 to 2 mm) may be treated as Ellis II fractures with dental follow-up within 24 hours.[2–6,14,15,18,19] Complete coverage of the fractured crown may be difficult in these cases. Dental dry foil or tin foil may provide adequate coverage. Any root canal manipulation is fraught with complications, even in the hands of Endodontists. Emergency Physicians are well advised to avoid these procedures.[2,15,18]

Fractures of the root are much less common than crown fractures and occur in less than 7% of dental injuries.[2,4] Root fractures are uncommon in primary teeth as they have short roots.[2] Root fractures may be described as either horizontal or vertical. Horizontal root fractures are described according to their location along the tooth root (**Figure 182-4**). Vertical root fractures occasionally extend into the crown. All root fractures are prone to infection and impaired healing, and may ultimately lead to pulpal necrosis and tooth loss.

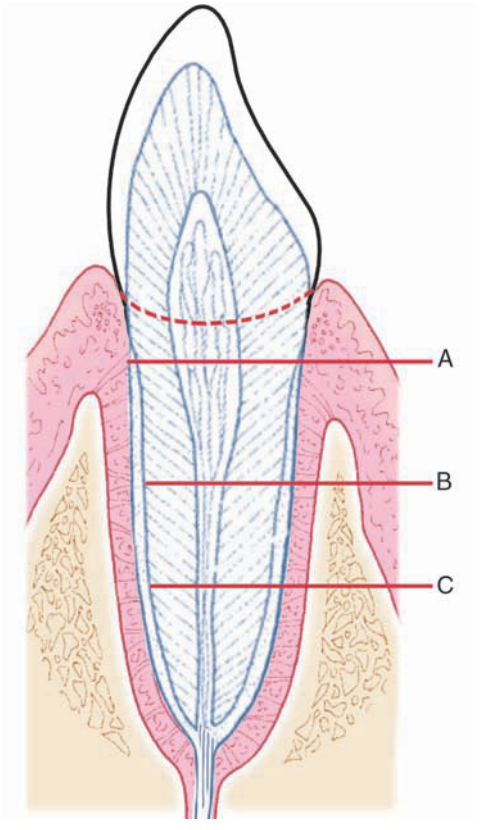

FIGURE 182-4. Classification of root fractures according to their location. **A.** Incisal or coronal third fracture. **B.** Mid-root fracture. **C.** Apical third fracture.

The clinical diagnosis of root fractures is challenging at best, even with the aid of radiographs readily available in the Emergency Department setting (i.e., Panorex). Root fractures classically present with pain, mobility, and sometimes displacement of a tooth fragment. However, these fractures are often insidious and found only on dental radiographs after follow-up reveals continued sensitivity. **Emergency Physicians must maintain a high level of clinical suspicion for these injuries and probably err on the side of cautious overtreatment.[2,4]**

Vertical root fractures and root fractures in the coronal portion of the root have a poor prognosis. Horizontal root fractures elsewhere along the tooth root have a good prognosis if treated before a coagulum can develop between the fragments, generally within 24 to 72 hours.[2,15] Immediate reduction and immobilization with one of the various splinting techniques is the treatment of choice. Refer to Chapter 181 for the details regarding dental splinting techniques. Root fractures in the primary teeth require extraction.[19]

INDICATIONS

Fractured teeth may require no treatment or a significant amount of treatment based upon the type of injury as described by the Ellis classification system. Fractured roots must be treated based upon the level of clinical suspicion.

CONTRAINDICATIONS

There are no absolute contraindications to the temporary repair of a fractured tooth or tooth root. Concerns for the ABC's (airway, breathing, and circulation), concomitant major morbidity, and aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth repair.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe, or a 3 mL syringe, with a 2 inch, 25 to 27 gauge needle
- Dental explorer
- Discoid-cleoid carver
- Dental drill or emery board
- Sterile saline
- Sterile 2 × 2 gauze squares
- Sterile cotton rolls
- Applicator or molding sticks; tongue depressor or the wooden end of cotton swabs will substitute
- Calcium hydroxide paste (e.g., Dycal), mixable or premixed (preferred)
- Copalite cavity varnish or clear acrylic nail polish
- Zinc oxide—eugenol paste (e.g., ZOE or IRM)
- Dental dry foil or tin foil
- Frazier tip suction catheter
- Suction source and tubing
- Good overhead lighting or headlight
- Dental floss

PATIENT PREPARATION

Explain the risks, benefits, and aftercare to the patient and/or their representative. Obtain an informed consent for the procedure. Position the patient upright in a multipositional procedure chair in a well-lighted environment. Provide tetanus prophylaxis as required. Provide anesthesia to the patient. Refer to Chapter 176 for the complete details regarding dental anesthesia and analgesia.

Irrigate the oral cavity and dental repair region with warm saline to remove any gross contaminants or clotted blood. Warm gentle irrigation is usually less sensitive to exposed dentin.[15] **A dry and uncontaminated field is mandatory.** This can be achieved via dabbing with sterile cotton pellets or gently blowing with compressed air. Maintain a dry working environment by isolating the traumatized tooth with sterile cotton rolls on either side. Inject a small amount of local anesthetic solution containing epinephrine directly into the pulp if continued bleeding from a large pulpal exposure is problematic.

TECHNIQUES

ELLIS I FRACTURES

Ellis I fractures are clinically minor injuries. The management includes smoothing of any sharp edges with a dental drill or a nail file to prevent injury or irritation to the soft tissues of the oral cavity. **Use care to avoid over-aggressive smoothing and exposure of the dentin (i.e., iatrogenic Ellis II injury).**

ELLIS II FRACTURES

Ellis II fractures are clinically more important than Ellis I fractures. They require coverage of the exposed dentin to prevent infection and reduce sensitivity. Paint small or large dentinal exposures with calcium hydroxide paste covering all of the exposed dentin.[6,15,17] Apply the premixed calcium hydroxide paste in a thin layer with any small, blunt instrument or the wooden handle of a cotton-tipped applicator. If not premixed, apply equal amounts of the calcium hydroxide base and catalyst on a piece of paper. Mix these two components thoroughly with a blunt instrument or wooden stick and then apply it to the tooth. Allow the calcium hydroxide paste to dry. Apply three to four coats of cavity varnish or clear acrylic nail polish over the dry calcium hydroxide paste. Allow adequate drying time between the coats. This will relieve any sensitivity. Alternatively, place a tin foil dressing over the tooth to act as a bandage following placement of the calcium hydroxide paste.[6,15,16] With cautious care, a calcium hydroxide dressing will typically last 2 to 3 days.[18]

ELLIS III FRACTURES

Ellis II fractures are true dental emergencies and should be treated by a Dentist or Oral Surgeon. Treat pulpal exposures, if no specialist is immediately available, by applying a saline-moistened or lidocaine-moistened cotton pledget over the exposed pulp and holding it there until the bleeding stops. This may take 2 to 5 minutes. Apply a thick mixture of calcium hydroxide paste over the exposed pulp and dentin. Apply the calcium hydroxide paste over an adjacent tooth to form a temporary hold. Contour the calcium hydroxide paste so that it does not irritate the surrounding tissue. The majority of these injuries will require root canal therapy. Refer the patient to a Dentist within 24 hours if they are not seen in the Emergency Department.

ASSESSMENT

Reassess the patient for pain and any occlusal discrepancies prior to discharge.

AFTERCARE

Most of these patients will have some degree of sensitivity until definitive treatment by a Dentist. Prescribe appropriate outpatient analgesics. Nonsteroidal anti-inflammatory drugs supplemented with a narcotic analgesic will provide adequate pain control for Ellis II and III fractures. Antibiotics are generally not necessary unless the initial presentation had been significantly delayed, suppuration is present, or a significant delay is expected in obtaining dental follow-up. Instruct the patient to avoid extremely hot or cold substances, to begin a liquid or soft diet until seen by a Dentist, to avoid chewing in the area of the injured tooth, and to avoid topical analgesics (such as oil of cloves) due to the propensity for sterile abscess formation.[2,4,15] Always warn patients about continued sensitivity.

COMPLICATIONS

Complications of dental trauma include pain, cosmetic deformity, loss of tooth viability, and unsuspected or unrecognized injury to adjacent teeth with later complications. A permanent tooth may develop abnormally in a younger child if injured. Infection can form locally and advance to an abscess, osteomyelitis, and/or systemic infectious complications. Ensuring prompt follow-up with a Dentist can abate the majority of these complications. The Emergency Physician should be ever vigilant for cases suspicious for child abuse or neglect.

SUMMARY

Dental fractures are relatively common traumatic injuries. Appropriate clinical assessment and treatment requires an understanding of basic dental anatomy, terminology, and pathophysiology. Management includes addressing patient discomfort, stabilization, and coverage of the exposed vulnerable tooth components. Arrange prompt follow-up with a Dentist for definitive care of any dental injury.

183 Temporomandibular Joint Dislocation Reduction

Marilyn M. Hallock

INTRODUCTION

Mandible or temporomandibular joint (TMJ) dislocations usually occur in the setting of prior musculoskeletal problems of the jaw.[1–3] This includes joint laxity, prior injury or dislocation, inherent hypermobile syndromes (e.g., Marfan, Ehlers-Danlos), or neuromuscular problems (e.g., dystonic reactions) that pull the mandible out of its joint. The mandibular dislocation typically results from TMJ hyperextension or trauma. The Emergency Physician must be able to reduce a TMJ dislocation. The procedure is easy, simple, and straightforward.

ANATOMY AND PATHOPHYSIOLOGY

The TMJ is an unusual joint (**Figure 183-1**). It is composed of two joints separated by an articular disk. The TMJ functions as a hinge and gliding joint. A discussion of the mechanics of the TMJ is beyond the scope of this chapter. Anterior dislocations are most commonly seen in the Emergency Department. The etiology of the dislocation includes laughing, chewing, opening the mouth wide (e.g., eating, for procedures, yawning, vomiting), seizures, and trauma. All of these actions can result in the mandibular condyle sliding forward and anterior to the articular eminence of the temporal bone. Anatomic abnormalities of the TMJ have a greater predisposition for mandibular dislocation. These include a shallow articular eminence, weak or torn temporomandibular ligaments, an overstretched joint capsule, previous TMJ dislocations, or hypermobile syndromes (e.g., Marfan's or Ehlers-Danlos syndrome).[4] The muscular attachments of the mandible result in a pulling of the condyle superiorly and in front of the articular eminence (**Figure 183-2**). This causes the mandible to become fixed in dislocation and rarely spontaneously reduce.[5]

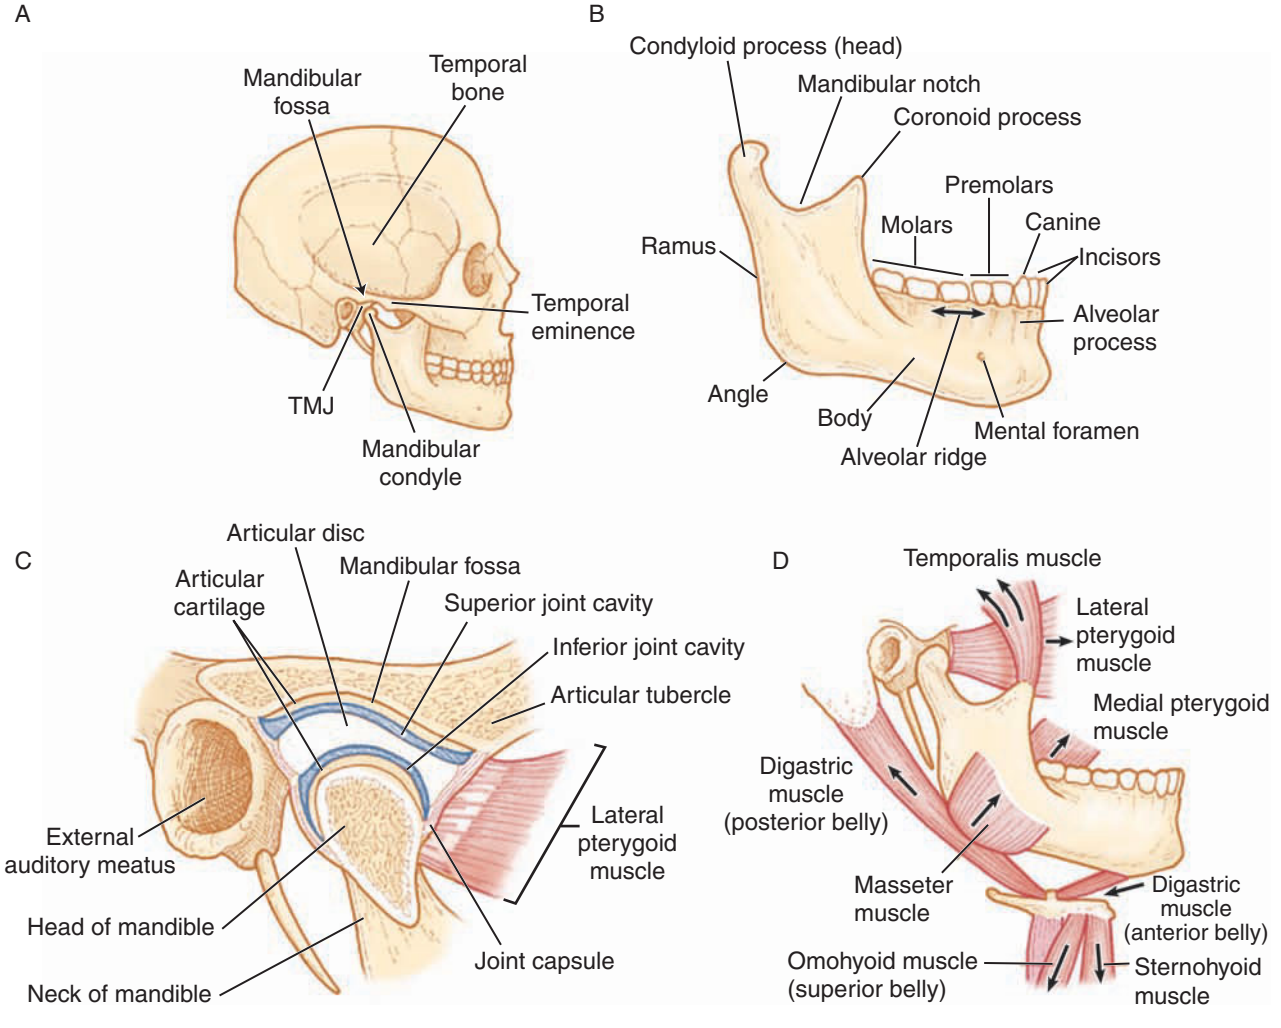

FIGURE 183-1. Anatomy. **A.** Lateral view of the head and temporomandibular joint. **B.** Anatomy of the mandible. **C.** Sagittal section through the temporomandibular joint. **D.** The attachment of the muscles of mastication to the mandible. The arrows represent the direction of pull of the muscles.

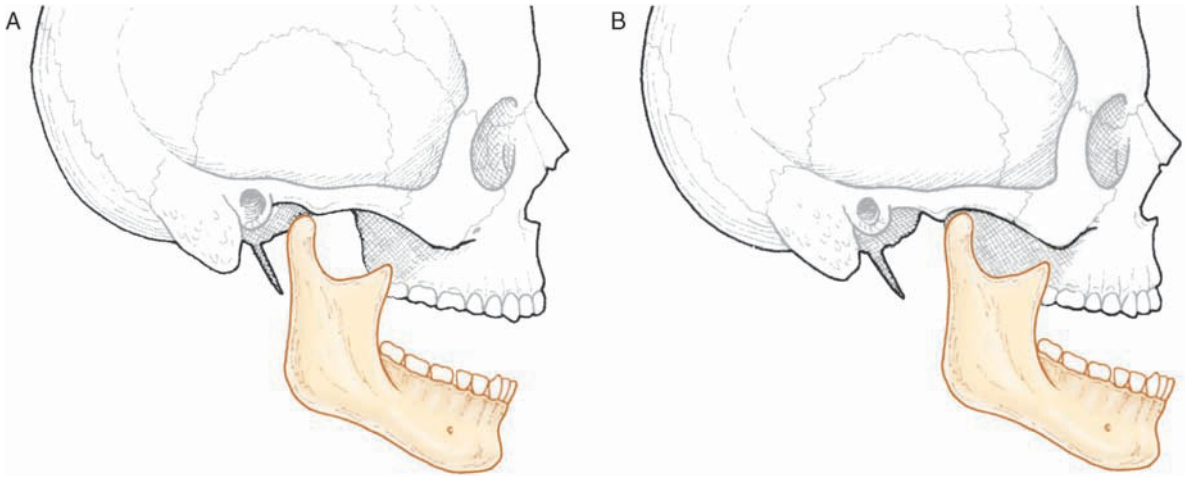

FIGURE 183-2. Anatomic relationships of the mandible. **A.** The fully opened mandible. **B.** An anterior TMJ dislocation.

TMJ dislocations are commonly anterior, but may be in any direction. Anterior TMJ dislocations may occur spontaneously in normal individuals and can occasionally reduce spontaneously. Dislocations of the TMJ are usually bilateral, but can occur unilaterally. Posterior, superior, and lateral dislocations are much more rare. They are seen in the context of direct trauma to the mandible, with or without an associated mandible fracture, cervical spine fracture, or a skull fracture.[6,7]

The diagnosis can often be made clinically in a cooperative patient with a nontraumatic history. The patient will present in pain with an open mouth, protruding mandible, and malocclusion. A unilateral dislocation will cause the mandible to protrude toward the nondislocated side. A depression, both palpable and visible, will be noted in the preauricular area. The mandible appears symmetrical in bilateral anterior dislocations and deviated to the opposite side of the dislocation in the case of a unilateral anterior dislocation.

Mandibular radiographs are indicated when trauma is involved to rule out an associated fracture. The dislocation is often best seen on the Panorex view of the mandible. TMJ views, if available, are also useful. Computed tomography (CT) scanning is warranted if an associated basilar skull fracture, intracranial injuries, or facial fractures are suspected.

INDICATIONS

Attempt to reduce a closed anterior TMJ dislocation without a concomitant mandible fracture in an alert, cooperative, and consenting patient.

CONTRAINDICATIONS

Mandibular dislocations that are open, superior in direction, lateral in direction, or posterior in direction require an Oral Surgeon or Otolaryngology consultation prior to reduction attempts. Dislocations, regardless of the direction, associated with mandible fractures require consultation prior to reduction attempts. The inability to reduce an anterior mandible dislocation by the closed method requires consultation and reduction under general anesthesia. Patients presenting with cranial nerve injuries associated with the dislocation require emergent consultation prior to the reduction.

EQUIPMENT

- 25 gauge needle
- 3 mL syringe
- Gauze 4 × 4 squares or rolls
- Gloves
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- Equipment and supplies for procedural sedation

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient sitting in a multipositional procedure chair with a solid headrest to support their head. Alternatives include placing the patient supine on a gurney or in a chair with an assistant standing behind the patient to stabilize their head (**Figure 183-3**).

The mandible can often be reduced without anesthesia. This is not recommended. **Adequate analgesia and muscle relaxation will allow easier manipulation of the mandible back into its anatomic position.** Strongly consider the use of parenteral

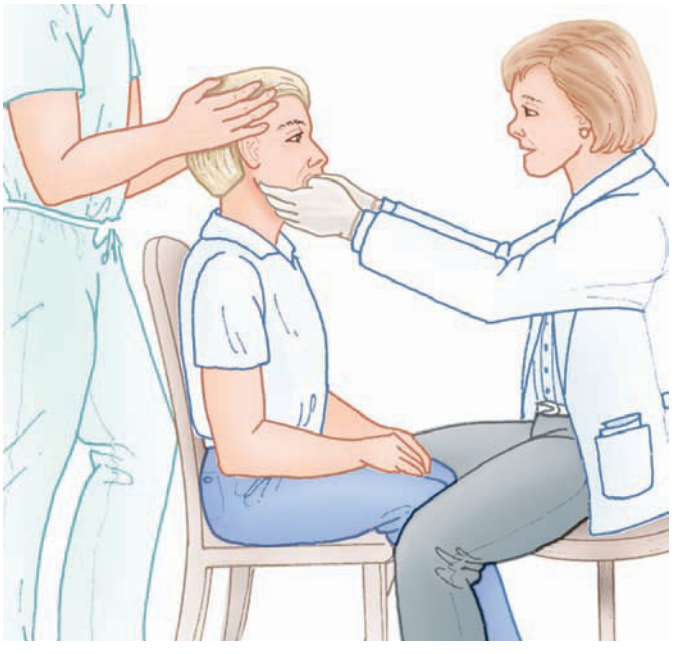

FIGURE 183-3. Alternative positioning of the patient.

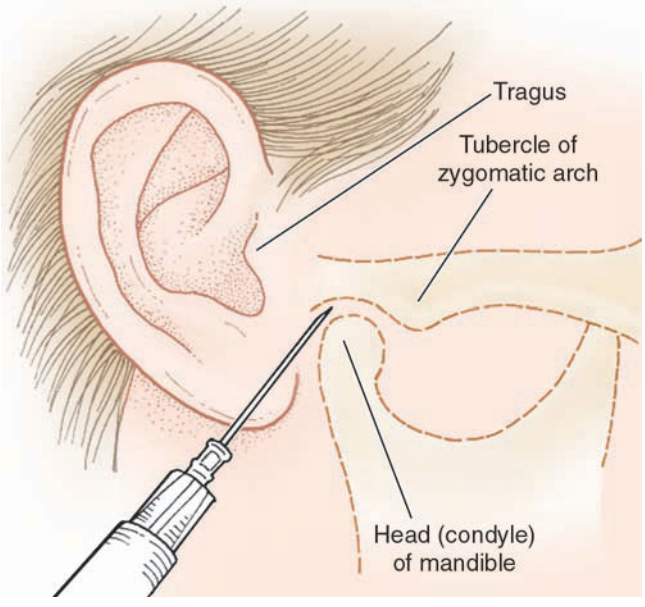

FIGURE 183-4. Anesthesia of the temporomandibular joint. Insert the needle 2.5 cm anterior to the tragus of the auricle and just above the mandibular condyle.

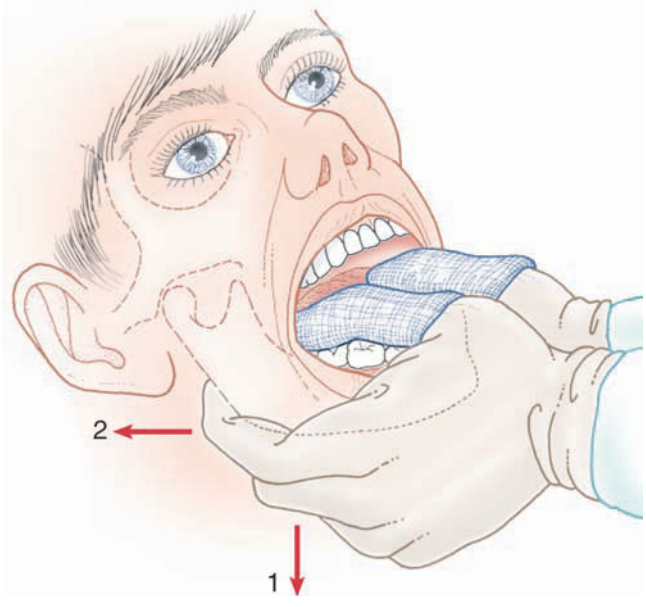

FIGURE 183-5. Proper thumb and hand placement for the reduction of an anteriorly dislocated mandible. Apply downward pressure with the thumbs (1) followed by posteriorly directed pressure (2) to reduce the dislocation.

analgesics, sedatives, and/or muscle relaxants. Procedural analgesia and sedation may be required to overcome the patient's pain and masticatory muscle spasm. This is especially true to relax the muscles of mastication and allow reduction if the mandible has been dislocated for more than 6 to 8 hours. Refer to Chapter 129 for the complete details regarding procedural analgesia and sedation.

An alternative, or adjunct, to the administration of parenteral medications is to inject local anesthetic solution into the TMJ space (**Figure 183-4**). This injection is simple, quick, and relieves significant discomfort. Locate the depression 2.5 cm anterior to the tragus of the pinna and just above the head (condyle) of the mandible. This is the location of the TMJ space. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin over the TMJ space and allow it to dry. Insert a 25 gauge needle perpendicular to the skin and directed medially. Advance the needle 0.5 cm and into the TMJ space. Inject 1 mL of local anesthetic solution without epinephrine. Inject the contralateral TMJ space if the dislocation is bilateral. Consider injecting the contralateral TMJ space in a unilateral TMJ dislocation. The patient may experience pain in their contralateral TMJ from muscle spasm due to the increased pressure on it from the dislocation.

TECHNIQUE

The actual reduction requires no specialized equipment beyond nonsterile gloves and gauze 4 × 4 squares. Position the patient as mentioned previously. Apply gloves and then wrap several layers of gauze around each thumb. **The gauze squares on the thumbs are to prevent possible lacerations to the Emergency Physicians' thumbs when the mandible reduces.**

This technique is the most commonly used method to reduce an anterior TMJ dislocation. Stand or sit in front of the patient (**Figure 183-3**). Place both thumbs into the patient's mouth and onto the most posterior molars of the mandible bilaterally (**Figure 183-5**). Alternatively, the thumbs can be placed on the mandibular ridge immediately posterior to the molars. Wrap the index, middle, ring, and little fingers below the mandible, with the index fingers behind the angles of the mandible (**Figure 183-5**). Slowly apply downward and backward pressure to allow the muscles of mastication to stretch and overcome the muscle spasm (**Figure 183-5**). The downward pressure releases the mandibular condyle from the articular eminence of the temporal bone. Instruct the patient to further open their jaw to accentuate the deformity. This may disengage the impacted mandibular condyle from the anterior articular eminence of the TMJ. The masseter muscle will cause a rapid and sudden closing of the patient's jaw when the condyle of the mandible snaps back and over the articular eminence.[8]

ALTERNATIVE TECHNIQUES

Numerous alternative techniques have been developed to reduce a TMJ dislocation. One technique is to place the thumbs on the buccal aspect of the molars. This avoids the potential injury to the thumbs when the mandible relocates. This method limits the force placed upon the mandible and may not result in a reduction. Another technique requires the physician to stand behind the patient and place downward and backward pressure on the lower molars (**Figure 183-6**). Inducing a gag reflex with a tongue depressor to relax the spasming muscles and free the condyle so it snaps back into anatomical position has been used to successfully reduce an anterior TMJ dislocation.[9] Placing both thumbs on the occlusal surface of the molars on the dislocated side may allow additional pressure to reduce the dislocation that is not reduced using the traditional method.[10] A final method to reduce an anterior TMJ dislocation is the wrist pivot method (**Figure 183-7**). Wrap the index and middle fingers of both hands with gauze. Place both thumbs under the patients' chin and the wrapped fingers of both hands on the patients' premolars and molars (**Figure 183-7**). Apply upward pressure with the thumbs while simultaneously applying downward pressure on the mandible with the fingers to unlock the mandible and reduce the dislocation.

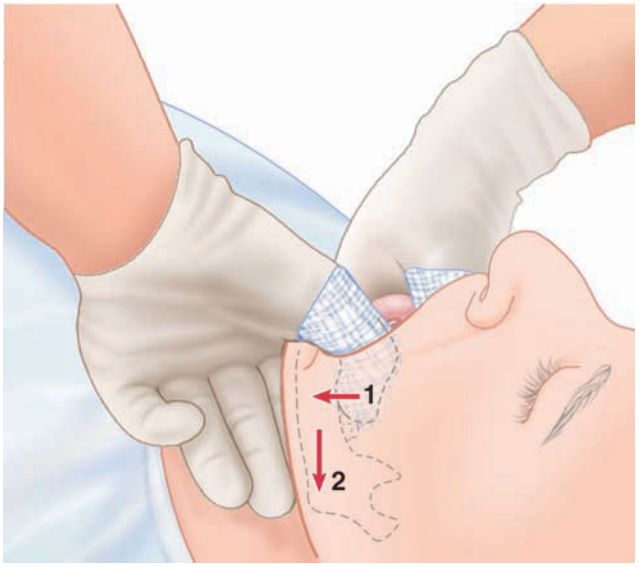

FIGURE 183-6. An alternative method to reduce an anterior TMJ dislocation. The patient is supine. Downward and backward pressure is applied on the molars to reduce the dislocation.

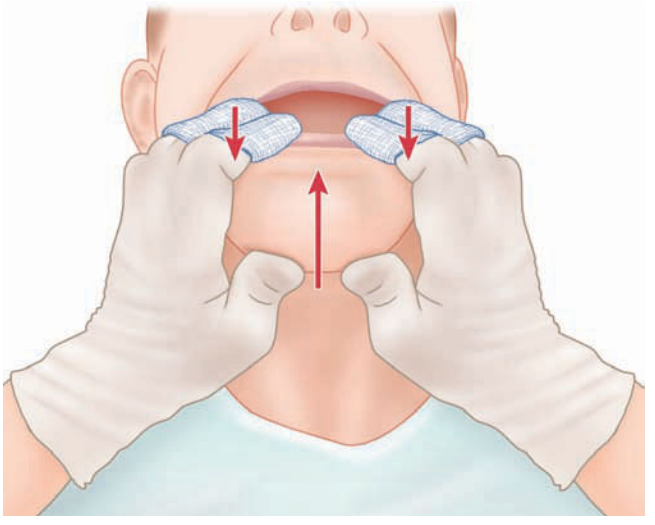

FIGURE 183-7. The wrist pivot method to reduce an anterior TMJ dislocation.

ASSESSMENT

The patient should be able to open and close their mandible without any difficulty after a successful reduction. Postreduction radiographs are not necessary unless a fracture was present or suspected on prereduction radiographs.

AFTERCARE

Refer the patient to an Oral Surgeon or Otolaryngologist within 24 to 48 hours.[11] Chronic or recurrent dislocations may require surgical fixation, intermaxillary wiring, surgical alteration of the articular eminence (e.g., eminectomy or eminoplasty), sclerosing of the TMJ, or the injection of botulinum toxin into the lateral pterygoid muscles.[12] Instruct the patient to avoid excessive jaw opening (over 2 cm), to avoid "gummy" foods and hard foods, and to begin a soft diet to avoid excessive strain on the TMJ. Instruct the patient to support their mandible with their hand when yawning so that it does not open widely and dislocate. Nonsteroidal antiinflammatory drugs will provide adequate analgesia, if needed at all. The application of warm compresses to the TMJ may provide additional pain relief.

A Barton's bandage can be applied around the head to keep the mandibular condyle in its fossa and minimize mandible opening. This bandage is often applied for 2 weeks in patients with chronic dislocations or acute recurrences. Only apply a Barton's bandage in consultation with an Oral Surgeon or Otolaryngologist. Patients often do not like this bandage, are noncompliant, and remove it before follow-up.

COMPLICATIONS

Complications of the initial injury include fractures, intrusion of the mandibular condyle into the external auditory canal (posterior dislocation) or basal skull (superior dislocation), cerebral contusions, facial nerve injuries, and middle or inner ear injuries with hearing and balance impairments. Recurrent dislocations are possible in the future after the mandible has been dislocated once.

The reduction technique is rarely associated with complications. Significant pain after a successful reduction may signify a fracture or articular cartilage avulsion. Fractures are rarely iatrogenic. They are often present on initial radiographs but not identified until retrospectively examined. A fracture may be displaced during the reduction. The Emergency Physician's thumbs can be crushed and/or lacerated by the patient's teeth.

Closed reduction may be unsuccessful. The patient will require reduction under general anesthesia. This is particularly true of chronic dislocations, dislocations for longer than 12 hours, and recurrent dislocations. An avulsed articular cartilage or articular disc may be interposed and prevent closed reduction.

SUMMARY

Uncomplicated anterior mandible dislocations can be managed with basic anesthesia and sedation techniques. A gentle and progressive reduction will allow the mandibular condyle to relocate into the TMJ space without significant complications. Dislocations that are complicated by fractures, overlying skin damage, nonanterior in location, or have associated neurological injuries require an emergent consultation and reduction by an Oral Surgeon or an Otolaryngologist.

184 Ingrown Toenail Management

Jeff Schaider

INTRODUCTION

An ingrown toenail (onychocryptosis) is a common affliction that can occur in any toe. It most commonly afflicts the great toe, occurring when the lateral edge of the nail plate penetrates the soft tissue of the lateral nail fold. There are three stages of ingrown toenails. Stage I includes erythema, slight edema, and pain when pressure is applied to the lateral nail fold. Stage II includes the stage I findings plus signs of infection and a purulent drainage. Stage III is a magnification of the two previous stages with the addition of granulation tissue formation and lateral nail fold hypertrophy. Most ingrown toenails can be definitively managed in the Emergency Department by the Emergency Physician.

ANATOMY AND PATHOPHYSIOLOGY

The toenail usually does not grow into the soft tissue. Instead, the soft tissue overgrows and obliterates the nail sulcus in response to external pressure and irritation.[1–5] The toenail itself is usually normal, although some older patients may have incurved nails. The causes of an ingrown toenail are multiple and include trimming the toenails too short, using sharp tools to clean the toenail gutters, wearing improperly fitted (too tight) shoes, rotated digits, and bony deformities. Improper toenail trimming can result in a small nail spike on the lateral aspect of the toenail (**Figure 184-1**). As the toenail continues to grow, the spike will irritate the soft tissue causing the end result of chronic inflammation and an infection.

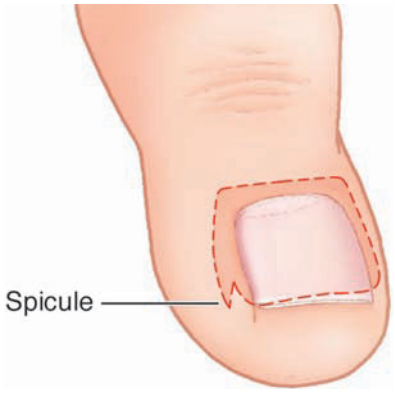

FIGURE 184-1. An ingrown toenail. Note the nail spicule and the overgrowth of the adjacent soft tissues.

INDICATIONS

Warm soaks, oral antistaphylococcal antibiotics, and shoes with an adequate toe box may be curative in mild cases (stages I and II). Elevate and maintain the nail edge above the soft tissues or trim the edge of the nail (**Figure 184-2**). More severe cases (stage III) require partial toenail removal. Have a lower threshold for toenail removal in diabetic patients to prevent a more severe infection from forming. Other indications for removal of an ingrown toenail include chronic or recurring ingrown toenails, failure of conservative therapy, fungal infections of the toenail, and severe pain.

CONTRAINDICATIONS

The only relative contraindication to toenail removal is a decreased vascular supply to the toe. Trim the toenail edge if possible and minimize any injury to the adjacent soft tissues. These patients require an evaluation by a Podiatrist and a Vascular Surgeon to minimize future complications.

EQUIPMENT

General Supplies

- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Sterile gloves
- Curved hemostat
- Freer or another periosteal elevator
- Cotton
- Scissors or nail splitter
- Tourniquet or sterile Penrose drain
- Curette
- Topical antibacterial ointment
- 4 × 4 gauze squares
- Tape, 1 inch wide

Chemical Matrix Ablation

- Above listed general supplies
- Cotton-tipped applicators
- 89% phenol solution
- 70% isopropyl alcohol solution
- Silver nitrate matchsticks

Surgical Matrix Excision

- Above listed general supplies
- #15 scalpel blade on a handle
- Needle driver
- 5-0 nylon suture

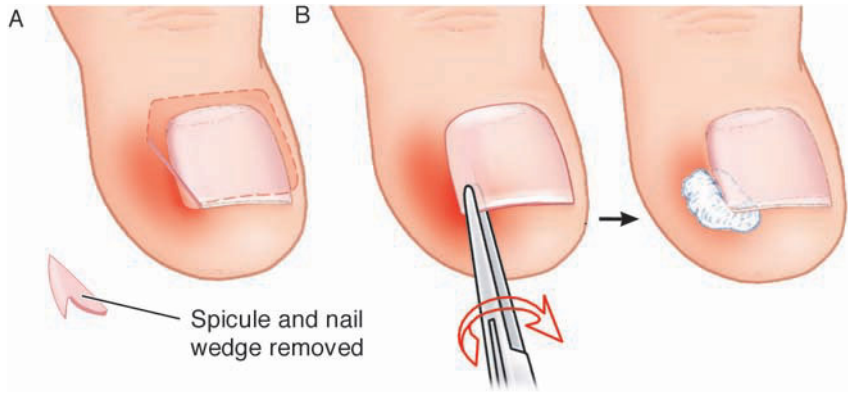

FIGURE 184-2. Management of stage I and II ingrown toenails. **A.** Trimming the lateral nail edge. **B.** Elevation of the lateral nail edge.

Nail Matrix Cauterization

- Above listed general supplies
- Electrocautery unit, disposable

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Obtain an informed consent for the procedure. Place the patient supine on a gurney or procedure table. Flex the patient's hip and knee so that the plantar surface of their foot is flat against the gurney. An overhead light source is essential to provide appropriate illumination. Perform a digit block using aseptic technique. Refer to Chapter 126 regarding the details of digital anesthesia. While rare, an occasional nervous or uncooperative patient may require an intravenous anxiolytic or even procedural sedation prior to the digital anesthesia. The young child will require physical restraint with a sheet or commercial device (e.g., Papoose board) and procedural sedation. Apply povidone iodine or chlorhexidine solution over the involved toe and allow it to dry. Apply a sterile drape to delineate a sterile field.

TECHNIQUES

Manage early ingrown toenails (stages I and II) with conservative therapy. Remove the medial or lateral one-quarter of the toenail along with the germinal matrix at the base of the toenail for stage III ingrown toenails. The entire nail may be removed if both sides are ingrown. It may be necessary to prevent any new nail growth in the area once the nail has been removed. Three options include chemical ablation of the matrix, surgical excision of the matrix, and electrocautery of the nail matrix. The treatment of the pediatric patient is no different than the adult patient.

TOENAIL ELEVATION AND TRIMMING

Ingrown toenails in the first two stages can be trimmed or elevated to relieve the patient's symptoms (**Figure 184-2**). Trim the distal edge of the nail plate to remove the ingrown portion (**Figure 184-2A**). Remove the distal one-third to one-half of the nail plate. Smooth the nail plate edge so that it will grow out freely. Remove any debris along the lateral nail fold (paronychia) or nailbed.

An alternative is to elevate the edge of the nail plate (**Figure 184-2B**). Insert the jaws of a hemostat so that one is above and the other is below the ingrown nail edge. Clamp the jaws of the hemostat onto the nail plate. Slowly rotate the hemostat to elevate the edge of the nail plate above the adjacent soft tissues (**Figure 184-2B**). Insert a wad of cotton under the nail edge to maintain it above the adjacent soft tissues. Release the hemostat. Teach the patient and/or their representative this technique so that they can replace the cotton wad daily until the nail plate grows out and past the soft tissues. The main disadvantages of this technique are that the patient or their representative must elevate the nail edge and replace the cotton daily as well as maintain the nail plate elevation for 3 to 6 weeks. This can be quite a challenge, if it is even possible, in the young child.

TOENAIL REMOVAL

Apply a tourniquet along the base of the afflicted toe (**Figure 184-3A**). The tourniquet may be a commercially available product for the digits or a Penrose drain. Refer to Chapter 104 for several examples of digital tourniquets. Separate the nail from the underlying nail bed. Grasp and stabilize the toe with the nondominant hand. If available, use a Freer periosteal elevator to lift the soft tissue off the lateral and proximal toenail. The elevator can also be used to separate the nail plate from the underlying nail bed, but this is optional. Insert one jaw of a curved hemostat under the distal toenail margin and along the medial or lateral side of the nail plate, depending upon which side is ingrown (**Figure 184-3B**). Advance the hemostat until the jaw is at the proximal corner of the involved side of the ingrown nail (**Figure 184-3C**). Grasp the nail by clamping the jaws of the curved hemostat on the toenail.

Dislodge the ingrown nail from the skin, the nail bed, and the nail matrix by rotating the hemostat away from the ingrown portion (**Figure 184-3D**). Continue to rotate the hemostat until the entire ingrown portion of the nail is separated from the skin, the nail bed, and the nail matrix. A large and complete portion of the underlying toenail will emerge from under the skin fold (**Figure 184-3E**). The nail plate might have broken and a significant piece may still be under the inflamed skin border if only a small amount of the nail is visible after rotating the hemostat. Expose this area and use the curved hemostat to remove any remaining nail plate.

Cut away the ingrown portion of the toenail, from distal to proximal, with a heavy scissors or nail splitter (**Figure 184-3F**). **Make sure that the points of the scissors or nail splitter are facing upward to prevent injury to the nail bed.** The granulation tissue overlying the nail bed must be removed to prevent another ingrown toenail (**Figure 184-3G**). Trim the granulation tissue using a #15 scalpel blade or a curette (**Figure 184-3H**). Remove the tourniquet and control any bleeding.

Some Emergency Physicians prefer to perform the above-described procedural steps in a slightly different order. Apply a tourniquet along the base of the afflicted toe. Grasp and stabilize the toe with the nondominant hand. If available, use a Freer periosteal elevator to lift the soft tissue off the lateral and proximal

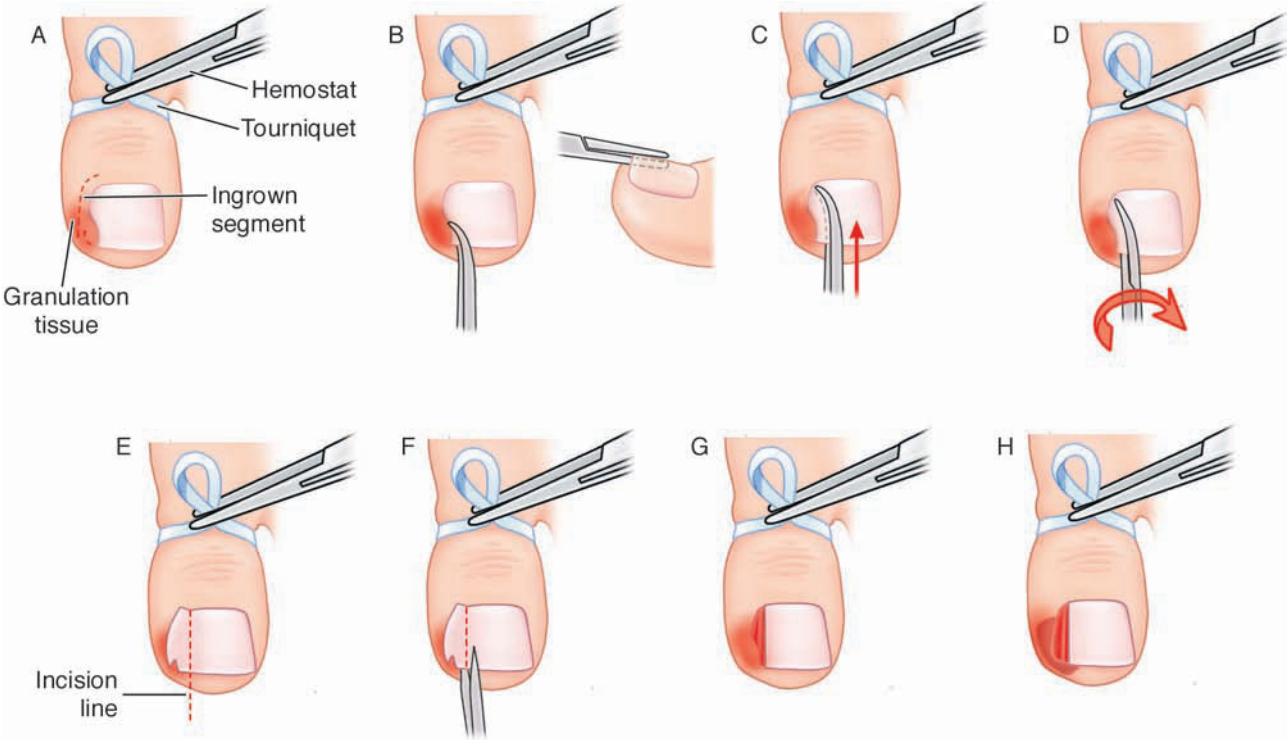

FIGURE 184-3. Ingrown toenail removal. **A.** Placement of a tourniquet. **B.** Place one jaw of the hemostat above the nail plate and one jaw beneath the nail plate. **C.** Advance the hemostat toward the base of the nail plate. **D.** Rotate the hemostat to elevate the edge of the toenail. Be sure to elevate and expose the proximal nail segment at the base of the nail in the region of the nail matrix. **E.** Determine where to cut the nail plate. **F.** Cut the nail plate with a heavy scissors or a nail splitter. **G.** The lateral one-fourth of the nail plate has been removed. **H.** The granulation tissue has been trimmed away.

toenail. The elevator can also be used to separate the nail plate from the underlying nail bed, but this is optional. Cut away the ingrown portion of the toenail, from distal to proximal, with a heavy scissors or nail splitter. **Make sure that the points of the scissors or nail splitter are facing upward to prevent injury to the nail bed.** Insert one jaw of a curved hemostat under the distal toenail margin and along the medial or lateral side of the nail plate, depending upon which side is ingrown. Advance the hemostat until the jaw is at the proximal corner of the involved side of the ingrown nail. Grasp the nail by clamping the jaws of the curved hemostat on the toenail. Dislodge the ingrown nail from the skin, the nail bed, and the nail matrix by rotating the hemostat away from the ingrown portion. Continue to rotate the hemostat until the entire ingrown portion of the nail is separated from the skin, the nail bed, and the nail matrix. A large and complete portion of the underlying toenail will emerge from under the skin fold. The nail plate might have broken and a significant piece may still be under the inflamed skin border if only a small amount of the nail is visible after rotating the hemostat. Expose this area and use the curved hemostat to remove any remaining nail plate. Remove the granulation tissue overlying the nail bed to prevent another ingrown toenail using a #15 scalpel blade or a curette. Remove the tourniquet and control any bleeding.

CHEMICAL NAIL MATRIX ABLATION

Chemical ablation of the nail matrix with phenol has several advantages.[6,7] The procedure is easy, quick, and simple to perform. No special equipment is required. The use of an incision or electrocautery, and their associated complications, is avoided.

Chemical ablation of the matrix with phenol is the author's preferred method. Remove any obvious remaining nail matrix and nail bed with a blunt instrument such as a curette. **Completely dry the field of any blood and fluid.** Dip a cotton-tipped applicator in a phenol solution. **Avoid excessive saturation of the swab.** Introduce the swab between the roof and the root matrix (i.e., under the eponychium) of the removed nail section (**Figure 184-4**). Rotate the cotton-tipped applicator slowly for 30 seconds (20 seconds for children) and then remove it. Repeat the phenol application two additional times using a fresh phenol-soaked cotton-tipped applicator.

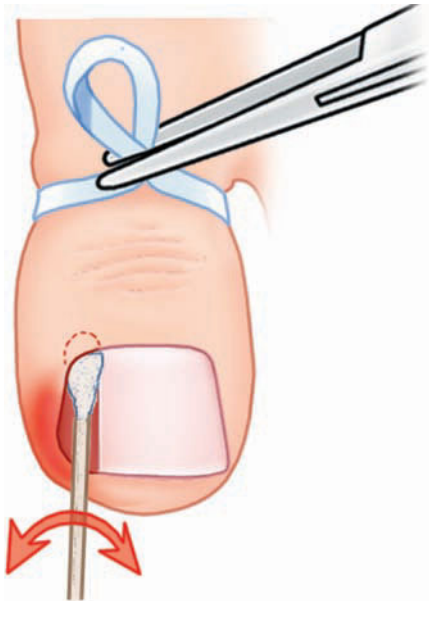

FIGURE 184-4. Chemical nail matrix ablation.

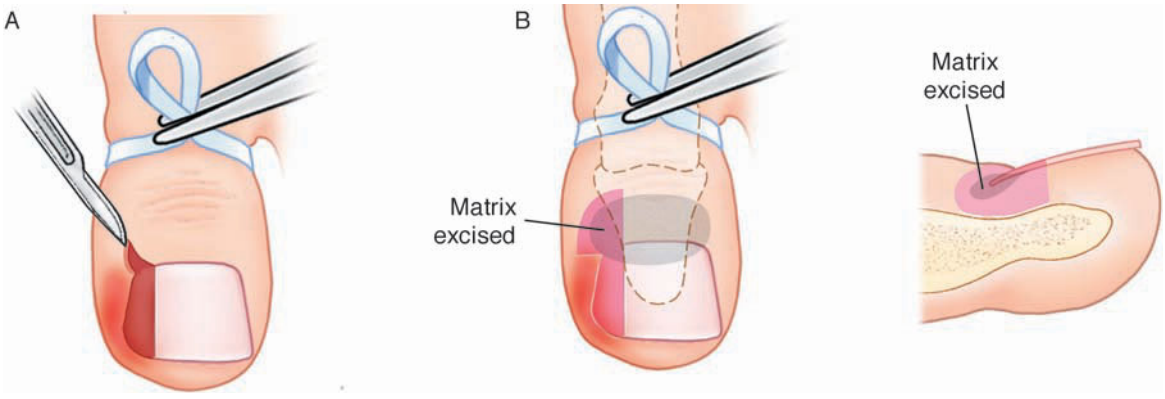

FIGURE 184-5. Surgical nail matrix ablation. **A.** An incision in the eponychium to expose the matrix. **B.** Removal of the matrix. The pink shading represents the areas of tissue to be removed.

Do not allow the phenol to contact normal skin. Immediately wipe off any phenol that contacts the skin. The phenol will turn the tissue pale or gray. Dip a cotton-tipped applicator in isopropyl alcohol. Swab the area in similar fashion as the phenol swab. The isopropyl alcohol neutralizes the necrotizing effect of the phenol.[6–8]

An alternative to phenol is silver nitrate. The preferred technique is a phenol matrixectomy. Silver nitrate may be used if phenol is not available. The main disadvantage of silver nitrate is that it turns the tissues black. Insert the silver nitrate matchstick under the eponychium (**Figure 184-4**). Roll the matchstick around for 5 to 10 seconds to ablate the matrix.

SURGICAL NAIL MATRIX ABLATION

Surgical excision of the toenail matrix requires more time and experience than chemical ablation.[4] This technique is usually reserved for the Podiatrist or the Orthopedic Surgeon. An experienced Emergency Physician can easily perform this technique in the Emergency Department. Expose the nail matrix by retracting the adjacent overlying skin. Make an oblique proximal incision from the proximal corner of the nail if necessary to fully expose the nail matrix in the ingrown area (**Figure 184-5A**). Make an incision with a #15 scalpel blade to separate the nail matrix to be removed from the remaining nail and matrix (**Figure 184-5B**). Grasp the corner of the matrix with a hemostat. Use the scalpel blade to separate the matrix from the underlying tissues. Remove the nail matrix. Do not forget to remove the dorsal and deep matrix that envelops the base of the toenail under the skin fold. Remove any remaining nail matrix and nail bed with a curette. Close the skin incision with 5-0 nylon suture.

ELECTROCAUTERY NAIL MATRIX ABLATION

Electrocauterization of the nail matrix is rapidly performed but requires access to an electrocautery instrument. Apply electrocautery between the roof and the root matrix of the removed nail section to destroy the matrix in this area. Avoid excessive burning of the surrounding tissues. This technique can cause significant damage to normal tissue and should be reserved for the Podiatrist or the Orthopedic Surgeon.

AFTERCARE

Apply a topical antibiotic ointment and a small compressive gauze dressing over the toe. The patient requires follow-up in 24 to 48 hours for a dressing change and evaluation of the wound. Saturate the dressing with saline or sterile water to make the removal process less painful. Instruct the patient to elevate the foot for the first 2 to 3 days to prevent bleeding and edema. Large shoes, sandals, or cast shoes are best used in the immediate postprocedure days. The use of oral antibiotics is restricted for patients who are immunocompromised, have an associated cellulitis, or whose vascular supply to the toe is decreased. Prescribe nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics as needed for pain control. Instruct the patient to return to the Emergency Department immediately if they experience increased pain, develop a fever, a purulent discharge, or notice increased redness of the toe or foot. Demonstrate the proper method to trim toenails (**Figure 184-6**).

Chemical ablation of the matrix with phenol induces a chemical burn. The patient may experience a serous drainage for a few days up to 2 weeks.[1] The use of nonsteroidal anti-inflammatory drugs can limit the duration and the amount of drainage.[1] Instruct the patient to soak the foot in warm water three times a day for 10 to 15 minutes each time. Apply a topical antibiotic ointment after each soak. Prolonged drainage may be due to a superficial infection and requires evaluation.

COMPLICATIONS

The most common complication is the persistence of toenail horns or spikes due to incomplete ablation of the nail and matrix. These can be managed with nail trimming if mild or en bloc excision of the area if severe. Ensure that the portion of the nail is completely removed and that no fragments remain under the nail folds. Use care to not lacerate the nail bed when elevating or cutting the nail plate. Lacerations of the nail bed can bleed significantly, cause chronic pain once healed, and result in a deformed

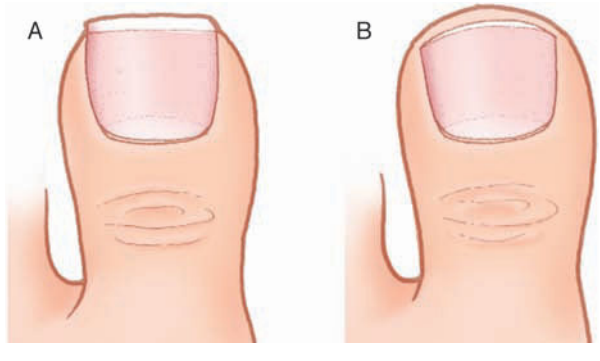

FIGURE 184-6. The technique of toenail trimming. **A.** Correct. **B.** Incorrect.

nail. Repair any nail bed lacerations. Refer to Chapter 104 for a complete discussion regarding nail bed repair.

Phenol will deteriorate if it is exposed to air or light. Store the phenol solution in a cool, dark place. Replace the solution frequently. The field must be dry before applying phenol. Phenol mixed with blood results in an alteration of the pH of the phenol, decreasing its effectiveness, and turning the tissues black. The ingrown toenail will recur if the phenol is old or exposed to light before it is used, if the phenol is not properly applied, or if fragments of the toenail or matrix remain. The patient may experience a chemical burn if too much phenol is applied or it is not neutralized with isopropyl alcohol.

SUMMARY

An ingrown toenail can be managed easily, quickly, and definitively in the Emergency Department. Perform a partial toenail removal on patients with clinical stage III toenails characterized by pain, overgrowth of inflamed and infected tissue, and drainage. Remove the lateral or medial one-quarter of the nail. Apply phenol solution to the nail matrix to prevent further growth of the nail and a recurrence.

185 Toe Fracture Management

George Chiampas and Steve Zahn

INTRODUCTION

Toe fractures result from a direct blow (from an object falling on an unprotected toe) or a "stubbing" injury.[1] The incidence of toe fractures has been estimated at 140 cases per 100,000 people per year.[2] The significance of toe fractures depends upon which digit is affected. Most important is the great toe, as it is the main propulsive segment of the forefoot. Many patients do not present to the Emergency Department as they consider the injury trivial. Those who do present often do so because of severe pain and/or a large subungual hematoma.

Toe fractures are common injuries that rarely require surgical treatment. They may be completely and definitively managed in the Emergency Department. Most toe fractures require only a properly placed splint. An intraarticular fracture with severe displacement of the great toe may require open reduction and internal fixation to prevent deformity and arthritis in the joint. Complications of a toe fracture include damage to the articular cartilage, hypermobility of fracture segments, malposition, and malunion.

ANATOMY AND PATHOPHYSIOLOGY

The foot can be anatomically divided into the forefoot, the midfoot, and the hindfoot (**Figure 185-1**). The forefoot is composed of the metatarsals and their respective phalanges. Sesamoid bones often lie along the plantar surface of the metatarsal heads. The sesamoid bones of the great toe lie in a groove on the plantar surface of the metatarsal head and within the tendon of its respective flexor hallucis brevis muscle belly.

Each toe has two pairs of digital nerves that course along the superior and inferior aspects of the digit. The digital artery and vein accompany the nerve. The great toe often receives superficial cutaneous nerves along its dorsal surface.

Anteroposterior and oblique radiographic views will demonstrate most fractures. Lateral views may be necessary to identify phalangeal fractures of the great toe. Obtain the lateral projection with toes 2 through 5 passively dorsiflexed to avoid overlap. An alternative method to achieve adequate radiographic views of the great toe in the lateral projection is to insert dental X-ray film between the first and second toes and direct the X-ray beam laterally.[3]

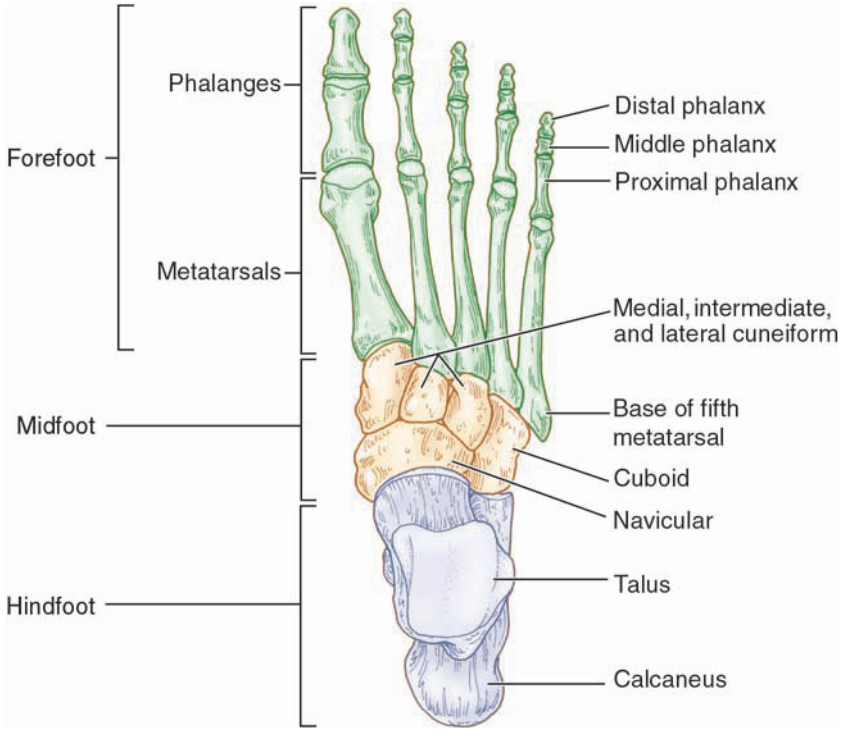

FIGURE 185-1. The bony anatomy of the foot.

INDICATIONS

The indications for simple splinting of toe fractures are to relieve pain and allow for healing. The management of closed fractures depends upon the digit involved. Manage nondisplaced phalangeal fractures of the great toe with buddy taping to the adjacent normal toe as a splint. Mildly displaced phalangeal fractures of the great toe can be reduced using local anesthesia, gentle traction, and buddy taping. Manage nondisplaced phalangeal fractures of toes 2 through 5 with buddy taping. Mildly displaced phalangeal fractures of toes 2 through 5 can be reduced using local anesthesia, gentle traction, and buddy taping. Exact anatomic reduction of toes 2 through 5 is not a concern as long as the general alignment of the toe is satisfactory.[4]

CONTRAINDICATIONS

Consult an Orthopedic Surgeon or Podiatrist for open fractures, extensive crush injuries to the forefoot, injuries with the potential to develop a compartment syndrome, intraarticular fractures, or severely displaced toe fractures (especially of the great toe). The incidence of arthritis and malunion is quite high with these injuries. Fractures of multiple toes on one foot cannot be treated with buddy taping.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 25 or 27 gauge needle
- 5 mL syringe
- 2 × 2 gauze squares or a soft corn pad
- Finger trap, optional
- Bunion pad
- Metatarsal bar or wooden tongue depressors
- Permeable tape, ½ inch wide
- Fluoroscopy unit, optional

The use of a fluoroscopy unit, if available, will make the reduction technique much easier and quicker. It allows for the immediate evaluation of the reduction, multiple reduction attempts without the waiting time to obtain plain radiographs after each reduction attempt, and the reduction to be completed and splinted before the anesthesia wears off.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Obtain a signed informed consent for the procedure. Obtain plain radiographs or a fluoroscopic image to assess the severity of the injury. Place the patient sitting upright so that the affected foot is suspended above the floor in order to allow adequate space for manipulation and splinting of the toe. An alternative is to place the patient supine with their hip and knee flexed, so that the sole of the foot is flat against the gurney. If a subungual hematoma is present, it should be drained to relieve the pressure on the nail bed and improve patient comfort. Refer to Chapter 102 for the complete details regarding the management of a subungual hematoma.

The use of anesthesia is Emergency Physician and patient dependent. Buddy taping of nondisplaced fractures of toes 1 through 5 or minimally displaced fractures of toes 2 through 5 requires no anesthesia. Consider performing a digital block if the patient is significantly tender and a displaced fracture must be reduced. Clean the web spaces of the affected toe of any dirt or debris. Apply povidone iodine or chlorhexidine solution to the web space and surrounding skin. Allow the solution to dry. Arm a 5 mL syringe containing local anesthetic solution (e.g., lidocaine or bupivacaine) without epinephrine with a 25 or 27 gauge needle.

Insert the needle into the dorsal surface of the web space. Aim the needle 45° downward and toward the posterior aspect of the phalanx (**Figure 185-2A**). Advance the needle while injecting 1 to 2 mL of local anesthetic solution. **Do not puncture the plantar surface of the toe.** The local anesthetic solution will easily inject into the areolar tissue of the web space. Withdraw the needle. Shift the needle so that it is aimed along the dorsal surface of the toe (**Figure 185-2B**). Advance the needle while injecting 1 to 2 mL

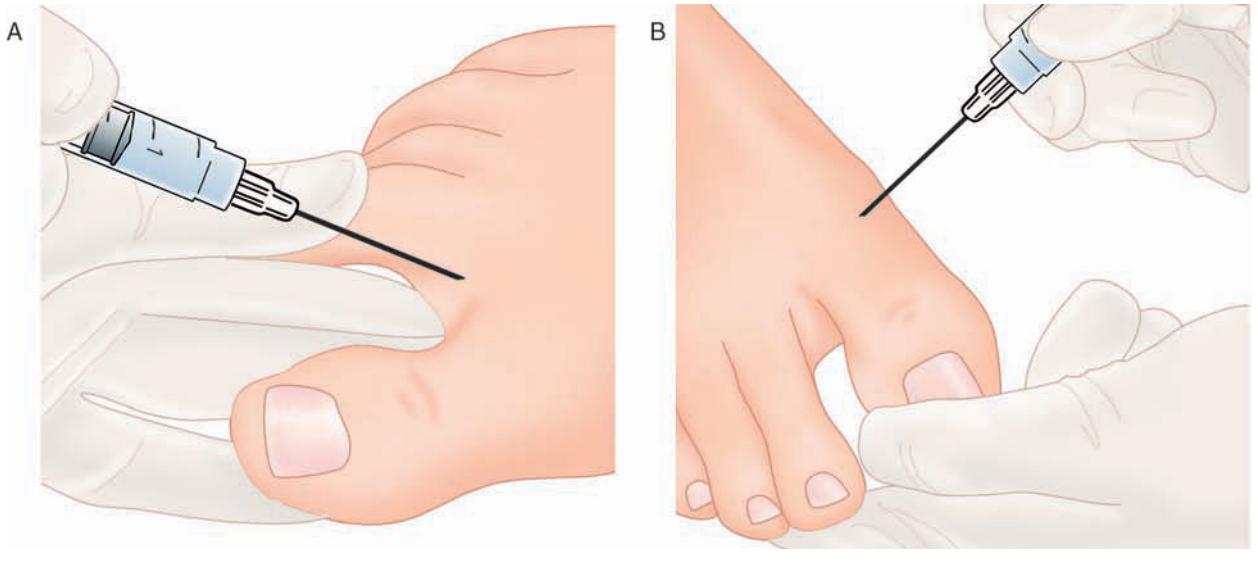

FIGURE 185-2. Digital block of the toe. **A.** Needle position and direction for infiltration of the lateral surface. **B.** Needle position and direction for infiltration of the dorsal surface.

of local anesthetic solution over the dorsal surface. Completely withdraw the needle. Inject local anesthetic solution into the contralateral side of the affected toe in the same way as in the first web space. Allow 5 to 10 minutes for the block to take effect. Reassess the patient to determine whether the block was successful. An additional injection along the plantar surface of the toe may be required to provide total anesthesia, especially of the great toe. Refer to Chapter 126 for additional details regarding digital anesthesia.

An alternative is to perform a hematoma block by injecting local anesthetic solution directly into the fracture site. Clean and prepare the skin. Insert the needle over the fracture site. Advance the needle until it enters the fracture. Aspirate a small amount of blood to confirm that the tip of the needle is properly positioned within the fracture. Inject 2 to 3 mL of local anesthetic solution into the hematoma. Allow 5 to 10 minutes for the local anesthetic to take effect before proceeding. Refer to Chapter 125 for a more complete discussion of a hematoma block.

TECHNIQUES

FRACTURE REDUCTION

Closed reduction can be achieved with the use of a finger trap or straightforward axial traction. Place the anesthetized affected toe in the finger trap (**Figure 185-3**). Elevate and suspend the foot by the affected toe in the finger trap (**Figure 185-3**). Allow the weight of the leg to slowly distract the fracture site. Reduce the fracture (**Figure 185-4**). Grasp the forefoot near the base of the affected toe or fractured phalanx with the nondominant index finger and thumb. Grasp the distal aspect of the fractured phalanx with the dominant index finger and thumb. Apply distally directed inline traction with the dominant hand and simultaneous countertraction with the nondominant hand to distract the fracture site. Remove the toe from the finger trap. Obtain a radiograph or fluoroscopic image to confirm the reduction. Buddy tape the toe to the adjacent toe as described below.

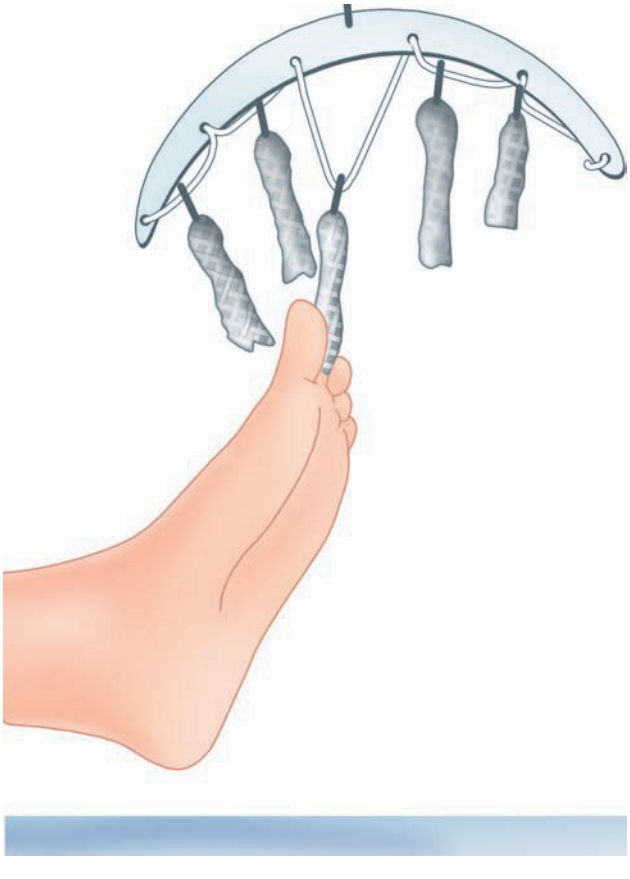

FIGURE 185-3. Use of the finger trap to aid fracture reduction.

FIGURE 185-4. Manual fracture reduction.

The alternative is to reduce the fracture manually without the use of a finger trap (**Figure 185-4**). Grasp the forefoot near the base of the affected toe or fractured phalanx with the nondominant index finger and thumb. Grasp the distal aspect of the fractured phalanx with the dominant index finger and thumb. Apply distally directed inline traction with the dominant hand and simultaneous countertraction with the nondominant hand to distract the fracture site. Reduce the fracture. Obtain a radiograph or fluoroscopic image to confirm the reduction. Buddy tape the toe to the adjacent toe as described below.

BUDDY TAPING

Buddy tape the toe after the reduction (**Figure 185-5**). Place a piece of folded 2 × 2 gauze or a corn pad between the fractured toe and its neighboring toe (**Figure 185-5A**). The gauze or corn pad will prevent maceration and pressure necrosis of the skin. Tape the toes together (**Figure 185-5B**).

ASSESSMENT

Reassess the toe's perfusion by checking the capillary refill time after any attempt at reduction. Obtain a postreduction radiograph or fluoroscopic image to verify proper alignment. Mild to moderate displacement in phalangeal fractures of toes 2 through 5 is quite acceptable as long as the toes are not rubbing together. Repeat the reduction process as necessary to reduce the fracture. Consult an Orthopedic Surgeon or Podiatrist if the fracture cannot be adequately reduced.

AFTERCARE

All toe fractures are persistently painful. They require analgesia and splinting for 2 to 3 weeks. Prescribing nonsteroidal anti-inflammatory drugs (NSAIDs) supplemented with narcotic analgesics has been the standard of care. New research may shift future management from the use of NSAIDs as these medications can delay fracture healing.[5] The patient can apply ice packs for 10 to 15 minutes every 3 hours to help decrease pain and swelling.

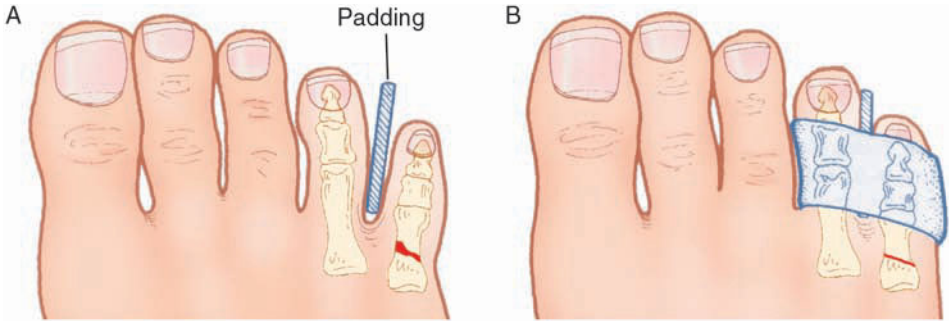

FIGURE 185-5. Buddy taping the fractured toe. **A.** Place gauze or a corn pad between the fractured toe and an adjacent toe. **B.** Tape the toes together.

Provide the patient with a hard-soled shoe, wooden-soled shoe, or Reese orthopedic shoe. It is felt that dorsiflexion of the forefoot in walking causes the most pain in toe fractures.[3] The use of these shoes, as opposed to the patient's own shoes, minimizes pain with walking.

An alternative to the orthopedic shoe is to place a metatarsal bar for patient comfort.[6] Use a commercially available unit or make a metatarsal bar by taping wooden tongue depressors together (**Figure 185-6**).[3] Obtain four tongue depressors and cut one in half (**Figure 185-6A**). Place two tongue depressors side by side (**Figure 185-6B**). Place the third tongue depressor to cover the seam of the adjacent tongue depressors (**Figure 185-6B**). Tape the tongue depressors together to form the longitudinal support (**Figure 185-6C**). Apply the cut tongue depressor to form the transverse support (**Figure 185-6D**). Tape the transverse support to the longitudinal support (**Figure 185-6E**). Apply the metatarsal bar to the sole of the patient's shoe (**Figure 185-7**). Additional support and pain control can be achieved by immobilizing the foot in a short leg walking cast with a toe plate for no more than 1 to 2 weeks if the patient complains of persistent pain.[4]

Instruct the patient to continue weight bearing as tolerated and, when not walking, to elevate the foot above the level of their heart to minimize swelling. Teach the patient how to re-apply the buddy taping splint, as it must be changed every 2 to 3 days for up to 6 weeks. All patients with great toe fractures should follow-up with an Orthopedic Surgeon or Podiatrist within 48 hours for a reevaluation.

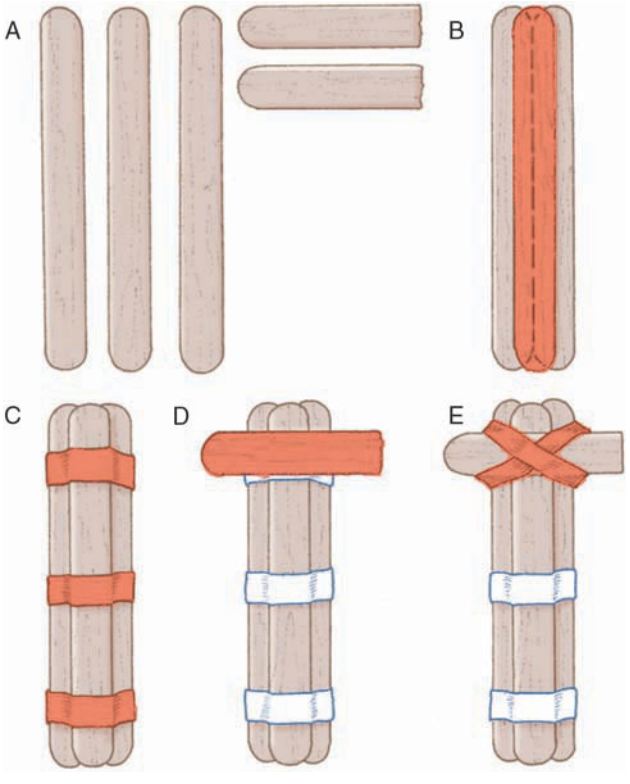

FIGURE 185-6. Fabricating a metatarsal bar from tongue depressors. **A.** Lay out four tongue depressors, one of which is cut in half. **B.** Place two tongue depressors side by side. Place the third tongue depressor to cover the seam between the first two. **C.** Tape the tongue depressors together to form the longitudinal support. **D.** Apply the cut tongue depressor to form the transverse support. **E.** Tape the transverse support to the longitudinal support.

COMPLICATIONS

Long-term sequelae from toe fractures are rare. Persistent angulation at the fracture site with a malunion may result in a "sore area" on the plantar surface of the toe. Refer the patient to an Orthopedic Surgeon or Podiatrist if such areas remain symptomatic and functionally disabling. A simple surgery can correct the problem. Any fractures involving the joint space will result in some degree of arthritis. Warn the patient of this possible complication before they are discharged.

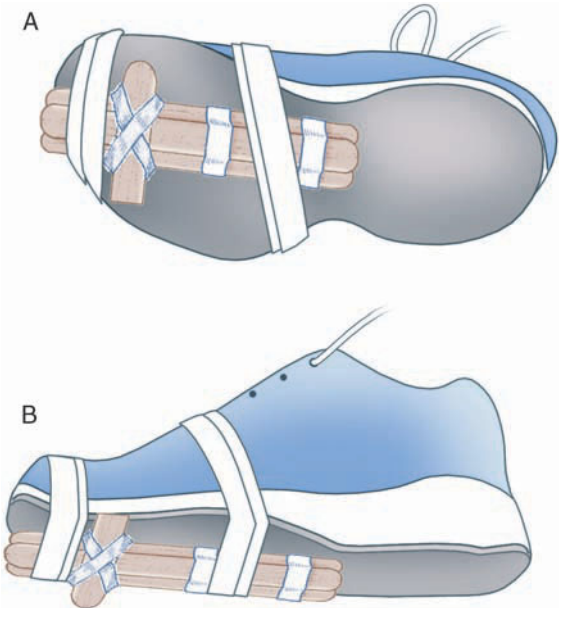

FIGURE 185-7. Application of the metatarsal bar to the patient's shoe. **A.** Inferior view. **B.** Lateral view.

Few complications are associated with the management of toe fractures. Incomplete reduction can result in an angulated toe. Persistent angulation can result in the toe pushing against adjacent toes, skin irritation, and possible skin ulceration. Always place a pad between the toes before buddy taping to prevent irritation, pressure necrosis, ulceration, and maceration of the skin.

SUMMARY

Toe fractures are commonly seen in the Emergency Department. They may cause the patient significant pain and discomfort. Simple conservative management with the use of buddy taping and appropriate footwear helps the fracture heal in 3 to 6 weeks. Open or closed surgical reduction of phalangeal fractures may be required to achieve proper reduction. Intraarticular or severely displaced toe fractures, especially those of the great toe, should be referred to an Orthopedic Surgeon or Podiatrist. Most toe fractures can be satisfactorily and definitively managed by the Emergency Physician with a minimum of complications.

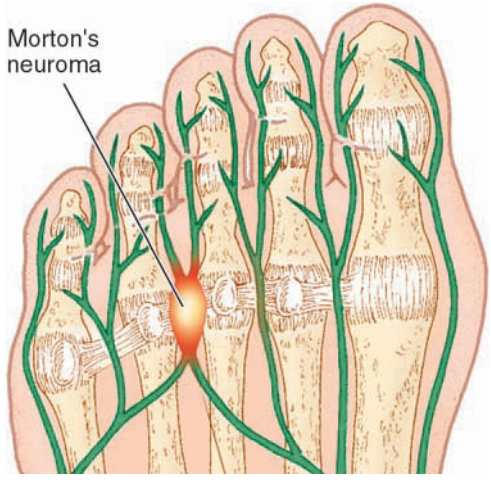

FIGURE 186-1. Morton's neuroma most commonly occurs in the third intermetatarsal space beneath the transverse metacarpal ligament.

186 Neuroma Management

Eric R. Snoey and Stephen Miller

INTRODUCTION

Morton's neuroma, also referred to as an interdigital neuroma, is one of the most common painful disorders of the forefoot. It was first described in 1845 by Dulacher. It is named after Thomas Morton, who presented a case series of patients afflicted with this disorder in 1876. Patients with an established Morton's neuroma are usually cared for by a Podiatrist or an Orthopedist. They may present to the Emergency Department with a previously undiagnosed neuroma or with a painful exacerbation of a previously diagnosed neuroma.

The term neuroma is actually a misnomer. Histologic investigation does not reveal the typical proliferation of axons found in true neuromas. Instead, there is a fibrosis and thickening of the perineural tissue with corresponding degeneration of the underlying nerve in a Morton's neuroma.[1] This most commonly affects the third plantar common digital nerve located in the third interspace, between the third and fourth metatarsal heads. It may also occur less commonly in the second interspace, between the second and third metatarsals. A neuroma is rarely seen in the first or fourth interspaces, between the first and second or the fourth and fifth metatarsals, respectively.

Morton's neuroma most commonly affects women between their fourth and sixth decades.[2] It is especially common in those who wear high-heeled shoes, poor fitting shoes, worn shoes, shoes with poor or no padding, or shoes that are narrow at the forefoot. Persons with pronated or pes cavus feet are similarly at risk.[3] Neuromas do not usually become symptomatic until their transverse diameter reaches more than 5 mm.[4]

ANATOMY AND PATHOPHYSIOLOGY

Neuromas form just proximal to the bifurcation of the plantar common digital nerves (**Figure 186-1**) and below the deep transverse intermetatarsal ligament (**Figure 186-2**). The deep transverse intermetatarsal ligament connects the metatarsal heads on the plantar aspect of the foot (**Figure 186-2**). The neuroma is made up of branches from both the medial and lateral plantar nerves (**Figure 186-1**). Most commonly affected is the third interdigital nerve. It is the largest of the interdigital nerves and may explain the increased frequency of neuroma formation in this location.

Morton and others postulated that the increased mobility of the fourth and fifth metatarsal heads relative to the more fixed medial portion of the foot results in disproportionate trauma to the third interdigital nerve. These mechanical factors, combined with the impingement and stretching from a tight transverse intermetatarsal ligament, result in repetitive microtrauma. Histologic evaluation reveals perineural fibroma formation consistent with compression-induced trauma.[2] Injury begins with edema of the endoneurium, followed by fibrosis beneath the perineurium, axonal degeneration, and finally neuronal necrosis.

Some authors believe that a more significant contributor to neuroma formation is enlargement of the interphalangeal component of the intermetatarsophalangeal bursa, leading to microvascular trauma.[5] Movements of the bursa result in minor compressive effects on the adjacent digital arteries, leading to ischemia of local neural tissue.

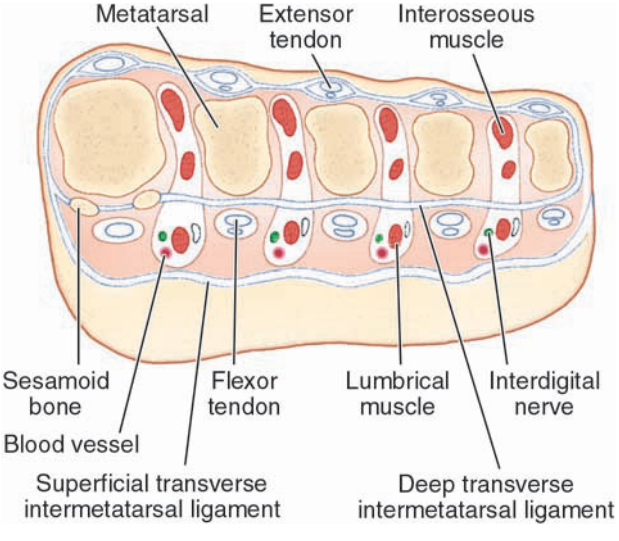

FIGURE 186-2. Anatomy of the forefoot. Cross section through the distal metatarsals.

The diagnosis of a Morton's neuroma is usually made clinically, based upon classic historical features and physical examination findings.[1] The pain of a neuroma usually begins intermittently, becoming more frequent with time and eventually constant. The patient may complain of pain, burning, electric shocks, or tingling over the involved intermetatarsal space. Attacks typically occur suddenly after a period of walking, running, or standing.[5] Some patients may complain of pain disturbing their sleep.[5] Hyperesthesia or hypoesthesia in the involved toes and web space is common. Patients often complain of the unilateral feeling of "walking on a lump." Symptoms are aggravated by walking, particularly in narrow shoes, and relieved by rest and shoe removal.

Physical examination localizes the pain to the involved interspace with minimal involvement of the adjacent metatarsal heads. Moderate pressure applied proximally in the affected web space reproduces the pain. A small mass, representing the neuroma, can be palpated in approximately one-third of the cases. A positive Mulder's sign is diagnostic.[6] This is a click felt in the interspace with medial and lateral compression of the metatarsal heads during simultaneous palpation of the interspace (**Figure 186-3**).

Radiographic imaging may be helpful in confirming the diagnosis and exploring alternative etiologies. Plain radiographs will not demonstrate a neuroma. They may reveal splaying of the involved toes when the neuroma is especially large or alternative diagnoses such as stress fractures or arthritis. Ultrasound represents the most efficient and effective imaging modality.[2,7] An experienced operator may identify hypoechoic neuromas as small as 2.9 mm.[8] Magnetic resonance imaging (MRI) is quite effective at identifying the presence of a neuroma, but cost and access issues make it a less practical choice, especially in the Emergency Department.[1] Computed tomography (CT) may be useful if an MRI is contraindicated or not available. The sensitivity of CT scanning is less than that of MRI or ultrasound.[2]

FIGURE 186-3. Examination for Mulder's click. The thumb and forefinger of the examiner's dominant hand are used to compress the interdigital space. The nondominant hand then performs medial and lateral compression of the metatarsal heads (*arrows*). A palpable click is diagnostic, while pain alone is suggestive of a neuroma.

INDICATIONS

Injection of the presumed neuroma will provide significant relief to the patient and confirm a Morton's neuroma as the etiology of the patient's complaints. Injection is indicated after less invasive methods have failed.[9,10] These include foot elevation and rest, nonsteroidal anti-inflammatory drugs, arch supports, orthoses, and changing footwear to prevent forefoot compression (i.e., low heels and wide toe boxes). Corticosteroid injections can provide partial or complete relief in up to 80% of patients.[9,11]

CONTRAINDICATIONS

The primary contraindication to injection of a Morton's neuroma is failure to make a correct initial diagnosis. The differential diagnosis for forefoot pain includes a wide variety of pathologies, many of which may closely mimic the presentation of a neuroma. Alternative diagnoses include tarsal tunnel syndrome, peripheral neuropathy, capsulitis, bursitis, rheumatoid arthritis, foreign bodies, avascular necrosis, stress fractures, and peripheral vascular insufficiency. A careful history and physical examination with discretionary use of imaging modalities will lead to a correct diagnosis.

Some specialists believe injection therapy to be contraindicated in serious athletes.[3] They propose that steroid injection may result in fat pad atrophy, degeneration of the volar plate, and degeneration of the collateral ligaments. A discussion of alternative therapies to injection therapy is provided later in this chapter.

EQUIPMENT

- Sterile gloves
- Sterile drapes
- Povidone iodine or chlorhexidine solution
- 3 mL syringe
- 22 or 25 gauge needle
- 0.5% bupivacaine without epinephrine
- Injectable methylprednisolone or triamcinolone
- Sterile bandage

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Place the patient supine on a gurney with their hip and knee flexed so that the sole of the affected foot is flat on the gurney. Clean the skin overlying the neuroma of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a sterile field.

Prepare the injection solution. Mix 1 mL of 0.5% bupivacaine without epinephrine in a 3 mL syringe with 10 mg of methylprednisolone or triamcinolone. Another local anesthetic agent, without epinephrine, may be used instead of bupivacaine. Long-acting local anesthetic agents are preferred as they provide the patient with longer pain relief after the injection.

TECHNIQUE

Instruct the patient to moderately dorsiflex their toes to separate the metatarsal heads. **Use a dorsal approach to the neuroma, as this is less painful than penetrating the sole with a needle.** If the neuroma is palpable, insert the needle perpendicular into the skin overlying the neuroma. Advance the needle perpendicular to the skin and into the neuroma or into its fascial plane (**Figure 186-4**). Inject the affected interspace with 1 to 2 mL of the combination long-acting local anesthetic agent and steroid.

FIGURE 186-4. Injection of the neuroma.

In the absence of a palpable neuroma, insert the needle approximately 1 to 2 cm proximal to the web space. Direct the needle into the facial space between the deep and superficial transverse metatarsal ligaments. Note that this space is deep to the metatarsal heads on the plantar aspect of the foot (**Figure 186-2**).

ALTERNATIVE TECHNIQUES

Various types of conservative treatment can be initiated once a Morton's neuroma is diagnosed. A wide range of success rates have been reported (20% to 80%) using a combination of injections with other conservative therapy including orthoses, metatarsal pads, shoes with wider toe boxes, and physical therapy.[12,13] Orthoses are used to help control abnormal pronation, although some studies have shown this to be ineffective.[13] Metatarsal pads serve to spread the metatarsal heads at the involved interspace and decrease compressive trauma (**Figure 186-5**). The types of physical therapy employed include massage, ultrasound, electrical stimulation, and whirlpool immersion. A trial of acetaminophen or nonsteroidal anti-inflammatory drugs may be helpful in the short term.

FIGURE 186-5. Placement of a metatarsal pad.

Two recent studies have described the injection of dilute alcohol into the site of the neuroma using ultrasound guidance. The effect is to sclerose and harden the perineural tissues. The injection is typically repeated every 1 to 2 weeks and on average 4 to 7 times, with treated patients experiencing a significant reduction in symptoms and neuroma size.[14,15]

Podiatrists and Orthopedists may offer more aggressive and definitive therapy when conservative measures fail. Surgical excision using a dorsal approach has success rates as high as 84% to 93%.[16–18] The podiatry literature offers increasing support for endoscopic decompression of the deep transverse intermetatarsal ligament, thus leaving the nerve intact. The advantage is a shorter recovery time, which may make this especially desirable for athletes. No long-term results have been reported, but short-term results appear quite promising.[3] Excision using a carbon dioxide laser is yet another treatment option that may allow for an even shorter recovery.[7]

ASSESSMENT

Allow 10 to 20 minutes for the local anesthetic agent to take full effect. The patient will experience a rapid resolution of symptoms if the injection is successful. The relief of pain confirms that the corticosteroid has been injected into the correct location, allowing it to work on the neuroma.

AFTERCARE

Pain may be controlled with the use of acetaminophen or nonsteroidal anti-inflammatory drugs. Instruct the patient to wear flat shoes, shoes with flat and wide toe boxes, and to avoid shoes whose heel is elevated above the metatarsals (usually a heal no higher than 0.5 to 1.0 inches). The patient should avoid activities that place repeated pressure on the forefoot (e.g., bicycling, jogging, and sports). Apply a metatarsal pad to decrease compressive forces on the neuroma. Place the dome of the pad between the third and fourth metatarsals and just posterior to the metatarsal heads (**Figure 186-5**). Cold packs can be applied for 10 to 15 minutes every 3 hours to decrease inflammation and pain, especially after activities that aggravate the patient's symptoms. Refer the patient to a Podiatrist or Orthopedic Surgeon for follow-up, additional injection therapy, orthoses, physical therapy, and possible surgical management.

COMPLICATIONS

Complications associated with neuroma injection are exceedingly rare. They include the introduction of infection, damage to neurovascular structures, local fat pad and skin atrophy secondary to the effects of the steroid, skin depigmentation or hyperpigmentation, telangiectasias, and thinning of the skin.[14,15] Fat pad atrophy on the dorsal foot is primarily a cosmetic issue. Fat pad atrophy on the plantar aspect of the foot can result in painful ambulation and gait disturbances.[19] Skin changes and fat pad atrophy can be prevented by ensuring the injection is deep and properly placed so that the corticosteroids do not leak into the subcutaneous tissues.[20] It is common for the pain to recur in days to weeks, even when the injection is successful. Single injections may not totally relieve the patient's symptoms. The patient often requires a series of injections every 1 to 2 weeks to be successful.

SUMMARY

Morton's neuroma is one of the most common causes of forefoot pain. Injection therapy is useful in alleviating the symptoms of a neuroma and in confirming the diagnosis. Arrange Podiatric or Orthopedic follow-up for all patients given this diagnosis, as more invasive procedures may be needed for long-term resolution of symptoms.

SECTION 16

Miscellaneous Procedures

187 Relief of Choking and Acute Upper Airway Foreign Body Removal

Tamara Espinoza, Shekhar Menon, and John Bailitz

INTRODUCTION

Accidental foreign body obstruction of the airway is the leading cause of accidental death in children less than 6 years of age.[1] Airway foreign body obstruction accounts for over 4000 adult and pediatric deaths per year in the United States.[1] Tragically, 90% of these deaths occur in children less than 4 years of age, with 65% occurring in infants.[2] The most common cause of an airway foreign body obstruction in infants are feeding liquids while the most common etiologies in older children are candy, grapes, peanuts, and vegetables. Mortality due to airway foreign body obstruction is bimodal and increases again in the elderly, with 13.6 deaths per 100,000 people greater than 75 years of age.[3,4] Food impaction is the primary etiology with the elderly, with those intoxicated and institutionalized being at an increased risk.[3,4]

ANATOMY AND PATHOPHYSIOLOGY

The clinical presentation and patient management is dependent on three related factors: the anatomical site of obstruction, the degree of obstruction, and the size of the foreign body. Autopsy reports have found the foreign body obstruction to be located supraglottic in 32% and infraglottic in 68%.[5] Patients with a supraglottic obstruction classically present with inspiratory stridor while those with an infraglottic obstruction present with expiratory wheezes. Infraglottic foreign bodies lodge in the trachea or the mainstem bronchus and require instrument removal. A foreign body that simply contacts the vocal cords while moving through the glottis may result in laryngospasm that can completely obstruct the airway, even after the expulsion of the foreign body.[6]

Partial airway obstructions often allow limited amounts of air passage and their removal by the patient's cough reflex. Complete airway obstructions can result in a silent cough followed by loss of consciousness, thus requiring higher pressures for removal. A larger foreign body is more likely to lodge above or at the vocal cords causing a complete airway obstruction. Sharp, small, and thin foreign bodies are more likely to obstruct between or below the vocal cords and result in difficulty breathing and odynophagia.[7]

Pediatric and adult patients provide different clues to an airway foreign body obstruction. Adults and older children typically indicate the "universal choking sign" by clutching or pointing to their neck and nodding affirmatively when asked if choking. An infant or toddler will present after a witnessed or suspected acute foreign body ingestion. Their symptoms range anywhere on a spectrum from subtle stridor and wheezing to cyanosis and unconsciousness.[8]

Dr. Henry Heimlich first proposed the Heimlich maneuver in 1974. Controversy soon followed as he publicly denounced the recommendations made by the American Red Cross and the American Heart Association. He claimed that back blows previously listed as a first-line treatment were "death blows" and that various national organizations were involved in "Watergate cover-ups" intended to prevent acceptance and widespread use of his maneuver.

No prospective clinical trials have been reported on the various techniques used to relieve an airway foreign body obstruction. Physiologic data demonstrate that each technique produces varying effects on intrathoracic pressure and airflow to overcome the static resistance of the obstructing foreign body.[9] Back blows generate a substantial increase in intrathoracic pressure over a very short period of time, potentially dislodging an airway foreign body without its expulsion from the airway. Conversely, abdominal thrusts generate more prolonged increases in airway pressure and flow rates, theoretically allowing for expulsion of the dislodged foreign body. Rescuers must be prepared to quickly utilize a combination of these techniques for the dislodgement and expulsion of an airway foreign body obstruction.[4]

DIGITAL REMOVAL (FINGER SWEEP)

Perform digital removal of an intraoral foreign body only when it is directly visualized in the patient's mouth or oropharynx. Blind finger sweeps are contraindicated to prevent inadvertently pushing the foreign body into a more distal location, thereby converting an incomplete supraglottic obstruction into a difficult to remove and complete infraglottic obstruction.[7]

Open the patient's mouth and airway using the thumb and fingers of the nondominant hand to grab the tongue and mandible then lift it anteriorly. Use a hooking action with the index finger of the dominant hand to dislodge and remove the foreign body.

The most important potential complication is the conversion of a partial airway obstruction into a complete airway obstruction. Local trauma can result in intraoral abrasions, bleeding, and dental trauma. The rescuer can sustain digital abrasions and lacerations from the patient's teeth. **Do not place your fingers into the mouth of a conscious patient as this can result in a significant bite injury.**

BACK BLOWS AND CHEST THRUSTS IN INFANTS

An uncoordinated swallow mechanism and the lack of molar dentition predispose the infant to an airway foreign body obstruction within their narrow and pliable glottis and trachea.[10] **Perform back blows and chest thrusts on the infant with a witnessed or suspected airway foreign body obstruction who suddenly develops respiratory distress, appears cyanotic, or becomes unconscious. This technique should be used on infants less than 1 year of age. Use the Heimlich maneuver if the patient is over 1 year of age. Continue to closely observe the infant but do not intervene if they are maintaining their airway as indicated**

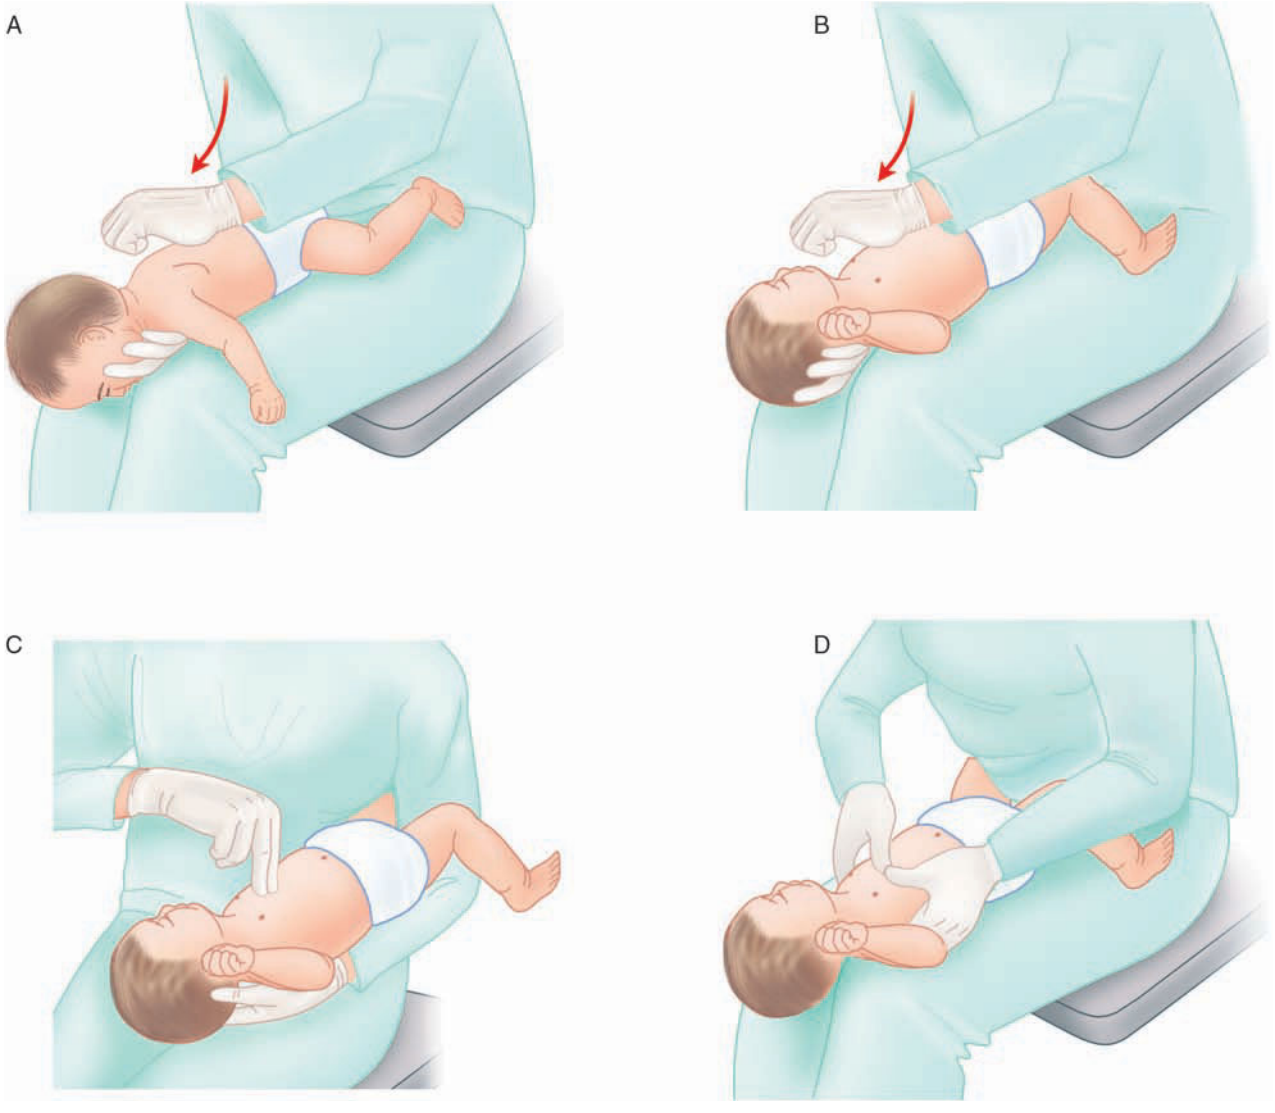

FIGURE 187-1. Relief of an airway foreign body obstruction in the infant. **A.** Back blows using the heel of a hand. **B.** Chest thrusts using the heel of a hand. **C.** Chest thrusts using two fingers. **D.** Chest thrusts using both thumbs.

by clear breathing and an effective cough. Their cough reflex may allow them to dislodge and expel the foreign body.

Place the choking infant with their head angled down in a prone position over the arm or thigh of the rescuer (**Figure 187-1A**). This head-down position allows gravity to assist in the expulsion of the dislodged foreign body. Perform five firm back blows with the heel of a hand between the infant's shoulder blades (**Figure 187-1A**). Turn the infant around into the supine position with their head angled down. Perform five chest thrusts with the heel of a hand applied to sternum (**Figure 187-1B**). Repeat this sequence of back blows and chest thrusts until the foreign body is expelled or the infant becomes unresponsive.

Chest thrusts may also be performed using two other methods. The first is to apply the index and middle fingers just below the intermamillary line and compress the chest (**Figure 187-1C**). This is usually performed when there is one rescuer. The second method is to use both thumbs on the infant's sternum (**Figure 187-1D**). This method is performed when one or two rescuers are present. Place both thumbs together over the lower half of the infant sternum just below the intermamillary line. Encircle the infant's chest with both hands, spreading the fingers around the posterior thorax. Compress the sternum while squeezing the thorax to apply counterpressure.

The procedure is successful when the foreign body is expelled. Closely observe the infant after expulsion of the foreign body for any signs of persistent respiratory distress due to an incompletely expelled foreign body or injury from the removal techniques.

For the unresponsive infant, first check their mouth and remove any obvious foreign body. **Blind finger sweeps are always contraindicated.** Case reports describe wedging of foreign bodies into more distal locations and converting a partial airway obstruction into a complete airway obstruction.[7] In the apneic infant, immediately begin more advanced pediatric procedures as described below as well as Basic Life Support and Advanced Life Support maneuvers.

Back blows often result in back and chest wall contusions. The use of acetaminophen or nonsteroidal anti-inflammatory drugs should relieve any discomfort. Vigorous back blows can result in rib fractures. Occasionally, nausea and vomiting can result. Chest thrusts may result in rib and sternal fractures, myocardial contusions, punctured lungs, pneumothoraces, and intraabdominal injury.[4] While these potential complications are serious, not relieving an airway foreign body obstruction can result in death.

Maintain a low threshold for performing back blows and chest thrusts to relieve an airway foreign body obstruction in infants. An

airway foreign body obstruction in an infant is more likely, more difficult to assess, and more often fatal than in an older child, adolescent, and adult. **The key steps to remember include positioning the infant head down over the rescuer's arm or leg with their head lower than their trunk, performing five back blows alternating with five chest thrusts, and repeating this sequence continuously until the foreign body is expelled.**

ABDOMINAL THRUSTS (HEIMLICH MANEUVER) IN THE CONSCIOUS PATIENT

Perform the Heimlich maneuver in the conscious patient over 1 year of age with a witnessed or presumed aspiration who cannot speak, cough, or breathe effectively. Older children and adult patients will often present and be grasping or pointing to their neck with the "universal choking sign" (**Figure 187-2**). Young children will often have a history or presentation consistent with an airway foreign body obstruction. As long as the patient is conscious and has signs of a complete airway obstruction, perform this technique from behind. Do not perform the Heimlich maneuver in patients less than 1 year of age due to the significant risk of liver injury.[11] **Observe the patient closely while their cough reflex attempts to expel the partial obstruction if they are able to cough, speak, and breathe effectively. Perform abdominal thrusts only for a complete airway obstruction.**

Stand directly behind the patient (**Figure 187-2**). Wrap both arms around the patient's waist. Make a fist with one hand. Place this hand with the thumb side of the fist against the midline of the patient's upper abdomen, between the rib cage and umbilicus. Place the other hand over the fisted hand and grasp the fisted hand (**Figure 187-2**). **Press inward with a deliberate and quick upward thrust. Confine the force of the thrust to the hands without squeezing the rib cage.** Repeat the quick upward thrusts until the foreign body is expelled or the patient becomes unresponsive.

Closely observe the patient after the foreign body is expelled for signs of respiratory distress from persistent obstruction or from injury from the Heimlich maneuver. **If the patient becomes unresponsive, lay them supine and perform abdominal thrusts as described below.** Incorrect hand placement can result in sternal and rib fractures. Significant but rare complications include a punctured lung, pneumomediastinum, and intraabdominal trauma (e.g., liver laceration, splenic laceration, and bowel injury). While these potential complications are serious, not relieving an airway foreign body obstruction can result in death.

ABDOMINAL THRUSTS IN THE UNCONSCIOUS PATIENT

Perform abdominal thrusts in the patient with a witnessed or suspected airway foreign body obstruction, failure of the previously described maneuvers, or in the unresponsive patient. Do not perform this maneuver in patients less than 1 year of age due to the significant risk of liver injury.

Place the patient supine on a firm surface, usually on the floor. A bed is not firm enough to allow the appropriate generation of intraabdominal pressure. Open their mouth. **Perform a finger sweep only if a foreign body is clearly visible.** Place the heel of one hand in the midline of the abdomen and just above the umbilicus. Place the other hand over the first (**Figure 187-3**). Apply five rapid and forceful thrusts downward and upward, forcing the diaphragm upward and compressing the lungs. Reassess the patient's airway. Inspect their mouth for a foreign body. Remove the intraoral foreign body if it is visible. If the foreign body is not visible, repeat the abdominal thrusts or attempt another technique.

One case study reported that increased airway pressure was generated using a knees-to-chest approach in the supine position. While there are no further studies to support this technique, it may be a simple adjunct when other methods have failed.[12]

FIGURE 187-2. The Heimlich maneuver in a conscious patient.

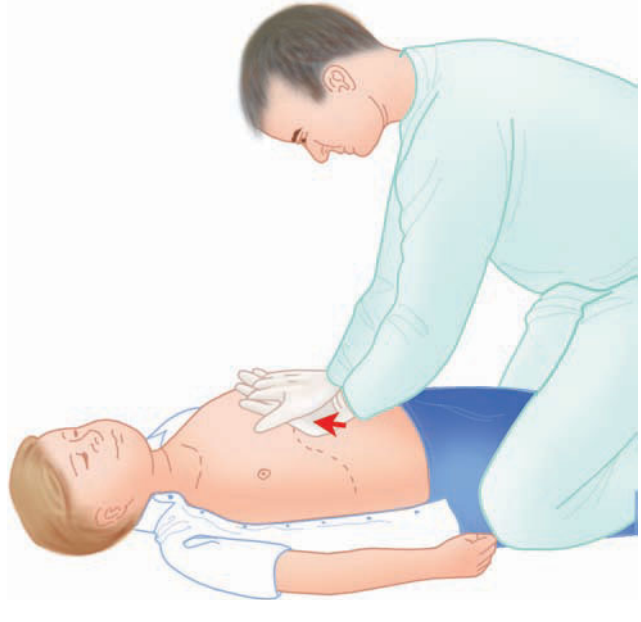

FIGURE 187-3. Abdominal thrusts in the unconscious patient.

Frequently reassess the patient for spontaneous breathing. Each time the mouth and airway is opened, look for a foreign body prior to ventilation attempts. Closely observe the patient after the foreign body is expelled for signs of respiratory distress from persistent obstruction or from injury from the abdominal thrusts. Incorrect hand placement can result in sternal and rib fractures. After the foreign body is removed, place the patient in the semirecumbent position or sitting upright if no contraindications exist.

Reported complications include abdominal pain, vomiting, pharyngeal abrasions, esophageal lacerations, intraabdominal trauma (e.g., liver laceration, splenic laceration, and bowel injury), fractured ribs, punctured lung, pneumothoraces, a pneumomediastinum, and even retinal detachment. While these potential complications are serious, not relieving an airway foreign body obstruction can result in death.

DIRECT LARYNGOSCOPY

Developmental differences in the pediatric airway make visualization and removal of foreign bodies more difficult than in the adult patient. The pediatric tongue occupies a larger percentage of the oral cavity and the oropharynx. Their epiglottis is larger, U-shaped, and more cephalad. The pediatric epiglottis does not attain the adult position until age four. The narrowest portion of the pediatric airway, and a likely site of obstruction, is below the vocal cords at the level of the cricoid cartilage, making removal more difficult.

The timing of endoscopy and airway foreign body retrieval must be based upon each individual patient. Do not waste time if impending airway obstruction exists. Immediately notify and mobilize an Anesthesiologist, Otolaryngologist, and the Operating Room, as this is an emergent situation. It is appropriate to wait for NPO status to be present and the stomach empty prior to proceeding to the Operating Room if the diagnosis of an airway foreign body is highly suspected and the patient is stable. This is considered a timely approach and may take up to 6 hours for children or 8 hours for adults. Waiting this time in the stable patient decreases the risk of aspiration and further compromising the situation. It is also appropriate to wait, in a stable patient, in order to assemble the appropriate and best nursing and anesthesia team to care for the patient. Using personnel who are unfamiliar with endoscopy can create a compromised and stressful situation.

It is always best not to manipulate the airway or attempt intubation in a stable patient with an airway foreign body and who is moving air and breathing. The airway may be best controlled in the Operating Room at the time of the actual foreign body removal. Once the airway is manipulated a foreign body can become dislodged, turning a partial airway obstruction into a complete airway obstruction. If this occurs in the Operating Room, the bronchoscopy equipment is available for urgent use by the endoscopist if needed.

It is possible to remove foreign bodies located within the hypopharynx in the Emergency Department. Typical foreign bodies that may be removed include pieces of food and fishbones. **The patient must be stable and in no risk of airway compromise.** Obtain anteroposterior and lateral soft tissue radiographs of the neck to localize, if possible, the foreign body. The use of CT scans to attempt to identify potential fish or chicken bones that may be lodged in the pharynx, hypopharynx, or esophagus is an option in the stable patient. Perform indirect laryngoscopy to identify the foreign body and its location. Refer to Chapter 173 regarding the complete details of laryngoscopy. Obtain intravenous access.

Perform a forceps removal of an airway foreign body in the patient with a complete airway obstruction or severe respiratory distress due to partial obstruction when less invasive measures have failed.[13] **Do not try to blindly grasp for a presumed airway foreign body.** Observation and removal in the Operating Room, and not an Emergency Department intervention, is indicated in the patient who is coughing, speaking, or otherwise breathing effectively. Begin with less invasive techniques before performing direct laryngoscopy and manual removal. Be ready to utilize multiple laryngoscope blades, clamps, and forceps to safely visualize and remove accidental foreign body obstruction.

EQUIPMENT

- Topical anesthetic spray (e.g., Cetacaine)
- Laryngoscope
- Laryngoscope blades, Miller and Macintosh, various sizes
- Tracheal suction catheter
- Magill forceps
- Pulse Oximeter
- Cardiac Monitor
- Noninvasive blood pressure cuff
- Oxygen
- Video laryngoscope, optional
- Surgical airway equipment

Direct laryngoscopy and bronchoscopy in a child or adult with an airway foreign body is a dangerous situation. The procedure may result in a partial airway obstruction becoming a complete airway obstruction. **Always have a cricothyroidotomy tray and/or percutaneous transtracheal jet ventilation device immediately available.** All equipment must be selected, assembled, and ready for use. Place the patient in full monitoring (i.e., pulse oximeter, cardiac monitor, and noninvasive blood pressure cuff). Apply a topical anesthetic spray to the oropharynx and the base of the tongue to blunt the gag reflex. Place the patient supine or semirecumbent. Administer a small dose of an intravenous sedative if required and not contraindicated.

Slowly and gently insert the laryngoscope blade. An alternative to a traditional laryngoscope, if available, is a video laryngoscope. The video laryngoscope may provide a better field of view with less manipulation. **Do not immediately insert the laryngoscope blade all the way.** Stop frequently to lift the laryngoscope and look for the foreign body. This slow insertion and frequent looks will prevent the laryngoscope blade from pushing the foreign body further into the airway. Elevate the patient's tongue and jaw. Grasp the foreign body with a Magill forceps. If the foreign body is too large or impacted, it may need to be crushed with the forceps to securely grasp it as a whole piece.[14] Withdraw the McGill forceps followed by the laryngoscope.

One case report describes passing a Foley catheter distal to the foreign body under direct visualization with a laryngoscope.[14] The balloon was then inflated with 5 mL of air and subsequently pulled back until the foreign body could be grasped and removed with a Magill forceps. There were no reported complications. However, it should be noted the foreign body in this case was impacted within the esophagus at the level of the cricoid cartilage. Do not use this technique with subglottic airway foreign bodies since retraction of a dilated catheter balloon through the glottic structures may cause injury, edema, bleeding, and further worsen the obstruction.

Observe the patient for persistent or delayed respiratory distress resulting from incomplete removal or procedural complications. The severity of the obstruction determines whether a patient may be safely discharged home or admitted for observation.

One review reported no complications with subglottic foreign body removal when utilizing Magill forceps under direct

laryngoscopy.[13] Potential complications include oropharyngeal trauma resulting in glottic edema and bleeding.

OROTRACHEAL INTUBATION

Attempt orotracheal intubation in the Emergency Department if the airway obstruction progresses rapidly and the patient cannot ventilate. Intubation can be used to force the foreign body into one mainstem bronchus and allow ventilation of the other lung. One-lung ventilation will keep the patient alive until the foreign body can be removed in the Operating Room.

Position the laryngoscope to visualize the larynx. If a foreign body is visualized, grasp the foreign body with a McGill forceps and remove it. If no foreign body is visualized, intubate the patient. Insert and advance the endotracheal tube as far as it will advance if the foreign body is not visualized or unable to be grasped. If the endotracheal tube will not pass, try passing a smaller size endotracheal tube. Withdraw and position the endotracheal tube with the tip above the carina to optimize ventilation. As an alternative, properly insert and position the endotracheal tube above the carina then advance a bougie through the endotracheal tube in an attempt to move the foreign body distally. **Always be prepared to perform a cricothyroidotomy or transtracheal jet ventilation.** Transtracheal jet ventilation allows for short-term oxygenation, is temporary, and may allow time for safe transport to the Operating Room so that endoscopy and foreign body retrieval can be performed in a more controlled environment with appropriate equipment at hand. Refer to Chapters 11, 25, and 24 regarding the details of orotracheal intubation, cricothyroidotomy, and transtracheal jet ventilation, respectively.

AFTERCARE

After the extraction, removal, or retrieval of an airway foreign body, most patients should be breathing spontaneously. An endotracheal tube may rarely, in the presence of significant laryngeal or tracheobronchial edema, need to remain in place temporarily. This would require admission to an intensive care unit. Humidified oxygen is helpful to keep the airway moist and prevent mucous crusts from forming. A postprocedural radiograph will help to determine any subcutaneous air, air in the soft tissues, a pneumothorax, or any changes to the lung fields following the extraction.

All patients who have undergone foreign body extraction, removal, or retrieval require at least a few hours of airway observation in a monitored setting. Racemic epinephrine treatments and intravenous Decadron can be administered as needed. Discharge from the hospital is acceptable when the patient is breathing comfortably and no longer in danger of airway compromise. Some patients may be discharged home the same day, while others may require multiple days of airway support and observation.

COMPLICATIONS

Complications from the foreign bodies themselves include hypoxia leading to cerebral anoxia if not identified. Cardiac arrhythmias can occur from hypoxia or direct pressure on the left main-stem bronchus. Other complications include laryngeal or tracheobronchial edema from the foreign body or the instrumentation of the airway. Mucosal irritation can instigate a bronchitis, pneumonia, or tracheitis. A pneumomediastinum and/or a pneumothorax is possible. The complications specific for each technique have been described previously in the respective sections.

A foreign body in the hypopharynx can be pushed distally and result in a total airway obstruction. The foreign body needs to be quickly removed, pushed back down into one of the mainstem bronchi to allow ventilation of at least one lung, or a surgical airway performed. Failure to react appropriately in this situation can result in asphyxiation and death.

SUMMARY

An airway foreign body obstruction is a significant cause of preventable morbidity and mortality in the pediatric, debilitated, and elderly patients. Prompt recognition and management is vital to preventing cardiopulmonary arrest. Do not intervene in the awake patient who is talking, coughing, or otherwise breathing effectively. Observe these patients to determine if their own cough reflex can expel the foreign body. Perform the age and condition appropriate maneuvers with a complete airway obstruction or severe respiratory distress with a partial airway obstruction. Multiple attempts with a combination of procedures are often required for the successful removal of an airway foreign body. Back blows and chest thrusts are first line for infants while abdominal thrusts may be performed on all others. Blind finger sweeps are always contraindicated. Perform manual removal with finger sweeps or direct laryngoscopy under direct visualization.

188 Induction of Therapeutic Hypothermia

Mark Hansen, Mike Nelson, and John Bailitz

INTRODUCTION

Sudden cardiac death claims approximately 450,000 victims in the United States every year.[1] The mortality rate for out-of-hospital cardiac arrest remains a staggering 65% to 95%, with only 10% to 20% of survivors discharged from the hospital with a good neurologic outcome.[2] **Therapeutic hypothermia for the treatment of comatose survivors of cardiac arrest is the only therapy proven to improve survival and neurological outcome.[3]**

Although many consider therapeutic hypothermia to be a relatively new concept, experiments with deep therapeutic hypothermia actually began in the 1940s with initially mixed results. In the 1950s, studies examining moderate hypothermia in the range of 26°C to 32°C (78.8°F to 89.6°F) in comatose survivors of cardiac arrest reported a trend toward improved outcomes but were complicated by difficult to control side effects. Additional animal studies of mild hypothermia in the range of 32°C to 35°C (89.6°F to 95°F) in the 1980s and small clinical trials in the 1990s demonstrated that even mild hypothermia provided the protective benefits with far fewer side effects.[2]

Two landmark randomized trials published in 2002 specifically examined the use of mild hypothermia in comatose survivors of witnessed cardiac arrests with initial rhythms of pulseless ventricular tachycardia or ventricular fibrillation.[4,5] **More recent meta-analysis report that only seven patients need to be treated to save one life and only five patients need to be treated to prevent one poor neurological outcome.[6,7]** Utilizing these studies' strict screening criteria resulted in only 10% of screened patients being eligible. Follow-up studies suggest a wider benefit in patients with other rhythms at presentation, cardiogenic shock, and those requiring percutaneous cardiac intervention (i.e., angioplasty and stenting).[2,3,8–16]

Preliminary studies of therapeutic hypothermia for other indications including traumatic brain injury, strokes, subarachnoid hemorrhages, myocardial infarctions, and ARDS have to date reported

only limited data or conflicting results. The exception being studies of neonates with perinatal asphyxia that reported similar results to adult cardiac arrest with a number needed to treat of six for one favorable outcome.[3] Extensive ongoing research is currently being conducted to determine the effectiveness of therapeutic hypothermia for other indications, as well as the optimal timing, duration, target temperature, and best techniques.

Despite recommendations for therapeutic hypothermia in the 2005 International Liaison Committee on Resuscitation Recommendations and American Heart Association Resuscitation Guidelines, a recent survey showed that 74% of physicians in the United States had not used therapeutic hypothermia.[15] They cited reasons such as not enough data, not part of ACLS protocol, too technically difficult, or that it had not been considered.[15] However, the induction of therapeutic hypothermia for comatose survivors of cardiac arrest is relatively straightforward in any Emergency Department. Similar to Early Goal Directed Therapy (EGDT) for septic shock, the creation of collaborative protocols between Emergency Physicians, Intensivists, Cardiologist, and Neurointensivists is essential to producing the best outcomes at each institution.

ANATOMY AND PATHOPHYSIOLOGY

The postcardiac arrest syndrome has recently been defined as a complex pathophysiological process involving brain injury, myocardial dysfunction, systemic ischemia and reperfusion response, and the underlying persistent precipitating pathology.[3] Brain injury is the reported cause of death in two-thirds of patients after an out-of-hospital arrests and one quarter of patients after in-hospital cardiac arrests.[16] Multiple cellular mechanisms contribute to neuronal apoptosis and necrosis including the formation of free radicals, disruption of calcium homeostasis, excitotoxicity, altered gene expression, mitochondrial dysfunction, and inflammation. At the tissue level, these cellular mechanisms lead to failure of cerebral autoregulation and ultimately hypotension, hypoxemia, brain edema, pyrexia, hyperglycemia, and seizures.[3]

Surprisingly, the postcardiac arrest state does not result in myocardial infarction but only myocardial stunning for 24 to 48 hours, producing a reduced ejection fraction and a reduction in end organ oxygen delivery.[3] The accumulated oxygen debt activates an inflammatory endothelial response further worsening oxygen delivery. The vicious cycle of oxygen debt and resultant inflammation does not end with reperfusion. Instead, the burst of reactive oxygen intermediates further exacerbates the inflammatory response and organ injury. The resultant state of systemic ischemia with reperfusion response leads to intravascular volume depletion, changes in vasoregulation, decreased oxygen utilization and delivery, and an increased risk of infection.

The underlying persisting pathology that caused the cardiac arrest also must be addressed. Acute coronary syndrome is strongly implicated in up to 50% of out-of-hospital cardiac arrests.[10] Elevations of troponin T are present in up to 40% of patients at the time of cardiac arrest, suggesting an ongoing cardiac ischemia or injury hours prior to the cardiac arrest. Additional etiologies of the cardiac arrest to consider include pulmonary embolism, primary pulmonary disease, sepsis, drug toxicity, or severe hemorrhage.

Hypothermia improves outcomes through several proposed mechanisms.[17] Metabolic demand is reduced 5% for each degree Celsius reduction in core body temperature. At the cellular level hypothermia decreases adenosine triphosphate demand, preventing intracellular acidosis and stabilizing cell membranes. At the tissue level hypothermia leads to decreased vascular permeability at the blood–brain barrier thus decreasing edema. Hypothermia interrupts the inflammatory cascade by inhibiting neutrophils, reducing the production of proinflammatory cytokines, and helping to prevent the free radical production associated with reperfusion injury.

INDICATIONS

Hypothermia is most effective in patients meeting the strict inclusion criteria of the initial landmark studies. Begin the induction of hypothermia in the Emergency Department for comatose survivors of cardiac arrest with a presumed cardiac etiology, an initial rhythm of ventricular fibrillation or pulseless ventricular tachycardia, and between 18 and 75 years of age.[3,7] More recent studies have demonstrated improved outcomes in patients with other initial rhythms (e.g., pulseless electrical activity and asystole), comatose survivors of in-hospital cardiac arrest, patients requiring percutaneous cardiac intervention, and those suffering from cardiogenic shock.[10,11,13,14,18] Consider the induction of therapeutic hypothermia when the cardiac arrest is witnessed, there is <30 minutes from the time of the collapse to the start of resuscitative efforts, it is <60 minutes from collapse to the return of spontaneous circulation (ROSC), the patient has a core body temperature >35°C (95°F), blood pressure can be maintained >80 mmHg with or without IV fluid boluses and pressors. Refer to **Figure 188-1** regarding a sample induction of therapeutic hypothermia checklist and clinical pathway.

CONTRAINDICATIONS

Hypothermia is contraindicated in patients with a known status of do not resuscitate (DNR) or do not intubate (DNI), have a terminal illness, have severe comorbidities, have multiorgan failure prearrest, or are comatose due to a noncardiac etiology. Patients with a preexisting coagulopathy or pregnancy have been excluded from most studies. One case of successful therapeutic hypothermia in pregnancy has been reported.[19] Other contraindications include patients when prehospital or in-hospital resuscitation is initiated greater than 15 to 30 minutes after collapse, with >60 minutes from the time of arrest to the ROSC, who are persistently hypoxic (SpO_2 < 85%) for greater than 15 minutes after the ROSC, if the arrest is related to blunt or penetrating trauma, when greater than 6 hours have elapsed since the ROSC, and if the patient spontaneously awakens with a normal mental status.

EQUIPMENT

General Supplies

- Arterial line equipment and supplies (Chapter 57)
- Nasogastric tube equipment and supplies (Chapter 58)
- Cardiac Monitor
- Ventilator
- Orotracheal intubation equipment and supplies (Chapter 11)
- Venous access equipment and supplies (Chapters 48 and 49)
- Analgesics (e.g., Fentanyl, Morphine, or Meperidine)
- Sedatives (e.g., Propofol, Ativan, or Versed)
- Neuromuscular blockers (e.g., Pancuronium, Vecuronium, or Rocuronium)
- Defibrillator–cardioverter unit and supplies (Chapter 30)

Cooling Supplies

- 4°C sterile normal saline or lactated Ringers
- Ice packs or ice water-soaked blankets
- Core temperature probe and monitor (e.g., esophageal, rectal, or urinary)

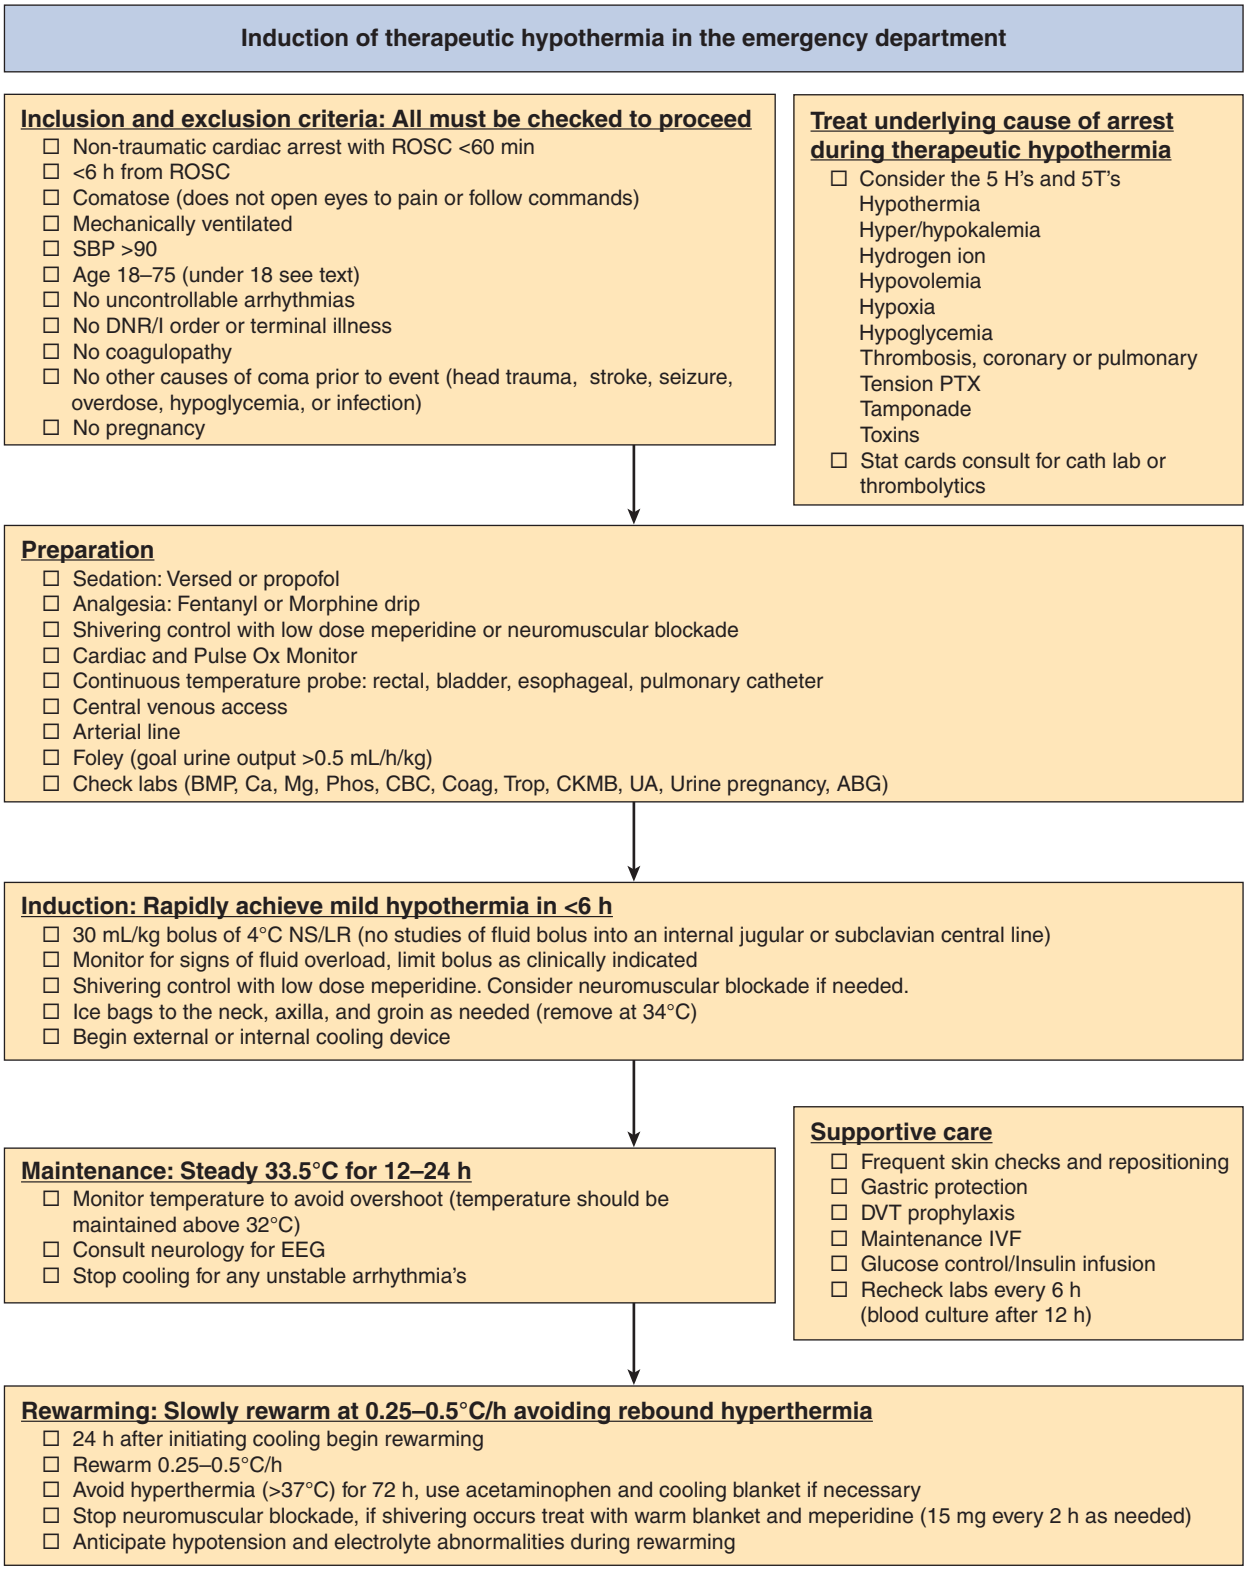

FIGURE 188-1. A sample induction of therapeutic hypothermia checklist and clinical pathway.

External Commercial Cooling Devices (Figure 188-2)

- Excel Cerebral Cooling System (Life Core Technologies LLC, Cleveland, OH)
- Medi-Therm III (Gaymar Industries Inc., Orchard Park, NY)
- Arctic Sun Temperature Management System (Medivance Inc., Louisville, CO)
- Cincinnati Sub-zero Blankets (Cincinnati Sub-zero Products Inc., Cincinnati, OH)
- InnerCool STx Surface Pad Systems (Phillips Healthcare, San Diego, CA)
- Thermosuit (Life Recovery Systems, Waldwick, NJ)

FIGURE 188-2. Examples of externally applied cooling devices. **A.** The Excel Cerebral Cooling System (Photo courtesy of Life Core Technologies LLC, Cleveland, OH). **B.** The Arctic Sun Temperature Management System (Photo courtesy of Medivance Inc., Louisville, CO). **C.** The Cincinnati Kool-Kit (Photo courtesy of Cincinnati Sub-zero Products Inc., Cincinnati, OH). **D.** The Thermosuit (Photo courtesy of Life Recovery Systems, Waldwick, NJ). **E.** The Medi-Therm (Photo courtesy of Stryker Medical, Orchard Park, NY).

Internal Endovascular Cooling Devices (Figure 188-3)

- Accutrol catheter (Phillips Healthcare, San Diego, CA)
- Cool Line, Icy, and Quattro catheters (Alsius, Irvine, CA)

Nasal cooling systems are currently being developed and tested (BeneChill, San Diego, CA and Johns Hopkins University, Baltimore, MD). These systems take advantage of the large surface area of the nasal cavity with an abundant capillary supply just below the mucosa as a heat exchanger. Early studies are promising. These systems may be used prehospital as well as in-hospital for the cooling of the postcardiac arrest patient. Further development and testing is required before these devices will be available for use.

PATIENT PREPARATION

Carefully consider inclusion and exclusion criteria for each individual patient utilizing pre-established institution-specific protocols. The risks, benefits, potential complications, and aftercare of the procedure should be explained to the patient's representative and an informed consent obtained whenever possible. The postarrest

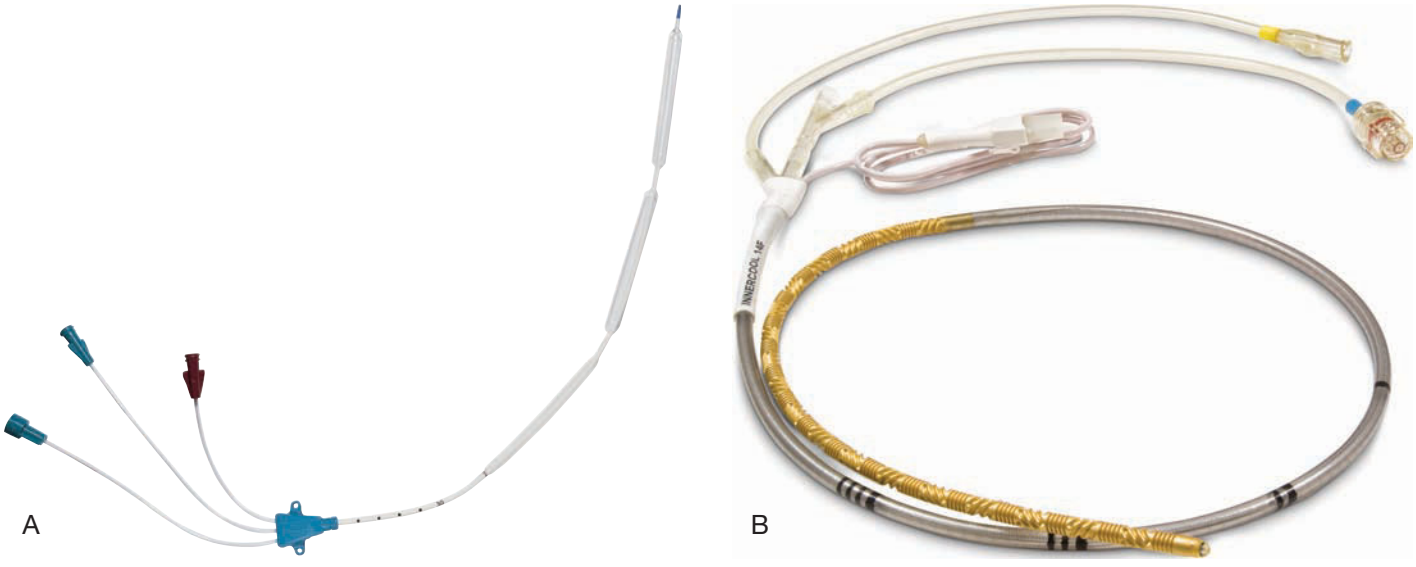

FIGURE 188-3. Examples of internally applied cooling devices. **A.** The Icy catheter (Photo courtesy of Alsius, Irvine, CA). **B.** The Accutrol catheter (Photo courtesy of Phillips Healthcare, San Diego, CA).

patient will be or should be intubated, have continuous pulse oximetry and cardiac monitors, and have frequent automated cuff or continuous arterial line blood pressure monitoring.

Perform a detailed examination to document a postarrest comatose state and the patient's baseline neurologic status including Glasgow Coma Scale, pupillary light reflex, corneal reflex, facial movements, eye movements, gag, cough, and motor response to painful stimuli. The retention of any neurologic function during or after cardiopulmonary resuscitation suggests a good prognosis. However, the absence of neurologic function immediately after the ROSC is not a reliable predictor of a poor outcome. The reliability of the neurologic exam to predict a poor outcome is time dependent. The absence of pupillary light reflexes, corneal reflexes, or motor responses to painful stimuli at day 3 provides the most reliable predictor of poor outcome.[3]

Prepare the patient for therapeutic hypothermia. Turn the ventilator's warm humidified air function off so as not to warm the patient. Perform an ECG. Obtain basic laboratory analyses to include electrolytes, renal function, calcium, magnesium, phosphorus, complete blood count, coagulation profile, cardiac markers, urinalysis, pregnancy, and arterial blood gas. Other laboratory analyses may include cortisol levels and thyroid function tests at the discretion of the admitting team. Titrate intravenous sedation and analgesia for comfort with mechanical ventilation. Shivering increases oxygen consumption, requiring control with low dose meperidine (15 mg IV Q 2 hours) and possibly neuromuscular blockade. Place a urethral catheter (Chapter 142) and monitor the urine output with a goal of >0.5 mL/hour/kg. Continuously monitor the core temperature with an esophageal, rectal, or urinary temperature probe. Place a nasogastric tube. Apply defibrillator/pacing pads (Chapter 30) in case they are required during the therapeutic hypothermia process. Otherwise, standard acute coronary syndrome and postresuscitation protocols apply.

TECHNIQUE

Therapeutic hypothermia is performed in three phases: induction, maintenance, and rewarming. There are multiple methods to perform all three phases. **However, the goals of each phase always remain the same. Rapidly achieve a hypothermic state of 32°C to 34°C (89.6°F to 93.2°F), maintain hypothermia for at least 12 to 24 hours, and then slowly rewarm at no faster than 0.25°C to 0.50°C (0.45°F to 0.9°F) per hour.**

INDUCTION

Beginning the induction phase of therapeutic hypothermia in the Emergency Department is straightforward and inexpensive. The typical temperature decrease seen in survivors of cardiac arrest begins the process even before it starts. The infusion of 4°C normal saline or lactated Ringers stored in a temperature-controlled refrigerator provides a reliable and safe method for rapid induction. Bolus 30 mL/kg or 1.5 to 2 L of fluid to create a 1.5°C to 2.3°C (2.7°F to 4.1°F) decrease in temperature.[20–22] **Monitor the patient for signs of fluid overload and adjust the rate and total volume accordingly.** Smaller repeat boluses of 500 mL may be given when required.[17] The application of ice packs to the head, neck, torso, and groin provides another safe and reliable method for rapidly decreasing temperature.[23] Patients requiring immediate angiography or admission to other locations may be transferred with both of these methods in place and without delay.[10,13]

Several commercially available external and internal cooling devices listed in the equipment section allow the Emergency Physician to set and maintain a target temperature through the use of continuous feedback from the patient's core temperature monitor. External systems utilize cooled circulated air, pads, or blankets. Internal systems require the placement of a femoral or subclavian central venous catheter with an endovascular cooling device. When available, these devices should be initiated while the fluid boluses and/or ice packs are applied.

To date there have been no studies comparing external versus internal cooling devices in cardiac arrest patients.[23] However, a manufacturer sponsored study of therapeutic hypothermia in neurosurgical patients demonstrated that the endovascular device reached target temperature faster (35 vs. 204 minutes), maintained a tighter control of target temperature, and had no significant increase in complications versus surface cooling.[24]

Beginning the induction in the Emergency Department with cooled IV fluids and ice packs, followed by the immediate transfer of the patient to the Intensive Care Unit for the application of more

expensive and delicate commercial cooling devices for maintenance of therapeutic hypothermia provides a clinically and cost-effective approach in any institution. These commercial cooling devices should be applied and the process of therapeutic hypothermia continued in the Emergency Department if there is any delay in transferring the patient to the Intensive Care Unit.

MAINTENANCE

Cooling should be stopped at 33.5°C (92.3°F) to prevent overshoot.[17] Use an external or internal cooling system with feedback control to maintain a core temperature of 32°C to 34°C (89.6°F to 93.2°F). Other methods include the use of cold wet blankets and ice packs placed around the head, neck, torso, and extremities. Although less expensive, these methods are more labor intensive, result in greater temperature fluctuations, and do not allow for controlled rewarming.[25] Maintaining hypothermia with fluid boluses alone is not possible.[26]

Supportive therapy with continuous cardiac monitoring should occur in the Intensive Care Unit setting. Continue administering analgesics, sedatives, and neuromuscular blockade as required. Maintain a goal mean arterial pressure of 65 to 100 mmHg with a central venous pressure of 8 to 12 mmHg. Monitor urine output and laboratory values to best manage the resulting cold diuresis. Maintain tight glucose control (108 to 144 mg/dL) to improve survival and neurologic outcomes.[3]

REWARMING

Rewarming typically begins 24 hours after the initiation of cooling. Gradual rewarming at a rate of 0.25°C to 0.5°C (0.45°F to 0.9°F) an hour over a 6 to 8 hour period helps prevent rapid changes in metabolic rate, electrolyte levels, and hemodynamics. Techniques include passive rewarming, resetting the temperature on commercial devices, and the application of heated-air blankets when needed.

Discontinue analgesics, sedatives, and neuromuscular blockade during the rewarming phase. In the landmark studies, Bernard stopped the neuromuscular blockade before 24 hours, while Holzer maintained blockade for 32 hours. Other published protocols call for medications to be held when the core temperature reaches 35.5°C to 36.5°C (95.9°F to 97.7°F). Treat shivering during the rewarming with a warm blanket and low dose meperidine.[27] Care must be taken to avoid hyperthermia/pyrexia (>37.5°C or 99.5°F) by treating with antipyretics and active cooling for 72 hours postarrest. Hypotension and hyperkalemia commonly occur during rewarming.[3] This requires close monitoring of the patient, the ECG tracings, and periodic laboratory analysis.[3]

Detailed protocols for therapeutic hypothermia from several institutions are available through the University of Pennsylvania's Center for Resuscitation Science at http://www.med.upenn.edu/resuscitation/hypothermia/protocols.shtml.

TECHNIQUE FOR PEDIATRIC PATIENTS

Although patients under the age of 18 were excluded from the landmark studies, the 2005 International Liaison Committee on Resuscitation recommends that the induction of hypothermia should be considered for 12 to 24 hours in children who remain comatose after resuscitation from a cardiac arrest. There are currently no published studies of the use of therapeutic hypothermia for pediatric survivors of a cardiac arrest. However, neonates with perinatal asphyxia have been treated successfully with external cooling elements for 72 hours with impressive results.[28] Consult a Pediatric Intensivist and Pediatric Cardiologist prior to inducing hypothermia in a patient under the age of 18 years. After considering the risks and benefits of therapeutic hypothermia, begin induction and maintenance with the techniques described previously.

AFTERCARE

Consult an Intensivist and Cardiologist. Admit the patient to the appropriate Intensive Care Unit. Therapeutic hypothermia requires Intensive Care Unit admission for ventilator management as well as the continuous monitoring of core temperature, cardiac rhythm, blood pressure, and central venous pressure. Sedatives and paralytics are required for patient comfort and shivering control. Obtain laboratory analyses every 4 hours or as clinically indicated. Further bedside cardiac testing or cardiac catheterization laboratory intervention may be performed by a Cardiologist to help determine and treat the precipitating coronary artery disease. Consult a Neurologist for an electroencephalogram (EEG) and other neurological testing to detect seizures and determine patient prognosis.[29]

Standard Intensive Care Unit and postcardiac arrest/acute coronary syndrome care should be applied to all patients after completion of therapeutic hypothermia. Consider the use of deep venous thrombosis prophylaxis with sequential compression devices, subcutaneous heparin, or subcutaneous low molecular weight heparin. Apply lacrilube to the patient's eyes every 4 to 6 hours to prevent a corneal abrasion or corneal ulceration from dry corneas. Consider the use of stress ulcer prophylaxis. Once the 24 hour therapeutic hypothermia period is completed, begin to rewarm the patient and wean any neuromuscular blockade and sedation. Extubation is determined and evaluated on a case-by-case basis.

COMPLICATIONS

Despite the proven safety and benefit of therapeutic hypothermia, Emergency Physicians must be aware of several complications. Shivering during the induction phase increases core temperature and oxygen consumption. Low dose meperidine, buspirone, and magnesium have been reported to lower the shivering threshold in awake hypothermic patients.[27,30] Magnesium sulfate has the added benefits of improving cooling rates through vasodilatation while acting as an antiarrhythmic.[31]

Pulmonary edema may occur with cooled IV fluid boluses. Arrhythmias may occur, especially with the use of endovascular cooling techniques. Hypothermic patients may be more susceptible to infection, especially pneumonia and sepsis. The landmark studies showed only an insignificant trend toward increased sepsis. Postcardiac arrest patients are at high risk of developing pneumonia in the first 48 hours, with aspiration being a key risk factor.[3]

A coagulopathy may occur due to changes in platelet function, clotting factor enzyme function, and fibrinolytic activity. However, thrombolytics, heparin, and aspirin may be safely administered during induction when clinically indicated.[14] A cold diuresis may lead to electrolyte abnormalities including hypophosphatemia, hypomagnesemia, hypocalcemia, and hypokalemia, or hyperkalemia. Hyperglycemia must be avoided to improve neurologic outcomes after cardiac arrest and in all critically ill patients. Increases in amylase and a transient rise in renal markers have been reported but are of unclear significance. Decreased core temperature often prolongs the duration of action of neuromuscular blockers such as Vecuronium as well as sedatives including Versed or Propofol.[32]

The cooling devices themselves may be as source of complications. The endovascular catheter of internal cooling devices increases risk of infections and venous thrombosis similar to any central venous catheter.[24] External cooling devices may cause skin breakdown and tissue necrosis.[23]

SUMMARY

The staggering number of sudden cardiac deaths and the often poor neurologic outcomes of survivors place an enormous burden on the healthcare system. Two well done landmark studies in 2002 clearly demonstrated improved survival and neurologic outcomes in comatose survivors of an out-of-hospital cardiac arrest with an initial rhythm of pulseless ventricular tachycardia or ventricular fibrillation treated with mild therapeutic hypothermia of 32°C to 34°C (89.6°F to 93.2°F) for 12 to 24 hours. These results were incorporated into both the 2005 recommendations by the International Liaison Committee on Resuscitation and subsequently by the 2005 American Heart Association Resuscitation Guidelines. These organizations recommend therapeutic hypothermia for comatose survivors of an out-of-hospital cardiac arrest with an initial rhythm of ventricular fibrillation or pulseless ventricular tachycardia. They also recommend the consideration of therapeutic hypothermia in other rhythms and in-hospital cardiac arrests. After establishment of institution-specific multidisciplinary protocols, the induction of therapeutic hypothermia is a straightforward, inexpensive, safe, and effective procedure in any Emergency Department.

189 Hypothermic Patient Management

Gary An and Nabil Issa

INTRODUCTION

Hypothermia is defined as a core body temperature below 35°C. The normal physiologic thermoregulatory responses start to fail once the core body temperature reaches this level, leading to the body's inability to generate enough heat to maintain bodily functions. Hypothermia can be subdivided into primary and secondary hypothermia.[1] Primary accidental hypothermia occurs when a previously normal individual is subjected to an environmental stress. Secondary accidental hypothermia occurs when a predisposing factor leads to disruption of temperature homeostasis and increases the individual's susceptibility to lesser environmental stresses (e.g., drug intoxication, trauma, and endocrine disorders). Drug intoxication and trauma are acquired conditions that are highly associated with the development of hypothermia.[1]

There are multiple reasons why trauma patients are at an increased risk to develop hypothermia. These include extended prehospital time, resuscitation with cold (i.e., ambient air temperature) intravenous fluids, exposure to environmental factors, and physiological characteristics of the trauma itself. Both bleeding and hypoperfusion alter thermoregulation. Hypothermia is an independent contributing factor for increased morbidity and mortality in trauma patients, regardless of the patient's Injury Severity Score (ISS). Hypothermia is associated with an increase in the incidence of coagulopathy, multiple organ failure, length of hospital stay, and mortality.[2]

Significant emphasis has been placed on the prevention of hypothermia as well as the early recognition and correction of hypothermia in the prehospital setting. **It is important to recognize that hypothermia can also progress after the patient arrives in the Emergency Department.** Studies in the trauma population have reported a significant percentage of patients to have a decrease in their core body temperature during their stay in the Emergency Department.[3–5] This recognition has led to the development of multidisciplinary approaches to maintaining normothermia as the patient moves through the hospital.[6] **The importance of continuity and communication in dealing with hypothermia cannot be overstated.**

ANATOMY AND PATHOPHYSIOLOGY

Hypothermia can be characterized as mild, moderate, and severe. Mild hypothermia is defined as a core temperature of 32.2 to 35°C or 90 to 95°F. Moderate hypothermia is defined as a core temperature of 28 to 32°C or 82.4 to 90°F. Severe hypothermia is defined as a core temperature of less than 28°C or 82.4°F. The scale can be amended in the trauma patient to 34 to 36°C or 93.2 to 96.8°F for mild hypothermia, 32 to 34°C or 89.6 to 93.2°F for moderate hypothermia, and <32°C or <89.6°F for severe hypothermia.

Mild hypothermia causes the body to increase heat production by shivering and increasing its metabolic rate. The heart rate increases and the patient may become tachypneic. Peripheral vasoconstriction may result in acrocyanosis. Neurologic symptoms may include confusion, dysarthria, and impaired judgment.

Moderate hypothermia is associated with a further decrease in the mental status. This includes lethargy, hallucinations, and loss of the pupillary reflex. The heart rate changes from tachycardia to bradycardia. The cardiac rhythm commonly converts from normal sinus to atrial fibrillation.[7] The respiratory pattern becomes depressed, with a decreasing respiratory rate and tidal volume. The patient stops complaining of "feeling cold" and shivers less.

The patient is usually comatose by the time severe hypothermia is present, often with evidence of cardiorespiratory collapse. Ventricular irritability becomes evident. Ventricular fibrillation becomes refractory to conversion below 28°C. Asystole occurs at 20°C. The characteristic electrocardiographic (ECG) finding of an Osborne J wave occurs at approximately 32°C (**Figure 189-1**). This is a positive deflection between the QRS and the ST segment. It is often best seen in ECG leads aVL, aVF, and the left chest leads.[8,9] Respiratory drive is increased during the early stages of hypothermia, but progressive respiratory depression occurs below 33°C, resulting in a decrease in minute ventilation. The ciliary action and the cough reflex are also depressed, predisposing to atelectasis and aspiration.

Metabolic problems associated with hypothermia include hyperglycemia (mild hypothermia), hypoglycemia (moderate and severe hypothermia), and impaired oxygen consumption (severe hypothermia). Oxygen consumption per unit time (VO_2) increases dramatically with any fall in body temperature.[10] A core temperature decrease of 0.3°C is associated with a 7% increase in VO_2. Temperature reductions between 0.3 and 1.2°C have been reported to result in a 92% increase in VO_2, with proportional increases in minute ventilation.[10] The resultant increase in oxygen utilization may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress.[11]

Serum electrolyte changes are often unpredictable in the hypothermic patient. Serum potassium is often slightly increased because of renal tubular dysfunction, acidosis, and the breakdown of liver glycogen. When interpreting blood test results, it is recommended that uncorrected values be used to guide therapy due to

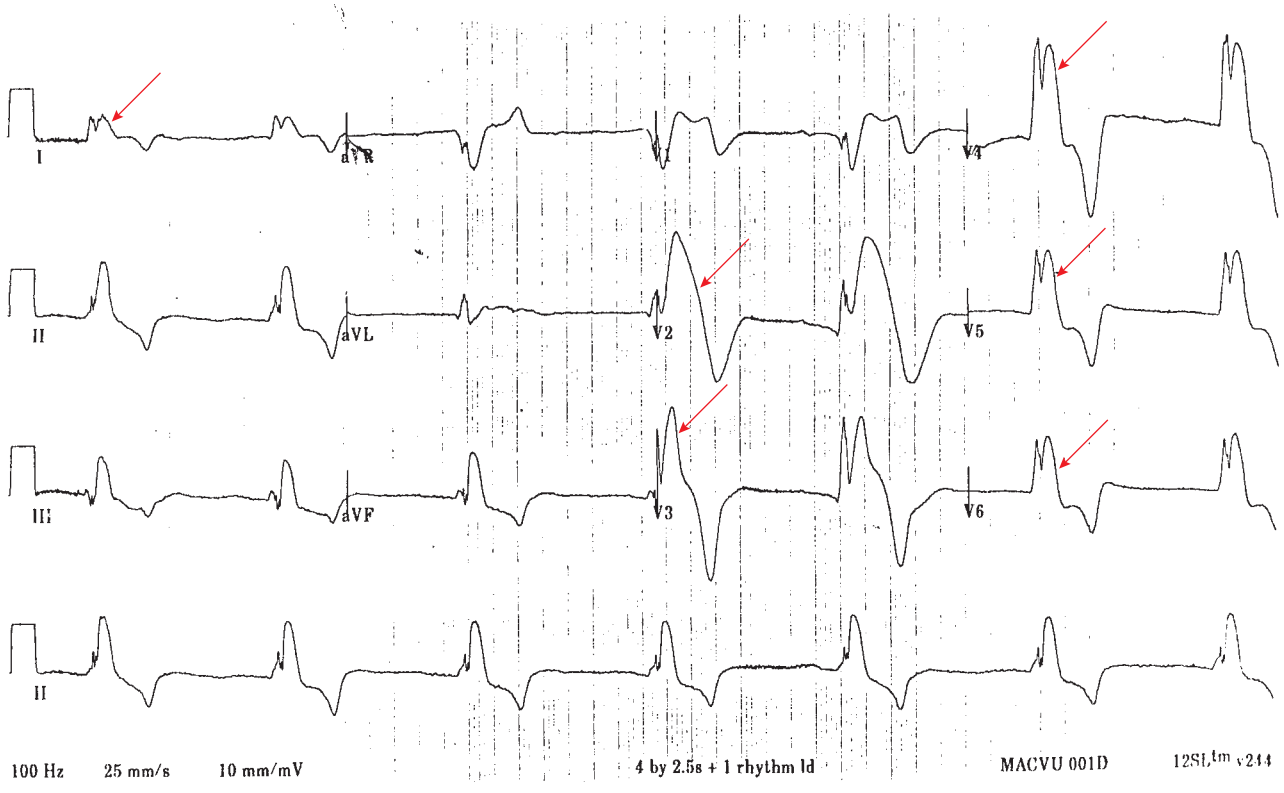

FIGURE 189-1. The Osborne or J wave associated with hypothermia is indicated by the arrows. This patient had a core temperature of 34°C.

the complexities of the acid–base balance associated with hypothermia. These derangements are reversible with rewarming.

Coagulopathy is one of the most clinically significant metabolic derangements seen with hypothermia. Evidence suggests that significantly increased clotting times occur at core temperatures less than 35°C.[1,3] Temperatures less than 32°C lead to severe platelet dysfunction despite normal platelet counts.[1,3] Cold platelets are known to undergo morphologic changes that affect adherence, including loss of shape, cytoplasmic swelling, and dissolution of cytoplasmic microtubules necessary for normal motility. Cold-induced slowing of the enzymatic reaction rate of thromboxane synthetase results in decreased production of thromboxane A2, a potent vasoconstrictor necessary for normal platelet aggregation.[12,13] These derangements are reversible with rewarming. Clotting factor dysfunction is another factor contributing to the coagulopathy in the hypothermic patient. This has been shown to be due to the direct effect of hypothermia on the clotting factors physiochemical activity.[14] It is important to remember that clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. Thus, tests of coagulation reflect clotting factor deficiencies, but are corrected for any potential effect of hypothermia on clotting factor function.

The heat deficit of a hypothermic patient can be calculated using the formula $Q = mc(t_2 - t_1)$, where Q is the heat loss (in kcal), m is the patient's body mass (in kg), c is the specific heat of the body (0.83 kcal/kg/°C), and $(t_2 - t_1)$ is the change in body temperature (°C). Application of this formula will allow the calculation of the amount of heat (in kcal) that must be transferred to a hypothermic patient to regain normothermia, assuming no additional losses. Knowing that the specific heat of water is 1.0 kcal/kg/°C allows one to calculate the expected rate of rewarming given the particular method used.

INDICATIONS

Patients presenting with core body temperatures in the ranges of hypothermia must be identified and treated. **Hypothermia should be easily identified, since a temperature evaluation is a vital sign checked in every patient that comes to the Emergency Department.** Treat all patients who present to an Emergency Department with an awareness of the potential that they can develop hypothermia, especially if they are trauma patients or have an altered mental status. **Cover all patients with warm sheets or blankets as soon as their initial evaluation and any necessary procedures are completed.**

CONTRAINDICATIONS

There are no contraindications to the treatment of accidental hypothermia. There are, however, circumstances in which medically induced therapeutic hypothermia may be of benefit.[15–18] Refer to Chapter 188 regarding the details of inducing therapeutic hypothermia. These situations are beyond the scope of this chapter.

SPECIAL RESUSCITATION CONSIDERATIONS

Certain components of the initial resuscitation of the hypothermic patient deserve mention. **All patients with hypothermia are identified by measurement of core body temperature on admission. Close subsequent monitoring is necessary and required.** The following challenges to routine temperature monitoring, and suggested remedies, were noted in a review article.[9] Poor peripheral perfusion may result in difficulty assessing the pulse and blood pressure, making the use of Doppler ultrasound necessary. Cutaneous probes for temperature and pulse oximetry have difficulty picking up signals in hypothermic patients. Oral and auricular temperature

probes are often inaccurate in the hypothermic patient. Consider using a bladder, esophageal, or rectal temperature probe.

Airway management is often required in patients with moderate and severe hypothermia due to a decreased mental status. Standard orotracheal intubation may be difficult due to jaw muscle rigidity. Neuromuscular blocking agents are not recommended for patients with core body temperatures less than 30°C. The use of topical vasoconstricting agents, smaller endotracheal tubes, and blind orotracheal intubation has been suggested. Fiberoptic guided orotracheal intubation can be utilized if available. Management of ventilated patients must include close monitoring of the endotracheal cuff pressure, as the volume and pressure may increase with patient rewarming. Ventilate patients at rates no greater than 8 to 12 breaths per minute to avoid respiratory alkalosis.[9]

Management of the circulatory system in those with moderate to severe hypothermia often requires fluid resuscitation, as these patients are volume depleted. Dextrose in the initial resuscitation fluid is not contraindicated. **Ringer's lactate solution is not recommended due to concerns about decreased hepatic metabolism of lactate in the hypothermic patient.** Dehydration results in hemoconcentration. Therefore, a low hematocrit suggests an underlying anemia and/or blood loss. **The heart is susceptible to arrhythmias. Avoid transthoracic central venous catheters and pulmonary artery catheters until rewarming has been achieved.** Use intravenous catheters in any of the extremities or the external jugular vein. An alternative is a femoral central line as the catheter and guidewire are not long enough to reach the heart and trigger an arrhythmia.

Treat nonperfusing cardiac rhythms (i.e., ventricular fibrillation, asystole, and junctional ventricular rhythms) using Advanced Cardiac Life Support (ACLS) guidelines. The presence of bradycardia, atrial fibrillation, and other dysrhythmias that do not reduce perfusion do not require pharmacologic support, as these will reverse with rewarming. **Defibrillation at core body temperatures less than 30 to 32°C may not be effective. Continue resuscitative efforts in conjunction with rewarming.**[8,9]

Resuscitation drugs are often ineffective at core body temperatures below 30°C. Lidocaine has decreased efficacy at these temperatures.[8,9] Procainamide has been suggested to increase ventricular fibrillation.[8,9] Bretylium has been demonstrated to be effective in animal studies, though information regarding optimal clinical dosage is not known in this patient group.[8,9] **Use caution when administering and dosing all resuscitation drugs, due to their decreased metabolism in hypothermic patients, which can lead to toxicity.** It is recommended that medications be administered at one-half the normal dose during the resuscitation of a moderately or severely hypothermic patient.[9] Avoid vasopressors due to their potential to cause arrhythmias.[9] Repeat the resuscitation cycle with every increase in core body temperature of 1 to 2°C until a core temperature of 32°C is achieved.[8] **Patients should not be pronounced dead until they are warm (>32°C) and dead.[9]**

FLUID MANAGEMENT

The administration of fluids or blood products can result in hypothermia or worsen it. Infusion of 1 L of crystalloid solution kept at room temperature (21°C) results in a decrease in core body temperature of 0.3°C.[1] **When patients are receiving large volumes of resuscitation fluid, active measures to prevent hypothermia must be taken.** This is even more important in patients receiving blood products, which are kept at 4.0°C. Transfusion of 1 L of blood products leads to a decrease in core body temperature of 0.54°C.[1] **A normothermic patient can be rendered hypothermic quickly when subjected to an aggressive fluid resuscitation.**

One of the mainstays in the prevention of hypothermia during resuscitation is to use fluid warmers to infuse intravenous fluids. Unfortunately, conventional fluid warmers use a coil/sleeve system in a water bath and pose problems at both slow and rapid infusion rates.[19] With a slow infusion rate, there is time for the fluid to reach room temperature in the tubing between the warmer and the patient. With a fast infusion rate, the length of time the fluid is exposed to the water bath is too short to effectively warm the fluid.

These problems have been addressed with two devices, both of which are useful in the Emergency Department. They both warm infused fluid to a temperature of 40°C. The first uses a jacket in which circulating warmed fluid covers the entire length of the intravenous tubing, from the warming device to the patient (Hotline, Sims Level 1, Rockland, MA). This device is more effective than conventional fluid warmers at flow rates between 50 and 6000 mL/h.[19] The second device uses an inline heating unit that warms the fluid rapidly and allows for substantially higher infusion rates (Systems 250/500/1000, Sims Level 1, Rockland, MA). This device can infuse crystalloid solutions or blood products at rates up to 2200 mL/min and is extremely useful in the resuscitation of patients in severe hemorrhagic shock.[19] Similar devices are available from a variety of manufacturers. **Use these devices to administer intravenous fluid to hypothermic patients or to those at risk for developing hypothermia.** These devices may be used as components in some of the techniques described below.

PASSIVE EXTERNAL REWARMING

Perform passive external warming on all patients who are mildly hypothermic or who have normal body temperatures and are undressed. Cover the patient with sheets and blankets as soon as they have been examined and any necessary procedures have been performed. If available, the use of warm blankets and sheets is preferred over those at room temperature.

TECHNIQUES

Remove any wet and/or cold clothing. Dry the patient before applying blankets (Figure 189-2). Blankets and sheets may be kept in a blanket warmer as insulating material cooler than the patient will extract heat. **Prevent secondary injury to the patient from**

FIGURE 189-2. Passive external rewarming. Remove any wet and/or cold clothes. Cover the patient with blankets.

FIGURE 189-3. Active external rewarming with a heating blanket.

blankets and sheets that are too hot. There is no reason for the blankets to be any warmer than normal body temperature for passive external rewarming.

ASSESSMENT

An otherwise healthy and normal patient will increase their core body temperature by 0.5 to 2.0°C/h with passive external rewarming. The body attempts to regain normothermia by increasing its metabolic rate. The patient may manifest evidence of increased cardiopulmonary stress and lactic acidosis during this time.[1]

COMPLICATIONS

Complications occur if attempts are made to place inappropriately heated objects directly on the patient. **Under no circumstances should heated intravenous fluid bags be placed in the axilla or groin, or in any other prolonged contact with the skin.** This may result in thermal injuries ranging from superficial blistering to full-thickness burns. Blankets and sheets that are too warm will also cause damage to the skin.

SUMMARY

Use passive external rewarming as a sole agent in otherwise healthy patients with normothermia who are undressed, patients with mild hypothermia, and as an adjunct to more aggressive rewarming techniques. Always be aware of the possibility of a patient developing hypothermia during their Emergency Department stay.

ACTIVE EXTERNAL REWARMING

INDICATIONS

Perform these maneuvers as sole therapy for patients with mild hypothermia, on awake and otherwise stable patients with moderate hypothermia, and in conjunction with more aggressive rewarming techniques.

CONTRAINDICATIONS

Do not use active external rewarming as the sole therapy for patients with moderate hypothermia who have altered mental status or hemodynamic instability. Active external rewarming is contraindicated as the sole therapy for patients with severe hypothermia (core temperature < 28°C). **There is no significant difference in the rates of rewarming between the different devices used for external rewarming. The use of radiant heaters and heating packs is not currently recommended due to the risk of potential complications and limited efficacy.**[20,21]

EQUIPMENT

- Warm blankets
- Forced air rewarming blankets
- Fluid circulating rewarming blankets
- Water bath and associated supplies

TECHNIQUE

Examine the patient. Determine if the patient is a candidate for active external rewarming. Place a forced air rewarming blanket or a fluid circulating rewarming blanket on the patient (**Figure 189-3**). **Do not place these blankets, particularly the fluid circulating ones, underneath the patient.** Placing the blanket under the patient may lead to excessive thermal transfer to areas with decreased blood flow due to pressure and prolonged time of contact. A thin sheet may be placed between a fluid circulating blanket and the skin. This is not necessary with forced air blankets. Warmed blankets and sheets may be placed over the warming blankets.

Active external rewarming can be accomplished by immersion of the patient in a warm water bath (**Figure 189-4**). This technique is easy, effective, and simple. Immersion therapy of the hypothermic patient is not performed in the Emergency Department for several reasons. The equipment is bulky, not portable, and occupies a fixed space. It is difficult to monitor the patient when immersed. Monitoring leads (e.g., electrocardiography and pulse oximetry) will not adhere to wet skin. The use of electrical monitoring equipment in a water bath should be avoided.

ASSESSMENT

Care must be taken to reassess any wounds for recurrent bleeding, any catheters or monitors for placement, and any pressure areas

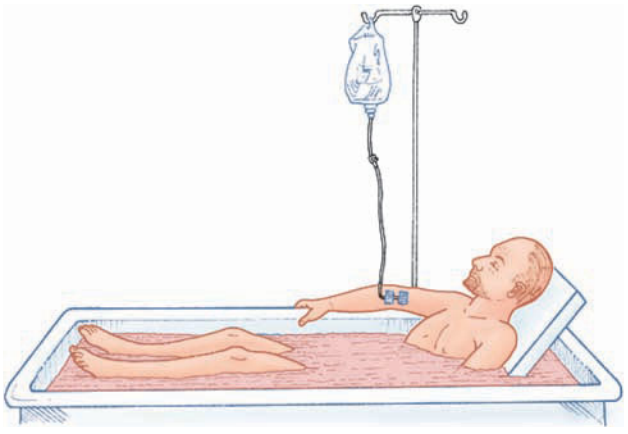

FIGURE 189-4. Active external rewarming with a water bath.

that might be in prolonged contact with the heating elements as the patient is covered with the warming device. With respect to the forced air blankets, check the air source connection to the blanket to make sure that the hot air is not blowing directly onto the patient. A directed flow of hot air onto the patient under the blanket may lead to thermal injury.

COMPLICATIONS

Thermal injuries are associated with active external rewarming. They result from improper use of the devices. Maintain vigilance regarding prevention of a focused delivery of heat to a region of skin, particularly one poorly perfused, to essentially eliminate these burns.

Afterdrop refers to a decrease in core temperature that occurs 15 to 20 minutes after active external rewarming begins.[8] This is thought to be due to vasodilatation of the peripheral tissues as they rewarm and a subsequent washout of cooler peripheral blood back to the central areas. Peripheral vasodilatation can lead to hypotension if fluid resuscitation is inadequate or the patient has cardiovascular compromise. Afterdrop can be attenuated by the concomitant use of core rewarming techniques.

SUMMARY

Active external rewarming is useful in treating moderately hypothermic patients who are awake and alert. Warming rates of 1.0 to 2.5°C/h have been reported.[9] When these devices are being used, frequent monitoring for potential thermal injuries is required in order to prevent secondary injury. This monitoring is easier when the patient is a cooperative partner who can participate in the process. Active external rewarming, like passive external rewarming, is often used in conjunction with more aggressive techniques or core rewarming. The problem of afterdrop is lessened when active external rewarming is used in conjunction with core warming techniques.

AIRWAY REWARMING

Airway rewarming with warmed and humidified oxygen is safe and easily achieved. It can be applied to any hypothermic patient. **However, airway rewarming is never used as a sole means of rewarming.**

INDICATIONS

The technique of airway rewarming may be used in any patient with hypothermia and in conjunction with other techniques. Any patient receiving supplementary oxygen can receive warmed and humidified oxygen. Its efficacy via endotracheal tube is greater than via mask or nasal prongs.

CONTRAINDICATIONS

There are no contraindications to airway rewarming. The more severely hypothermic patient will often need their airway controlled by orotracheal intubation due to a depressed level of consciousness. **Intubation for the sole purpose of airway rewarming is contraindicated.**

EQUIPMENT

- Nasal cannula
- Face mask
- Endotracheal tubes
- Humidifier tank
- Heating circuit
- Oxygen source

TECHNIQUES

Consult the Emergency Department Respiratory Therapist. They will gather, set up, administer, and monitor the required equipment. Connect the humidifier tank and heating circuit in line with the oxygen source. Humidify and warm the inhaled oxygen to 40 to 45°C. A rewarming rate of 1.0 to 2.5°C/h has been reported.[9]

SUMMARY

Airway rewarming can be applied to any hypothermic patient. The oxygen must be humidified to prevent fluid loss from evaporation.

GASTRIC AND BLADDER LAVAGE

These techniques, based on techniques familiar to most Emergency Physicians, are minimally invasive and can be readily performed with minimal interruption of continued resuscitative efforts.

INDICATIONS

These techniques are usually reserved for patients with severe hypothermia. They are rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available.

CONTRAINDICATIONS

The only contraindications to these techniques are the contraindications to the placement of a urethral catheter (Chapter 142) and a nasogastric tube (Chapter 58). Do not perform gastric lavage concurrently with cardiac compressions. Gastric and bladder lavage are of limited value in the management of the hypothermic patient. They are generally bypassed in favor of peritoneal lavage, pleural lavage, and extracorporeal warming.

EQUIPMENT

- Warmed (40°C) intravenous fluid, normal saline or Ringer's lactate
- 60 mL catheter-tip syringe
- See Chapter 142 for urethral catheterization supplies
- See Chapter 58 for nasogastric intubation supplies

TECHNIQUES

Place a Foley catheter (Chapter 142) and/or nasogastric tube (Chapter 58). Confirm proper placement. Instill sterile saline or Ringer's lactate warmed to 40°C. Inject 60 mL aliquots into the tube using the catheter-tip syringe. Instill a total of 300 to 400 mL into the stomach and 200 to 250 mL into the bladder. **Do not overdistend the respective organ.** Gastric overdistention can result in rupture or aspiration. Bladder overdistention can result in rupture and extravasation of fluid. Clamp the Foley catheter or nasogastric tube. Allow the fluid to dwell within the organ for 5 to 10 minutes. Remove the fluid by gravity drainage from the bladder or suction from the stomach. Repeat the process as necessary until the core body temperature increases.

COMPLICATIONS

Gastric lavage may be complicated by perforation of the stomach by either the nasogastric tube or overdistention. Aspiration is a potential complication with gastric lavage. Refer to Chapters 58 and 60 for a more complete discussion of the complications associated with nasogastric intubation and gastric lavage, respectively. Bladder irrigation is safe as long as the bladder is not overdistended. The small surface area of the bladder makes it an inefficient means of rewarming. Refer to Chapter 142 for a more complete discussion of the complications associated with urethral catheterization. Use only normal saline or Ringer's lactate. Do not use sterile water, as it can result in significant volume and electrolyte shifts.

SUMMARY

Perform gastric or bladder irrigation only if other types of body cavity rewarming are contraindicated. These techniques are easily initiated using standard equipment in an Emergency Department. These organs have relatively small surface areas, making these techniques inefficient. Overdistention can result in serious complications.

PERITONEAL LAVAGE

This technique is invasive, based on techniques familiar to most Emergency Physicians, and can be readily performed with minimal interruption of resuscitative efforts.

INDICATIONS

This technique is usually reserved for patients with severe hypothermia. It is rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available.

CONTRAINDICATIONS

Suspicion of injury to a hollow viscus is a contraindication to this technique. The presence of a previous laparotomy scar is a strong relative contraindication. The use of an open peritoneal lavage technique does not mesh well with the continuous infusion of fluid required for this procedure. Other contraindications are those associated with performing a diagnostic peritoneal lavage (Chapter 66).

EQUIPMENT

- Warm (40°C) intravenous fluid, normal saline or Ringer's lactate
- Warm (40°C) peritoneal dialysis fluid
- Fluid infuser device, optional
- Peritoneal lavage kits
- See Chapter 66 for peritoneal lavage supplies
- See Chapter 58 for nasogastric tube supplies
- See Chapter 142 for Foley catheter supplies

A commercially available, disposable, single-patient use peritoneal lavage kit is available from numerous manufacturers. The kit includes all the material required to perform a closed or semi-open diagnostic peritoneal lavage except lavage fluid. An example is the Arrow kit (Arrow International, Reading, PA). It contains 10% povidone iodine or chlorhexidine swabs, gauze squares, fenestrated drape, tubing for the administration of intravenous fluid, 1% lidocaine, 5 mL syringes, 22 and 25 gauge needles, an 18 gauge × 2.5 inch introducer needle, an 0.89 mm × 45 cm J-tipped guidewire, an 8 French lavage catheter, and a #11 scalpel blade on a handle. Refer to Chapter 66 for a more complete list of equipment.

TECHNIQUE

Prepare the patient by placing a nasogastric tube (Chapter 58) and a Foley catheter (Chapter 142). Place two peritoneal lavage catheters, one supraumbilical and one infraumbilical (**Figure 189-5**). Refer to Chapter 66 for complete details regarding placement of the peritoneal lavage catheters. Confirm the position of the catheters. Clamp the infraumbilical catheter. Infuse warm (40°C) intravenous fluid or peritoneal dialysis fluid through the supraumbilical catheter using the Level 1 infuser or a Hotline fluid warmer. The use of dialysate has the added benefit of potentially correcting some electrolyte abnormalities.[8,9] The fluid may be infused manually, but this technique is much less efficient. Infuse 1 to 2 L of fluid. Allow the fluid to bathe the peritoneal cavity for 10 minutes. Remove the clamp on the infraumbilical catheter and allow the fluid to drain from the peritoneal cavity. Repeat the procedure. Up to 10 L/h of

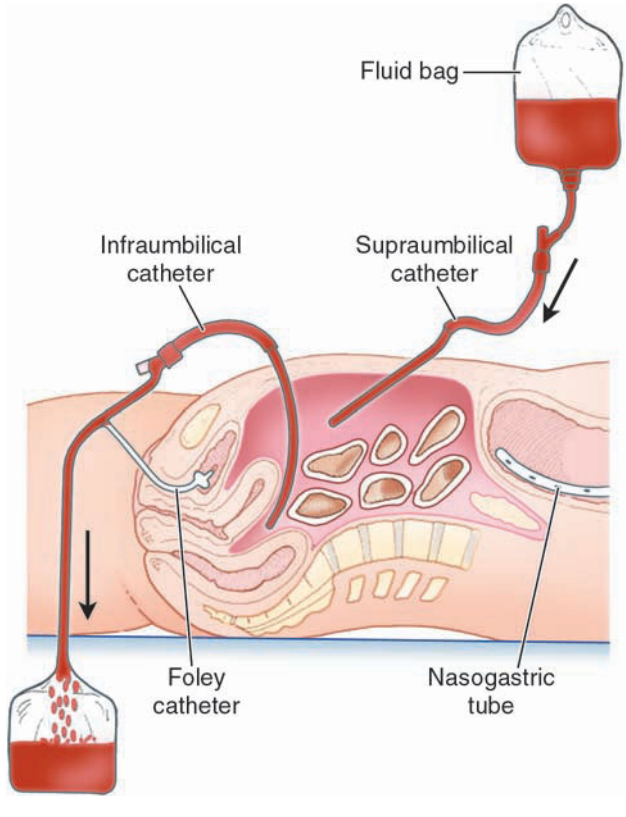

FIGURE 189-5. Active core rewarming with peritoneal lavage.

fluid may be infused in this fashion.[9] An alternative technique is to allow the fluid to flow at a moderate rate and continuously through the supraumbilical catheter, into the peritoneal cavity, and out the infraumbilical catheter. This can be performed manually or with a commercial device developed for this purpose (Veratherm Portable Hyperthermic Perfusion System, Thermal Therapeutic Systems Inc., Pittsburgh, PA).

COMPLICATIONS

The potential complications are primarily associated with the placement of the peritoneal lavage catheter. Refer to Chapter 66 for the details regarding these complications. The infusion and removal of the fluid are safe. Avoid using highly hyperosmolar peritoneal dialysates in patients with persistent hypovolemia or with a questionable perfusion status as this may worsen existing hypovolemia. Do not use sterile water, as it can result in significant volume and electrolyte shifts.

SUMMARY

Peritoneal lavage is the most widely recognized means of body cavity lavage. This is due in part to the familiarity of many Emergency Physicians with the diagnostic peritoneal lavage procedure. It has the advantage of being able to be performed concurrently with chest compressions and other resuscitative efforts. This technique can raise the core body temperature by 1 to 3°C/h.

PLEURAL LAVAGE

This technique is invasive, based on techniques familiar to most Emergency Physicians, and can be readily performed with minimal interruption of resuscitative efforts. Pleural lavage can be performed closed (via a tube thoracostomy) or open (via a thoracotomy incision).

INDICATIONS

This technique is usually reserved for patients with severe hypothermia. It is rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available.

CONTRAINDICATIONS

The presence of a pneumothorax and/or hemothorax is the only contraindication to pleural lavage.

EQUIPMENT

- See Chapter 39 for tube thoracostomy supplies
- Warm (40°C) intravenous fluid, normal saline or Ringer's lactate
- Warm (40°C) peritoneal dialysate
- Fluid infuser device, optional

TECHNIQUE

Place two chest tubes into the same pleural space, either the left or the right side, to perform closed pleural lavage (**Figure 189-6**). The left side is preferred by those who believe that the heart, aorta, and blood within the aorta will be warmed quicker than with right-sided chest tubes. Refer to Chapter 39 for the full details regarding chest tube placement. Place one tube anteriorly in the second or third intercostal space at the midclavicular line (**Figure 189-6**). Place the other tube posteriorly in the fifth or sixth intercostal space at the posterior axillary line (**Figure 189-6**). Secure the tubes

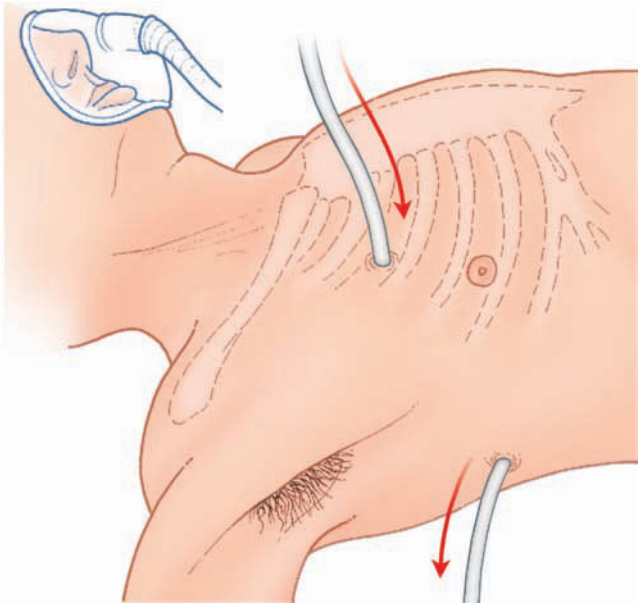

FIGURE 189-6. Active core rewarming with closed pleural lavage.

to the chest wall with suture and tape. Attach the fluid infuser to the anterior chest tube using a Christmas tree adapter. Apply a pleural drainage device to the posterior chest tube in the usual fashion. Infuse warm (40°C) fluid via the fluid infuser device at a rate of 180 to 550 mL/min.[8] Allow the fluid to exit into the pleural drainage device. The fluid will flow into the anterior chest tube, bathe the structures in the hemithorax (i.e., great vessels, heart, lung, and mediastinum), and exit via the posterior chest tube. This can be performed manually or with a commercial device developed for this purpose (Veratherm Portable Hyperthermic Perfusion System, Thermal Therapeutic Systems Inc., Pittsburgh, PA).

Pleural lavage may be performed using an open technique (**Figure 189-7**). This technique is used when a thoracotomy is indicated for other purposes, such as penetrating trauma or to perform open cardiac massage. Refer to Chapter 42 for full details regarding a thoracotomy. **Do not use this technique for the sole purpose of rewarming if other, less invasive or extracorporeal techniques**

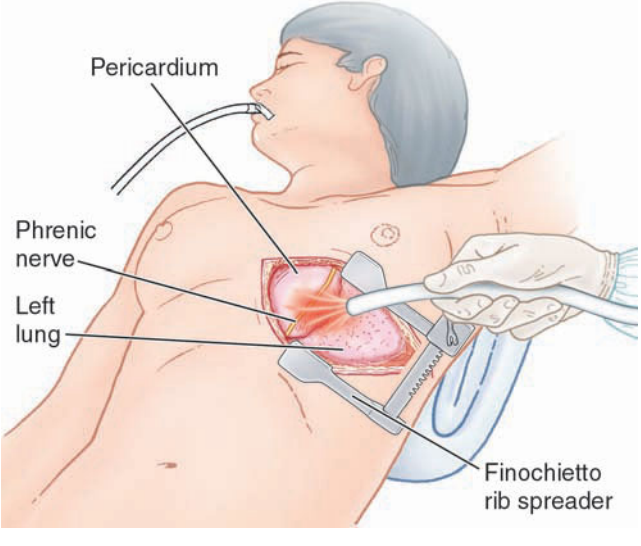

FIGURE 189-7. Active core rewarming with open pleural lavage.

are available. The advantage of open pleural lavage is that it allows direct cardiac rewarming and open cardiac massage.

COMPLICATIONS

The complications are primarily associated with the placement of the chest tube. Refer to Chapter 39 for the full details regarding these complications. Maintain free drainage of the irrigation fluid to avoid increasing the intrathoracic pressure.

SUMMARY

Closed pleural lavage is an effective means of rewarming. It can increase the core body temperature by 1 to 5°C/h. It is very similar in efficacy to peritoneal lavage. Chest tube placement is slightly more challenging than placement of a peritoneal lavage catheter. Free drainage is usually easier to achieve and maintain with a chest tube than with a peritoneal lavage catheter. The two techniques may be employed simultaneously and carried out in conjunction with other resuscitative measures.

EXTRACORPOREAL REWARMING

Extracorporeal rewarming is the most aggressive, effective, and efficient technique to correct severe hypothermia. It includes the use of hemodialysis, arteriovenous rewarming, venovenous rewarming, continuous venovenous hemofiltration, cardiopulmonary bypass, and extracorporeal membrane oxygenation. The choice between the techniques is made on the basis of available resources and the Emergency Physician's familiarity with each technique. Cardiopulmonary bypass is discussed but should not be performed by anyone who is not a Surgeon familiar with the procedure.

HEMODIALYSIS

Hemodialysis is readily available in most institutions. It requires the placement of a central venous line. The only contraindications to hemodialysis are those associated with central venous line placement (Chapter 49) and hemodialysis. An advantage of hemodialysis is that associated drug toxicity or significant electrolyte abnormalities can be simultaneously managed as the patient is being rewarmed.

EQUIPMENT

- See Chapter 49 for central line equipment
- Dual-lumen percutaneous hemodialysis (Quinton or Mahurkar) catheter
- Dialysis machine
- Dialysis nurse or technician
- Warmed (40°C) dialysis fluid

TECHNIQUE

Place a hemodialysis catheter into a femoral vein. Refer to Chapter 49 for the full details regarding the placement of a double-lumen central venous line. The catheter may be placed into a subclavian vein if femoral vein access is contraindicated. Femoral vein placement decreases the risk of inducing an arrhythmia with the guidewire.[9] There is a tendency to have fewer problems related to the positioning of the catheter and achieving appropriate flow rates with femoral catheters. Instruct the hemodialysis technician to set the temperature control on the dialysis machine to deliver a blood temperature of 40°C. Attach the dialysis machine tubing to the lumens of the catheter. Begin hemodialysis.

COMPLICATIONS

The potential complications are primarily associated with the placement of the central venous line. Refer to Chapter 49 for the details regarding these complications. The hemodynamic status of hypotensive patients may become worse upon initiation of hemodialysis, but this technique has been successfully used on such patients.[9]

SUMMARY

Hemodialysis is available at most institutions and is effective in rewarming a patient. The limitations of this technique include the need to have a dialysis technician or nurse available, the time required to obtain on-call personnel, and the time required to set up the equipment. Hemodialysis is a viable option for the rewarming of a hypothermic patient when other forms of extracorporeal warming are not available.

ARTERIOVENOUS REWARMING

This technique was initially described in 1992.[22,23] The authors described placing one large-bore catheter in the femoral artery and another in a central vein (i.e., femoral, internal jugular, or subclavian). This method allows for rewarming in the Emergency Department without the need for specialized equipment (dialysis or bypass machine) and personnel.

CONTRAINDICATIONS

Hypotension or the lack of a blood pressure makes this method moot. Known occlusive arterial disease, particularly in the iliofemoral region, is a relative contraindication.

EQUIPMENT

- See Chapter 49 for central line equipment
- Two 8.5 French introducer catheters
- Two 10 French single-lumen arteriovenous hemofiltration catheters
- Sims Level 1 System 250/500/1000 Fluid Rewarmer
- Luer-lock adapter, male-to-male
- Warmed (40°C) saline

TECHNIQUE

Place two catheters, one in the femoral artery and one in a central vein. Refer to Chapter 49 regarding the placement of a central venous catheter. The placement of the arterial catheter is similar to that of the venous catheter.

The tubing for the Level 1 rapid infuser consists of two intravenous spike-tipped lengths that come together in a Y. The Y then runs to a countercurrent warming chamber and then to the patient. Cut off the spike tip from one of the limbs of the Y and attach the male-to-male Luer-lock adapter. Note that if the rapid fluid infuser is a Sims Level 1 System 500, an additional length of wide-bore intravenous tubing may be needed to bridge the distance between the arterial catheter and the fluid-warmer tubing. This version of the Level 1 may be too tall to allow direct connection of one of the limbs to the arterial catheter. Connect this limb to the arterial catheter. Connect the other arm of the Y to a bag of intravenous fluid with the roller clamp closed.

Allow the system to prime with blood under the patient's arterial pressure. Connect the primed distal end of the tubing to the central venous catheter. The blood will travel via the arterial catheter

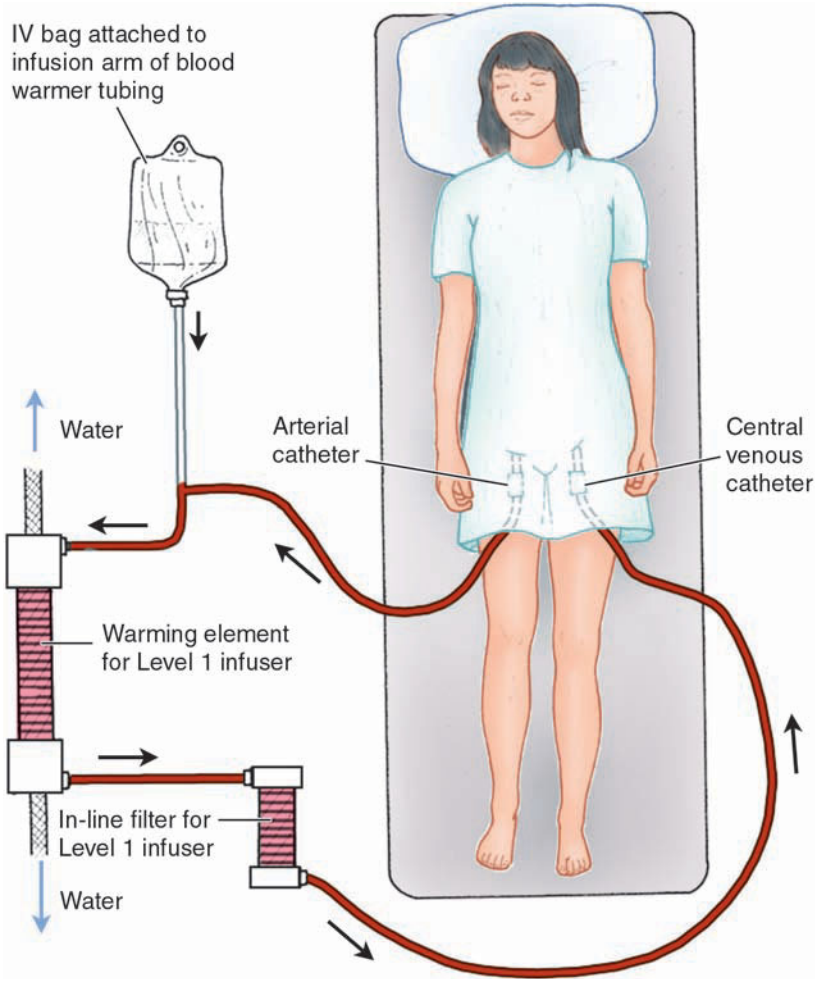

FIGURE 189-8. Arteriovenous rewarming.

to the extracorporeal circuit and through the proximal limb of the tubing to the warming chamber of the Level 1 infuser, through the heating elements to the distal tubing, and back to the patient via the venous catheter (**Figure 189-8**).

The driving force in this circuit is the patient's systemic blood pressure. Low-flow states will limit the efficacy of the system. However, you may use a pressure infusion of intravenous fluid via the other limb of the Y to augment flow. This fluid will be warmed as it reaches the patient, since this other limb of the Y is proximal to the warming element. Systemic anticoagulation is not required, as the tubing for the Level 1 infuser is heparin-bonded. Arteriovenous rewarming is faster and more efficient than venovenous rewarming.[33]

COMPLICATIONS

The complications outlined in the initial description of the procedure include the inability to achieve vascular access, a small hematoma at the arterial puncture site, and ischemia of the limb distal to the arterial catheter.[22] Refer to Chapters 49 and 57 for a full description of the complications that may arise in placing a central venous catheter and arterial catheter, respectively.

SUMMARY

Arteriovenous rewarming is an innovative means by which severely hypothermic patients may be rapidly rewarmed without the resources of a dialysis or bypass pump technician. Flow rates of 225 to 375 mL/min are achieved when the patient's systolic blood pressure is greater than 90 mmHg.[22] This technique transfers 94 to 157 kcal/h back to a patient with core temperature of 32°C.[22]

VENOVENOUS REWARMING

This technique is rarely utilized by Emergency Physicians due to the lack of a venous roller pump and inexperience with this piece of equipment. The technique is briefly described for the sake of completeness. The venovenous technique has two main advantages over arteriovenous rewarming. First is the lack of arterial cannulation, with its potential for limb ischemia. The second is nonreliance on systemic blood pressure/perfusion to drive the system. Flow may be independently determined and delivered by the roller pump. This may be particularly important in the severely hypothermic patient who presents in full cardiorespiratory arrest. The primary disadvantage of this technique is the requirement of expertise in using the roller pump, though advances in design may obviate this in the future.

CONTRAINDICATIONS

Persons not familiar with the function and operation of a venous roller pump should not attempt this technique.

EQUIPMENT

- See Chapter 37 for central line equipment
- Two 8.5 French introducer catheters

- Two 10 French single-lumen arteriovenous hemofiltration catheters
- Sims Level 1 System 250/500/1000 Fluid Rewarmer
- Luer-lock adapter, male-to-male
- Venous roller pump
- Warmed (40°C) saline

TECHNIQUE

The setup for this technique is similar to that for arteriovenous rewarming. Place two catheters, one in the femoral vein and one in another central vein. Refer to Chapter 49 for the details regarding the placement of a central venous catheter. Alternatively, place a dual-lumen hemodialysis catheter.[24] However, if the latter course is to be followed, make sure that the "outflow" port of the catheter is upstream and that the "inflow" port is downstream. This helps to reduce the amount of warmed fluid returning from the circuit that is immediately withdrawn by the roller pump. Place the venous roller pump in line with this circuit, usually between the patient and the warming elements. Adjust the flow rate within the tolerances of the particular device being used.

COMPLICATIONS

The primary complication associated with use of venous roller pumps is an air embolus. This usually happens when the roller pump is operated by a person unfamiliar with it. Recent advancements in roller-pump technology have made their operation simpler and safer. Refer to Chapter 49 for a complete description of the complications that may arise due to the placement of a central venous catheter.

SUMMARY

Venovenous rewarming is one step away from cardiopulmonary bypass. Its use in the Emergency Department is limited due to lack of equipment availability and familiarity. It is a viable option if a roller pump is available as well as a Physician familiar with this procedure.

CONTINUOUS VENOVENOUS HEMOFILTRATION

Continuous venovenous hemofiltration (CVVH) machines have become more widely available, making this an attractive means of rewarming. The use of CVVH machines has largely replaced the previously described venovenous rewarming technique. This technique has two main advantages over arteriovenous rewarming. First is the lack of arterial cannulation, with its potential for limb ischemia. The second is nonreliance on systemic blood pressure/perfusion to drive the system. The use of CVVH in the management of moderate-to-severe accidental hypothermia has been shown to be rapid, safe, and effective.[23,25]

CONTRAINDICATIONS

Persons not familiar with the function and operation of a CVVH machine should not attempt this technique.

EQUIPMENT

- See Chapter 49 for central line equipment
- Dual-lumen percutaneous hemodialysis (Quinton or Mahurkar) catheter
- CVVH Dialysis machine
- Dialysis nurse or technician, trained ICU nurse
- Warmed (40°C) dialysis fluid

TECHNIQUE

As with standard hemodialysis techniques, rewarming with CVVH utilizes a single intravenously inserted, dual-lumen catheter placed in a central vein and connected to the CVVH dialysis machine. Some CVVH dialysis machines have a built-in thermostat allowing for temperature control while others depend on circulating already warmed dialysis fluid bags. Passive and/or active external rewarming maneuvers should be used in conjunction to the CVVH technique. Continuous cardiopulmonary monitoring and frequent monitoring of core body temperature should be undertaken.

COMPLICATIONS

Recent advancements in CVVH technology have made their operation simpler and safer, particularly in terms of the prior concern over an air embolism. However, their use should be restricted to individuals familiar with the operation of these devices. Refer to Chapter 49 for a complete description of the complications that may arise due to the placement of a central venous catheter.

SUMMARY

CVVH is one step away from cardiopulmonary bypass. Its use in the Emergency Department is limited due to lack of equipment availability and familiarity. It is a viable option if the equipment is available as well as a Physician familiar with this procedure.

CARDIOPULMONARY BYPASS

Discussion of this technique is limited to some basic properties of rewarming with cardiopulmonary bypass. This technique should not be attempted by anyone who does not regularly use bypass modalities and without the support of an experienced pump technician. This technique represents the last resort of rewarming techniques. Bypass is usually achieved using femoral-femoral bypass. The cardiopulmonary bypass pump can provide complete hemodynamic and respiratory support during the resuscitation.[26–28] Core body temperatures can be raised 1 to 2°C every 3 to 5 minutes with flow rates of 2 to 3 L/min. If available, use heparin-bonded tubing to avoid systemic anticoagulation, which can worsen existing coagulopathies. The limitations of this technique are that it is extremely resource-intensive, not readily available in many institutions, and requires specific expertise with respect to surgical and mechanical techniques.

EXTRACORPORIAL MEMBRANE OXYGENATION

Although extracorporeal membrane oxygenation (ECMO) technology is a staple in most major Pediatric Intensive Care Units across the world, it continues to be rarely utilized in the adult population. The experience in utilizing ECMO for the management of accidental hypothermia in the adult population is limited to several case reports in the literature.[29,30] Similar to cardiopulmonary bypass, ECMO can be utilized in those patients with complete cardiac arrest and hypoxemia. Hypoxemia and asphyxia are recognized as major predictive adverse factor for survival and/or poor neurological outcome in the hypothermic patient.[31,32] ECMO provides appropriate support for both cardiac as well as pulmonary

functions with the added benefit of allowing for hemodialysis for restoration of electrolyte abnormalities and acid–base imbalances. Further description and discussion of this technique is beyond the scope of this textbook.

ALTERNATIVE TECHNIQUES

There has been much research in the last decade regarding the induction of therapeutic hypothermia. This research has primarily focused on those with brain injury, postcardiac arrest, and stroke. This has resulted in the development of a variety of externally applied and internally applied cooling devices. While not specifically designed to treat hypothermia, they can easily be used to manage the hypothermic patient.[34] Refer to Chapter 188 for a discussion of these methods and devices.

SUMMARY

The management and prevention of hypothermia in the Emergency Department is a challenging and perpetual task. The resuscitation of a severely hypothermic patient in full cardiorespiratory arrest can push the Emergency Physician and the Emergency Department to the limit of their abilities and resources. The real challenge in dealing with hypothermia lies in recognizing and managing the risk of hypothermia in the "routine" patient who presents every day. It is not possible to overstate the importance of continuity of care and the necessity of good communication as the patient is moved from the Emergency Department to either the Operating Room or the Intensive Care Unit, so that rewarming efforts may continue.

190 Hyperthermic Patient Management

Eileen F. Couture

INTRODUCTION

The heatstroke victim can be difficult and challenging, even after a successful resuscitation and stabilization in the Emergency Department. Heatstroke is a multisystem insult. More than 300 people die of heat-related illness in the United States each year.[1] This number was surpassed in a single week in 1995 during a heat wave in Chicago.[2–6] This heat wave resulted in more than 400 deaths and 3300 Emergency Department visits. Although heatstroke is an uncommon medical emergency, it is considered one of the most important of all the environmental heat illnesses because of its potential for high morbidity and mortality in large numbers.[7] Major complications of heatstroke include seizures, adult respiratory distress syndrome (ARDS), acute renal failure, liver disease, rhabdomyolysis, disseminated intravascular coagulation, and death.[8] Survival is possible for the great majority of patients with rapid recognition and aggressive management.

The most effective means of cooling remains controversial. The techniques rely upon prompt recognition of symptoms, immediate intervention in the field, and immediate intervention in the Emergency Department. Begin cooling the patient in the prehospital setting by removing the patient from the heat stress, keeping their skin wet, and fanning the patient in transport. **The patient must be exposed adequately and cooling must be initiated in the quickest and most efficient manner possible as stabilization is occurring.**

Cooling measures must be modified to avoid hypothermia once the core temperature reaches 39°C or 102°F. Decreasing the core body temperature to less than 39°C or 102°F within 30 minutes of presentation improves survival.[4] **Cooling must precede the investigation for the cause. Evaporation and convection are the simplest and most efficient means of cooling victims of heatstroke or heat exhaustion.** Evaporation of 1 g of water dissipates approximately seven times more heat than melting the same quantity of ice.[4] Skin blood flow is preserved as compared with the use of ice, because evaporation and convection are much more efficient modes of heat exchange.[9]

The information in this chapter primarily pertains to hyperthermia from heat-related illness. Despite this, some of these techniques may be used for other causes of hyperthermia. These include endocrine disorders, head injury, infection, intracranial hemorrhage, malignant hyperthermia, neuroleptic malignant syndrome, sepsis, serotonin syndrome, stroke, toxins, or other causes. Consider discussing the use of these techniques to treat hyperthermia with the appropriate consultant if the etiology is not heat-related.

ANATOMY AND PATHOPHYSIOLOGY

Heat-related illness comprises a spectrum of symptoms ranging from mild heat edema to heatstroke. Heat edema is self-limited. The patient presents with edema of the hands, feet, and ankles. This usually occurs in the first few days of heat acclimatization. Heat cramps occur most often in individuals who sweat profusely and are exercising or walking. The patient consumes water without salt, resulting in hyponatremia and muscle cramps. Heat syncope is dizziness or syncope after exposure to high temperatures. It is caused by vasodilatation and consequent postural hypotension. Heat exhaustion results from the excessive loss of body water, electrolytes, or both. The patient may complain of headache, nausea, vomiting, malaise, and myalgias. Heat exhaustion is distinguished from heatstroke by a normal mental status and, generally, a temperature below 39°C or 102°F.[2,8]

Heatstroke must be suspected in any patient who has acute mental status changes or other signs of central nervous system dysfunction in the setting of a high temperature and a history of heat exposure. The initial temperature is usually at least 40 to 42°C or 104 to 108°F. Central nervous system dysfunction may manifest as varying degrees of confusion, obtundation, seizures, delirium, or focal deficits.

Core body temperature is maintained within close limits by a balance between heat production and heat dissipation. Muscular and metabolic activity generates heat. Most fevers encountered are a response to microbial invasion. Some fevers are due to exposure to high temperatures or abnormalities in the thermoregulatory apparatus.[10] Heatstroke may occur in previously healthy individuals who are subjected to severe environmental thermal stress, usually during extreme physical exertion. It may occur in patients with compromised homeostatic mechanisms who are subjected to lesser degrees of exposure (classic heatstroke). Factors that may compromise protective thermoregulatory mechanisms include chronic illness, psychiatric disorders, cardiovascular disease, endocrine disorders, nutritional deficiencies, metabolic disorders, infection disorders, medications, substance abuse, poor judgment, or extremes of age (**Table 190-1**).[8]

It has been speculated that oxidative phosphorylation becomes uncoupled and enzyme systems cease to function when temperature regulation is lost and the core body temperature exceeds 42°C or 108°F. Energy stores become depleted as maximum metabolic demands escalate. This causes the cell membranes to become increasingly permeable, thus increasing sodium influxes. These phenomena have been postulated to be part of a positive feedback loop involving progressive depletion of ATP, increased ion flux,

TABLE 190-1 Factors Related to Heat Illness

Illness	Medications	Behaviors	Groups	Toxins
Autonomic neuropathies	Anticholinergics	Confining garments	Athletes	Alcohol
Cardiovascular disease	Antihistamines	Hot environments	Elderly	Amphetamines
CNS tumors	Diuretics	Inability to care for self	Infants	Cocaine
Dehydration	Lithium	Injudicious exertion	Military recruits	Hallucinogens
Delirium tremens	MAO inhibitors	Poor fluid intake	Neonates	
Diabetes	Phenothiazines	Social isolation	Prior heatstroke	
Hyperthyroidism	Sympathomimetics		Psychiatric	
Major burn scarring	Tricyclic antidepressants			
Parkinson's disease				
Pheochromocytoma				
Psychosis				
Thyroid storm				

CNS, Central nervous system; MAO, monoamine oxidase.

increased rates of membrane depolarization and neurotransmitter activity, and a subsequent increase in heat production. Cell membranes eventually lose their integrity. Heat production accelerates, proteins denature, and widespread necrosis occurs as temperature-control mechanisms fail, leading to organ failure. Cellular damage occurs as a result of the elevated temperatures and the length of exposure to heat.[8,11,12] Tissues at greatest risk for heat-related damage include the vascular endothelium, neural tissue, hepatocytes, and the kidneys.

Heat is dissipated by a combination of radiation, convection, conduction, and evaporation.[10] Radiation is the transfer of heat to objects not in direct contact with the subject. Radiation accounts for approximately 65% of heat loss in cool environments. It is a major source of heat gain in hot climates. Convection is the transfer of heat to circulating fluid or gas. The amount of heat dissipated by convection becomes minimal as ambient temperature rises. Convective heat loss varies directly with wind velocity. Conduction is the direct transfer of heat to another object by direct contact. Evaporation is the conversion of a liquid to the gaseous phase. Evaporation becomes the dominant mechanism of heat loss as ambient temperatures rise.[4,11]

INDICATIONS

Cooling will not harm patients who are hyperthermic, regardless of the etiology. Cooling can be lifesaving in those with true heatstroke. Heatstroke may be difficult to identify if cooling was initiated in the field and the patient's mental functioning is intact. **Initiate cooling immediately if there is any doubt.**[8]

CONTRAINDICATIONS

Patient stabilization always remains the top priority. Assess the patient's airway, breathing, and circulation first, despite the need for immediate cooling. Any life-threatening or limb-threatening conditions must be addressed simultaneously or before proceeding to cooling measures.

Do not initially waste time with typical fever treatments. The use of antipyretics such as acetaminophen and nonsteroidal anti-inflammatory drugs are not effective in treating hyperthermia due to heat-related illness. Do not administer medications used to treat malignant hyperthermia, neuroleptic malignant syndrome, or serotonin syndrome.[13] These treatments do not work for heat-related hyperthermia.

There are specific contraindications to the individual cooling techniques. Iced gastric lavage is contraindicated in patients with altered mental status or depressed airway reflexes unless the patient is endotracheally intubated. It is also contraindicated if nasogastric intubation (Chapter 58) is contraindicated. Iced peritoneal lavage is contraindicated if the placement of a peritoneal lavage catheter (Chapter 66) is contraindicated. Refer to Chapters 58 and 66 for the complete details of placing these devices.

EQUIPMENT

- Core thermometer (e.g., esophageal, rectal, or urinary)
- Large fans
- Spray bottles with a misting nozzle
- Water
- Ice
- Immersion tub
- Ice packs
- Wet sheets and towels
- Cooling blanket
- Peritoneal lavage kits
- Nasogastric tubes
- Iced saline

PATIENT PREPARATION

Immediately remove the patient from the heat-stress environment. Explain the cooling techniques to be employed to the patient and/or their representative. Remove the patient's clothes. Stabilize the patient's airway, breathing, and circulation as necessary. **Patient outcome is directly related to the length of time the tissues are exposed to the thermal challenge.** Cooling rates should not exceed 0.1 to 0.2°C per minute. Apply cardiac rhythm monitoring, a noninvasive blood pressure cuff, and pulse oximetry. Place an esophageal (if the patient is intubated), rectal, or urinary temperature probe to monitor the patient's core body temperature.

TECHNIQUES

EVAPORATION

This technique is simple and causes very little to no discomfort to the conscious patient. An additional benefit is access to the patient should other interventions be necessary.[4] Wet the exposed patient with tepid water. Place large and powerful fans to strategically direct high-flow air currents toward the patient's head, feet, and

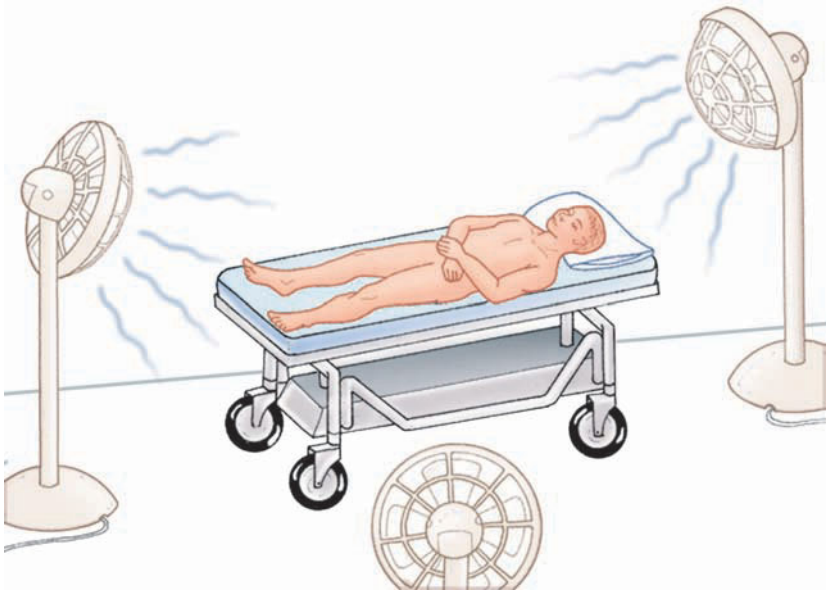

FIGURE 190-1. Evaporation using large fans at the head, foot, and side of the bed to direct high-flow air currents.

torso (**Figure 190-1**). Spray the patient with a mist of water from the spray bottles. Keeping the patient "wet and windy" provides a state-of-the-art cooling method for even the smallest Emergency Department without the need to purchase new or specialized equipment. Place ice packs wrapped in wet towels on the patient's groin, axilla, and neck.

Discontinue evaporative cooling when the core body temperature reaches 39°C or 102°F. Continued cooling can result in hypothermia as the core temperature continues to decrease after evaporative cooling is discontinued. Monitor the patient to ensure that their core body temperature does not increase.

The concept of evaporative cooling gained popularity with the Makkah Body Cooling Unit (BCU). The BCU is used today to provide field treatment for people participating in the annual pilgrimage to Mecca who may develop heatstroke. The BCU has been found to provide the fastest core temperature cooling rates of 0.31°C/min.[11]

ICE WATER IMMERSION

Immersion in an ice water bath is a common method of cooling heatstroke patients. Place the patient in a tub of ice water for 10 to 40 minutes (**Figure 190-2**). Briskly massage the patient's extremities to maintain peripheral circulation and promote heat loss.

FIGURE 190-2. Ice water immersion to cool a hyperthermic patient.

Monitor the patient's core temperature carefully. Rectal temperatures will decrease approximately 0.16 to 0.21°C/min.[8,11]

Ice water immersion is recommended by some authors as the initial technique for hyperthermia management.[6,13,14] Unfortunately, it has limited use in the Emergency Department.[4,11] Preparing an ice bath can result in a delay in cooling the patient. Contact with the ice water results in intense vasoconstriction, which blocks heat exchange, paradoxically increases core body temperature, induces shivering, and is uncomfortable for the patient. Heat transfer from the core to the surface is reduced. The practical issues of impairing access to the patient, monitoring the airway, and initiating resuscitative measures are challenging when the patient is in an ice water bath.[4,11,15] The tub and patient lift device are large, bulky, and not often available in the Emergency Department. Multiple caregivers are required to prevent the patient from drowning and to maintain their head above water.

A simpler and easier method is immersion of just the patient's hands and forearms.[16] This method requires less patient cooperation than full body immersion. It also allows for full patient monitoring during the cooling process.

ICE PACKING

Packing the heatstroke patient in ice is an alternative to ice water immersion. It can result in conductive heat loss that is as effective as evaporative cooling. Patients who are awake and alert do not often tolerate ice packing. Its use may require parenteral sedation. The complications and practical limitations are similar to those of ice water immersion.

Place the undressed patient in the center of the gurney. Completely cover the patient with ice. This technique requires a large quantity of ice, which may be unavailable in the Emergency Department. Consider placing plastic sheets or trash bags, with the edges curved upward, under the patient to prevent the ice and water from spilling onto the floor, as healthcare personnel may otherwise slip on the wet floor, fall, and sustain injuries. An easier alternative is to place the patient in a body bag and fill this with ice. Discontinue cooling when the core temperature reaches 39°C or 102°F.

ICE PACKS

The placement of ice packs over select body areas is a more reasonable option than ice water immersion or ice packing. It may be

used as the sole cooling method or in conjunction with evaporative cooling. Place plastic bags filled with ice or ice water in the patient's axilla and groin. Remove the ice packs when the core temperature reaches 39 °C or 102 °F.

ICED PERITONEAL LAVAGE

Peritoneal lavage in hyperthermia has been investigated in canine models but used infrequently in humans. The advantages of this technique include the large surface area exposed to iced saline and direct cooling of the core. This technique is invasive, time-consuming, requires significant equipment and expertise, and is associated with significant complications. A case report indicated that iced peritoneal lavage with 2 L of normal saline was successful in decreasing the rectal temperature to 39.5°C or 103°F.[9] The patient had responded only partially to external evaporative cooling and iced gastric lavage. Place 1 L bags of saline or Ringer's lactate solution into an ice water bath to cool down. The technique is similar to that used for warming the hypothermic patient. Refer to Chapter 189 for the complete details of this technique. Iced peritoneal lavage should be reserved for the patient who is not responding to other methods of cooling.

ICED GASTRIC LAVAGE

Central cooling techniques have not been studied extensively. An alternative core cooling technique is iced gastric lavage. This method has been compared to room-air cooling in an anesthetized canine heatstroke model.[10] Gastric lavage with iced tap water cooled the canine models rapidly and safely. The technique yielded cooling rates five to six times faster than in controls. Significant differences in hemodynamic parameters were noted to return to baseline more quickly in the iced gastric lavage group than in the control group. The technique is similar to that used for warming the hypothermic patient. Refer to Chapter 189 for the complete details of this technique. Instill 10 mL/kg of iced sterile saline, allow it to dwell for 30 to 60 seconds, and suction out the fluid. Repeat the procedure as necessary. Potential hazards using this technique include aspiration, gastric mucosal injury, electrolyte imbalances with water lavage, and dysrhythmias.[10]

ALTERNATIVE TECHNIQUES

There has been much research in the last decade regarding the induction of therapeutic hypothermia. This research has primarily focused on those with brain injury, postcardiac arrest, and stroke. This has resulted in the development of a variety of externally applied and internally applied cooling devices. While not specifically designed to treat hyperthermia, they can easily be used to manage the hyperthermic patient. Refer to Chapter 188 for a discussion of these cooling methods and devices.

ASSESSMENT

Monitor core body temperature closely with an esophageal, rectal, or urinary temperature probe. Monitor the patient's vital signs, neurologic function, urine output, and laboratory measurements (arterial blood gases and serum electrolytes). Consider monitoring central venous pressure and pulmonary artery pressure, especially in patients with heatstroke and limited cardiac reserve. Volume deficits may not be more than 2 to 3 L, especially in patients with classic heatstroke. Hypotension usually responds to intravenous fluids. If required, use an inotrope that produces little vasoconstriction, such as dobutamine. The use of H_2 blockers may decrease the incidence of gastrointestinal bleeding.[12] Treat rhabdomyolysis aggressively with saline diuresis, alkalinization of the urine, and an infusion of 0.5 gm/kg of mannitol with or without furosemide.[12] Treat seizures with benzodiazepines.[12]

AFTERCARE

Patients with minor heat-related illnesses may be safely discharged home after cooling. Instruct the patient to rest, drink plenty of fluids, and avoid the heat. Discuss with the patient the methods to remain cool if they are exposed to heat. This requires adequate rest, hydration before physical exertion, periods of rest during exertion when the individual can cool off, and adequate oral fluid intake during exertion. Arrange follow-up within 24 hours for a reevaluation.

Admission is required in several circumstances. Admit patients with heat exhaustion for 23 hour observation if they have abnormal vital signs, abnormal laboratory investigations, or if they remain symptomatic after fluid therapy. Admit all patients with heatstroke to an intensive care unit. Permanently altered and unstable thermoregulatory mechanisms in the survivors of heatstroke increase their susceptibility to future heat illness. Prevention through education should be a part of every discharge plan.

COMPLICATIONS

Further management of the heatstroke victim can be difficult, even after successful initial resuscitation and stabilization. Heatstroke is a multisystem insult that affects virtually every organ system. Neurologic complications of hyperthermia include seizures, cerebral edema, and localized brain hemorrhages. Irreversible brain damage often occurs above 42°C or 108°F. Cerebellar impairment may persist after recovery. Cardiac complications include tachyarrhythmias, high cardiac output heart failure, and myocardial infarction. Pulmonary edema may be cardiogenic in patients with a limited cardiac reserve or secondary to ARDS. Pulmonary aspiration can be encountered in obtunded patients. Acute renal failure may be due to direct heat damage, renal hypoperfusion, or rhabdomyolysis. Mucosal ulceration of the gastrointestinal tract is common and can lead to gastrointestinal hemorrhage. Liver damage and dysfunction are common. The extent of hepatic necrosis and cholestasis may not be apparent until 48 to 72 hours after the heat injury. Hematologic complications include hemolysis, thrombocytopenia, and disseminated intravascular coagulation. Megakaryocytes are especially sensitive to heat injury. Disseminated intravascular coagulation is triggered by diffuse endothelial and organ damage. Its onset is usually delayed 2 to 3 days and is associated with a high mortality.[17,18]

Complications can occur during the cooling of the hyperthermic patient. **Discontinue all cooling techniques when the core body temperature reaches 39°C or 102°F.** Continued cooling can result in hypothermia as the core temperature continues to decrease after cooling is discontinued. Monitor the patient to ensure that their core body temperature does not increase. The patient may experience muscle fasciculations, shivering, and shaking during the cooling process. These can be managed with intravenous benzodiazepines. Ice water immersion and ice packing make patient monitoring and management difficult if not impossible. Iced peritoneal lavage and iced gastric lavage are invasive procedures associated with significant potential complications. Refer to Chapters 58 and 66 regarding the complications associated with the placement of the peritoneal lavage catheter and the nasogastric tube, respectively.

SUMMARY

The best intervention for heat-related illness is prevention. If caught early, heat illness responds to rest, exposure to shade and a breeze, and the ingestion of cool liquids. External evaporative cooling is

acknowledged to be the safest means of cooling the hyperthermic patient. The tragedy of heatstroke is that it so frequently strikes highly motivated young individuals under the discipline of work, military training, or sporting endeavors. Heat-illness precautions should be implemented even in temperate zones during the hot summer months.

191 Autotransfusion

Carlos J. Roldan and Amit Mehta

INTRODUCTION

Trauma is the leading cause of death in children and adults under 44 years of age.[1] Exsanguination plays a significant role in as many as half of these deaths, most commonly after the patient reaches the hospital and within the first 24 hours after injury.[2] Hemorrhagic shock is a primary indication for the transfusion of homologous blood products. Transfusions with homologous blood products carry the possibility of associated complications including transfusion reactions, transmission of infectious diseases, and sensitization to antigens.[3] Massive transfusions are associated with the additional complications of acidosis, dilutional coagulopathy, and hypothermia. Transfusion of homologous blood products in the trauma patient has been independently associated with an increase in both morbidity and mortality, particularly when transfusing older, stored blood products.[4–6] Blood centers have more than doubled the prices of blood products in recent years due to a decline in blood donors, higher skilled labor costs, and increases in the cost of testing and processing blood.[7]

Alternative transfusion strategies have been developed for elective surgeries. These include autologous (acute) normovolemic hemodilution, autologous preoperative donation, and intraoperative cell salvage with autotransfusion. The first two are not possible in the acute Emergency Department setting. Cell salvage with autotransfusion represents a viable alternative to autologous transfusion in the Emergency Department, but has received limited attention in the trauma patient.

In the trauma setting, an autotransfusion was first performed by Elmendorf during the First World War on a soldier with a traumatic hemothorax.[8] It was subsequently used sporadically as a life-saving procedure.[9] A modified autotransfusion for a traumatic hemothorax was described in 1978.[10] This technique was simple, safe, and easy to practice. It was used in approximately 400 patients with a traumatic hemothorax without any noticeable complications. This technique is still applicable to current practice.

Many of the patients with a life-threatening hemothorax either die before reaching the Emergency Department or experience severe hemodilution that accounts for some deaths in the Emergency Department and the Operating Room. Since hypovolemic shock secondary to trauma is the most frequent indication for a massive blood transfusion in the Emergency Department, it is therefore an indication for an autotransfusion. Much of the controversy surrounding practice paradigms centers on the disagreement as to what constitutes the proverbial perfect procedure.

An autotransfusion may occur in the Emergency Department, Operating Room, and Surgical ICU with increasing frequency. In this procedure, the shed blood is collected, mixed with an anticoagulant, concentrated, washed or filtered, and then returned through an intravenous (IV) line to the patient. Harmful contaminants such as potassium, fat, and free hemoglobin are removed from the salvaged blood. This blood is returned through a 40 micron blood filter to collect particulate matter and microthrombi. An autotransfusion in the Emergency Department is generally limited to an acute traumatic hemothorax associated with clinically significant hypovolemia.

INDICATIONS

An autotransfusion should be considered with the anticipated loss of at least 20% of the patient's estimated total body blood volume. It should also be considered if the Emergency Department cannot obtain or provide cross-matched compatible blood. It can be used for the patient unwilling to accept homologous blood, but willing to accept salvaged blood. The average amount of blood to be autotransfused should be expected to be greater than 1 unit to make this procedure cost effective.[11–13]

There are numerous advantages to an autotransfusion. It is convenient and immediately available as a blood product replacement. The blood is already warmed and at, or just below, body temperature. It addresses any special needs of the patient such as when they have religious preferences or a rare blood type. There is no chance of allergic reactions, alloimmunization, disease transmission, febrile reactions, and transfusion reactions. An autotransfusion requires no work on the part of the blood bank, has no compatibility issues, and ensures that the patient receives compatible blood. It conserves homologous blood products for other patients. An autotransfusion results in the blood having a normal pH, viable platelets, and viable clotting factors when compared to homologous blood supplies. Higher levels of 2,3-DPG in autologous blood results in the easier release of oxygen from hemoglobin in the tissues. Finally, there is the positive psychological benefit to the patient when they are informed that they received their own blood.

CONTRAINDICATIONS

There are numerous contraindications to the use of an autotransfusion. The presence of a coagulopathy regardless of its etiology or when it occurs (i.e., in the Emergency Department, preoperative, intraoperative, or postoperative) or evidence of disseminated intravascular coagulopathy (DIC) may be more optimally managed with the administration of specific blood component therapy. Evidence or suspicion of serious infectious processes (e.g., mediastinal, pericardial, respiratory, or systemic) precludes the use of an autotransfusion. Do not autotransfuse blood if there is the presence of a malignant neoplasm at collection site (i.e., abdominal or chest cavity) that can lead to possible contamination of the blood with malignant cells. Do not autotransfuse blood which is collected from a potentially contaminated abdominal or thoracic cavity (e.g., esophageal tear). Do not autotransfuse from a cavity that was irrigated with a solution that can cause lysis of red blood cells prior to blood collection and potentially precipitate end-organ damage if the salvaged product is administered. This includes sterile water, hydrogen peroxide, alcohol, hypotonic irrigation solutions, or povidone-iodine antiseptic gels or solutions. Blood collected from body cavities that have had the administration of topical thrombin or microfibrillar hemostatic agents should not be autotransfused. Patients with renal or hepatic failure may not tolerate the increased levels of plasma-free hemoglobin or potassium that occurs with an autotransfusion. Relative contraindications include cesarean delivery and sickle cell disease.

EQUIPMENT

- Sterile gloves and gown
- Face mask with a face shield or goggles
- Cap

- Povidone iodine or chlorhexidine solution
- Chest tube drainage apparatus with either a water seal or a dry one-way valve
- In-line autotransfusion system blood collection bag
- Whole blood in-line microaggregate filter for reinfusion (usually 40 microns, but can vary between 20–170 microns)[14]
- Nonvented blood compatible IV administration set
- 250 mL bag of sterile normal saline for priming of IV tubing and microaggregate filter prior to blood infusion
- Pressure bag for rapid blood infusion
- Blood warming system if it is anticipated that multiple units of blood will need to be infused to help prevent hypothermia[15–17]
- Citrate anticoagulants
- Tube thoracostomy supplies (Chapter 39)

Anticoagulation for an autotransfusion in the ED setting is generally recommended to help prevent the formation of clots in the autotransfusion system. While the administration of anticoagulants can be beneficial, it is not without risk and its use and dosage are at the discretion of the treating Physician. Heparin anticoagulation is one option. However, the local administration of heparin can lead to the formation of platelet microaggregates and potentially lead to systematic heparinization which can result in further hemorrhage in a patient who is already bleeding.[18] **Citrate anticoagulants, which are considered local anticoagulants, are thus preferred over heparin.** Citrate works by binding with calcium ions to inhibit the conversion of fibrinogen into the insoluble protein fibrin, preventing the blood from clotting. Since citrate only binds with calcium, it only anticoagulates the blood it is collected with. The liver rapidly metabolizes the citrate once the anticoagulated blood is reinfused.[16]

Citrate phosphate dextrose (CPD) is a commonly used anticoagulant. It is recommended to use 1 mL of CPD for every 7 mL of blood. Because it is difficult to estimate the amount of blood in a patient's chest cavity, one approach is to instill 60 mL of CPD into the autotransfusion bag, enough to anticoagulate one unit of blood. When 1 unit of blood has been collected (about 500 mL total volume of blood plus CPD), it may be reinfused or additional CPD may be added to continue the collection. If bloody drainage is ongoing, prepare a new collection bag and inject anticoagulant before disconnecting the filled collection bag for reinfusion. The CPD injection may be facilitated by the use of a volume-control IV chamber. Run the desired amount of CPD into the chamber and then infuse it via the IV tubing to the injection port.

Citrate phosphate dextrose adenine (CPDA) may also be used as an anticoagulant at a ratio of 1 mL per 7 mL of blood. Some consider CPDA the anticoagulant of choice for an autotransfusion of a traumatic hemothorax. It provides a reduced pH mixture that is advantageous to the platelets. The CPDA solution maintains the viability of the platelets. It also reduces clot formation in autotransfusion equipment, plugging of the blood filter with microemboli, and clotting of the IV lines.

PATIENT PREPARATION

Assess the patient for the signs and symptoms of hypovolemia, hypoperfusion, and/or a hemothorax. Describe the procedure, its risks, and benefits to the patient and/or their representative. Obtain written or oral consent, if possible. **This procedure requires strict aseptic technique.** Clean any dirt and debris from the patient's chest wall. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Apply povidone iodine or chlorhexidine solution to the skin over the chest wall and allow it to dry. Apply sterile drapes to delineate a sterile field.

Much preparation is required before starting an autotransfusion. The autotransfusion system requires prior assembly. Therefore, consider setting up the autotransfusion components for patients who are at high risk for a hemothorax before inserting the chest tube. Otherwise, blood that drains immediately upon chest tube insertion is lost to recovery. **Refer to all manufacturers' directions for use, warnings, and cautions regarding anticoagulant medications, microemboli filters, and IV blood administration sets prior to their use.** Prophylactic broad-spectrum antibiotics may be administered immediately before the chest incision is made for the tube thoracostomy or just prior to the reinfusion. Follow all hospital protocols for blood handling, waste disposal handling, and infection control. Insert a large-bore chest tube. Refer to Chapter 39 for the complete details regarding the tube thoracostomy.

TECHNIQUES

There are several manufacturers of chest drainage and autotransfusion systems. The Pleur-Evac System (Teleflex Medical, Research Triangle Park, NC) is one of the commonly used systems in many Emergency Departments.[30] The Atrium Chest Drain Autotransfusion System (Atrium Medical Corp., Hudson, NH) is the second of the two more commonly used systems (**Figure 191-1**).[31]

Three different techniques for blood collection are in-line, self-filling, and continuous. The in-line autotransfusion blood bag is a standard bag that attaches to the chest drain (**Figure 191-2**). The

FIGURE 191-1. The Oasis 3650 chest drain system with autotransfusion blood recovery. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

FIGURE 191-2. An in-line autotransfusion bag. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

FIGURE 191-3. A self-filling autotransfusion bag. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

self-filling autotransfusion bag incorporates a low vacuum that is activated to improve the flow of fluid from the chest drain into the bag (**Figure 191-3**). The final option is the continuous autotransfusion. It is used to directly reinfuse shed autologous blood via a blood compatible infusion pump, a microemboli blood filter, and a nonvented blood compatible IV administration set. This is a true closed system and reduces the potential for contamination. It does not require the clamping and unclamping of tubes, exchanging autotransfusion bags, and the interruption of chest drainage to change autotransfusion bags. It results in less exposure to the patient's blood with a closed system. It saves time and money by not changing autotransfusion bags, filters, and IV tubing. Unfortunately, this closed system is rarely available in the Emergency Department and requires additional training for its use.

The technique chosen depends upon the chest tube drainage system used in your institution. Some chest tube drainage systems allow for more than one technique to collect blood for an autotransfusion. The specific port locations and connections will vary slightly among the different manufacturers, but the general concepts are relatively universal. The general technique will be described below. The specific steps depend upon the actual equipment available.

Attach the autotransfusion bag to the chest drain. Inject anticoagulant into the collection unit as soon as possible during or before the blood collection if this is required. Collect the blood. When one unit of blood has been collected (about 500 mL of blood plus the volume of anticoagulant), it may be reinfused. Remove the filled autotransfusion bag and replace it with a new one containing anticoagulant. Discontinue blood collection when it is determined that an autotransfusion is no longer required or there is no further bloody drainage from the chest tube.

Reinfuse the blood. Prime the IV blood administration and microemboli blood filter with sterile saline. Invert the autotransfusion bag so that the spike port points upward. Remove the protective cap covering the spike. Insert blood tubing into the spike port by using a constant twisting motion. Attach a microfilter onto the blood tubing. **Remove the air from the autotransfusion bag.** Keep the unit inverted and squeeze all the air from the bag carefully through the filter and the drip-chamber assembly to prevent an air embolus. Close the infusion set clamp. Invert the autotransfusion bag and suspend it from an IV pole with the plastic strap. Open the infusion set and flush the administration line to remove all of the air. Attach the distal end of the infusion set to the IV line. Infuse the blood using gravity or pressure.

Keep in mind some general principles when performing an autotransfusion. Do not hang or hand carry the autotransfusion bag by its tubing. Use the hanger provided. Replace the spike port cap immediately following removal of the blood filters and IV tubing to prevent air entering the system. The air vent must remain closed at all times when not in use. A new microemboli blood filter and IV blood tubing must be used for each autotransfusion bag. When using vacuum suction with the collection apparatus, it is important to use the lowest level possible to reduce the risk of red blood cell hemolysis during collection.[32] The recommended starting vacuum pressure is 20 mmHg.[15,33]

ASSESSMENT

Assess the patient's cardiopulmonary status and vital signs frequently during the autotransfusion and at least until 1 hour after the autotransfusion is complete. Periodically monitor laboratory data to include hematocrit, prothrombin time, partial thromboplastin time, platelet count, serum lactate, and arterial blood gas values. Monitor and mark amount and type of drainage from the collection system hourly for the first 8 hours, then every 2 hours as volume loss can cause hypovolemic shock. Evaluate and maintain drainage tube patency every 2 to 4 hours. Mark the drainage level on the outside of the drainage-collection chamber in hourly or shift increments. Document the assessments and laboratory values in the medical record.

AFTERCARE

Once the infusion of the autologous blood has started, it is important to monitor the patient's clinical status in response to the infusion during the patient's stay in the Emergency Department. This will involve monitoring their vital signs and other hemodynamic parameters, including central venous pressure.[12] Monitor laboratory data to assess the success and possible complications of the autotransfusion process. This generally includes electrolytes, renal function, hemoglobin and hematocrit, platelet count, coagulation profile, and DIC profile to assess for a consumptive coagulopathy.[12]

The Emergency Physician, in conjunction with the nursing staff, must also maintain the integrity of the autotransfusion system during the infusion of autologous blood. It is necessary to ensure the autotransfusion bag is replaced each time it is filled to capacity to prevent overflow of blood into the chest drainage apparatus. Ensure each collection bag has anticoagulant added to it prior to the collection of blood. A new microaggregate filter must be used for each collection bag prior to it being infused. Prior to infusing blood, inspect it through the collection bag for evidence of clotting. Discard the autotransfusion bag and do not reinfuse it if it contains clotted blood or particulate matter. Purge all the air from the collection bag, intravenous tubing, and microaggregate filter to prevent an air embolism. Observe the autotransfusion to ensure that the entire contents of the collection bag are not allowed to infuse through the microaggregate filter and intravenous tubing. The transfusion of shed blood collected under post-traumatic conditions should begin within 6 hours of initiating the collection at the longest so as to reduce the risk of bacterial overgrowth and minimize damage to the blood components during storage.[19]

COMPLICATIONS

In general, the complications from an autotransfusion are clinically insignificant if the proper technique is followed and if less than 3000 mL of blood is reinfused. Overall, the complications are categorized as hematologic and nonhematologic. Refer to Chapter 39 regarding the complications associated with a tube thoracostomy.

HEMATOLOGIC

A coagulopathy may occur in trauma patients following an autotransfusion. However, the autotransfusion itself has not been overwhelmingly proven to be the etiology.[3] These patients are more likely to have other independent risk factors for a coagulopathy such as hypothermia and acidosis.[20] This makes it difficult to determine the contribution of the autotransfusion to the development of a coagulopathy.[20] DIC is a rare complication but should be anticipated and treated accordingly. A dilutional coagulopathy may occur when greater than 3500 mL of autologous blood is transfused. Treatment includes administration of fresh frozen plasma and platelets to compensate for the proportional decrease in platelets and fibrinogen.[21] Hemolysis of red blood cells secondary to mechanical factors during the collection process, the use of hypotonic irrigation fluids, excessive suction pressure, aspiration of clotted blood, or the use of hemolytic solutions (e.g., povidone iodine, hydrogen peroxide, or alcohol) to collect blood.[22,23] Hemolysis can also occur secondary to the prolonged exposure of red blood cells to the serosal linings of traumatized body cavities.[24] Thrombus formation may occur as a result of increased plasma-free hemoglobin that promotes a procoagulant effect and increases the risk of free hemoglobin precipitation in the renal tubules.[25,26]

NONHEMATOLOGIC

Particulate embolism has been reported to occur during and after an autotransfusion. Most components of the equipment are designed for singe use. Resterilization or reuse may compromise the structural integrity and lead to device failure. An air embolism may result from inadequate use of the IV set or the microemboli blood filter. An air embolism has also been associated with the reinfusion of the entire autotransfusion blood bag contents that contain residual air and a pressurized infusion of the autotransfusion bag with the air vents open. Citrate toxicity and myocardial depression may occur after the rapid infusion of citrate-anticoagulated blood. The clinical manifestations of citrate toxicity include a perioral tingling sensation followed by abdominal cramping and cardiac dysrhythmias. Citrate toxicity can be prevented by ensuring that the ratio is not greater than 1:5 of the citrate anticoagulant to blood. Sepsis in patients with an isolated hemothorax is considered only a minimal risk. Sepsis has been associated with the difficulty that exists in maintaining a completely sterile environment in patients receiving an autotransfusion.[27–29]

SUMMARY

An autotransfusion is a basic technique that is possible in the Emergency Department. It is not the standard of care under all settings. The procedure requires familiarity with the equipment, continuing education, and quality control. This may be the reason it is underutilized in many Emergency Departments. Anticipation of which patients would benefit from this technique might be problematic and time consuming, especially when assembling equipment that may not be used frequently. Proper use of the devices can be advantageous to avoid the multiple complications associated to hypovolemic shock in trauma patients. The low risk of complications related to this technique make an autotransfusion a viable option to a homologous transfusion.

192 Helmet Removal

Eric F. Reichman

INTRODUCTION

The helmeted person who becomes injured presents unique challenges to prehospital healthcare providers, athletic trainers, and Emergency Department personnel in providing initial stabilization and management. Greater numbers of people are wearing helmets due to the increasing public awareness for the prevention of head injuries associated with recreational and athletic activities. This practice will limit the most severe outcomes from head trauma. However, the helmeted patient is not immune from life-threatening head and neck injuries. **Secondary injury due to improper helmet removal can adversely affect patient outcome.**[1]

Helmets vary in size, type, and accessories on the basis of the user's activity (**Figure 192-1**). They consist of a hard plastic, polycarbonate, and/or fiberglass shell over either a layer of foam covered by material, inflatable air bladders, or both. Motorcyclists and racers wear full-face helmets with or without retractable or removable visors. Football, lacrosse, and hockey players use open-faced helmets. These may have clear visors and/or face cages whose bases are screwed into the helmets. Bicyclists, kayakers, roller bladers, skateboarders, and skaters wear simple skull helmets. These helmets cover the top of the skull like a hat and have a strap that is snapped or clipped under the chin to maintain the helmet in position.

Athletes playing football and hockey wear protective shoulder padding in addition to protective helmets. Their facial injuries tend to be less severe.[2] With the helmets and shoulder padding, their cervical spines, in comparison to those of helmeted motorcyclists without shoulder padding, are more adequately stabilized.[2,3] Helmet removal with and without shoulder pad removal has been shown to result in head and cervical spine movement.[4,5] This can increase the risk of spinal cord damage in the helmeted patient with a cervical spine injury.[2,3]

Current recommendations for helmet removal are to leave the helmet in place until the patient arrives in the Emergency Department or Trauma Unit.[2–4,6–10] **The only exception permitting the removal of a helmet in the field is when it significantly delays lifesaving measures or if airway access is obstructed.**[2,3,6] This may occur in the unconscious and/or apneic patient. Prehospital healthcare providers should be able to maintain an adequate airway, stabilize a patient's cervical spine, and control associated hemorrhage with removal of only the face plate, guard, and chin strap of the helmet.[6,7]

ANATOMY AND PATHOPHYSIOLOGY

The type and fit of protective equipment, the mechanism of injury, the patient's age, and the patient's physical development all influence cervical spine injury. There is a greater risk of injury when the helmet is too loose. It has been noted that most people wear helmets that are too large for their heads. Inertia is defined as a body's ability to resist change of position and motion. A 4 pound helmet can exert a 200 pound force on the wearer's head and neck when impact occurs at 50 mph. Injury is often more serious when inertial forces cause excessive extension and flexion of the cervical spine without adequate protection for the lower head and neck.[7,11]

The anatomic location of cervical spine injuries tends to differ between children and adults. The immature pediatric spine is more susceptible to flexion and extension injuries in the upper cervical (C2 to C3) segments due to the child's proportionally larger head size, shorter neck with immature development, weak neck muscles, and the neck's higher degree of flexion and extension.[7,11,12] The relative amount of cartilaginous tissue in comparison to bone makes the pediatric patient more prone to spinal cord injury when subjected to high inertial forces. These injuries may be more difficult to detect on plain radiographs, as cartilaginous injuries are radiolucent.[11,12]

Similar conditions of disproportionate head-to-neck size are artificially created in the helmeted patient. The motorcycle helmet will often cause hyperflexion of the neck. Flexion and extension injuries without adequate lower neck protection result in an increased incidence of upper cervical spine (atlantoaxial, C1, and C2) injuries in comparison to lower cervical spine segments.[12,13] There is a greater incidence of lower cervical spine (C5 and C6) injury among football and hockey players.[13] The shoulder padding offers support to the lower head and upper neck. It decreases the amount of flexion and extension at the time of impact.

Flexion and distraction while removing a helmet may cause spinal cord compression, as demonstrated in unstable C1 to C2 injuries with helmet removal in cadaveric models.[13] Similar unfavorable results were demonstrated with neck flexion and extension during helmet and shoulder pad removal.[13] The properly fitting helmet is tight enough that a significant force must be applied to remove it in the field, thus increasing the chance of cervical spine movement. **Apply proper in-line cervical immobilization before helmet removal or medical intervention while avoiding in-line traction. In-line traction increases the risk of subluxation or distraction at the site of injury.**

It is recommended that the helmet and padding not be removed in the field. Overzealous manipulation of the patient or improper helmet and/or padding removal can complicate an underlying injury. The helmet can be secured to a long backboard with supplemental neck stabilization provided by use of neck immobilizers, foam-Velcro fitted supports, or sandbags. If shoulder pads or helmets are removed in the field, the posterior aspect of the neck and shoulders must be adequately supported while in-line immobilization is maintained to avoid further spinal cord injury. Cervical immobilization with and without helmet removal is best accomplished with at least two people to assure that the patient's head and neck remain stable.

FIGURE 192-1. Types of helmets. **A.** Simple skull helmet. **B.** Football helmet. **C.** Partial face covering helmet. **D.** Full face covering helmet. **E.** Full face covering helmet.

INDICATIONS

Under most circumstances, the helmeted patient can be assessed and stabilized in the field without removing their helmet or shoulder pads.[4,8–10] The patient can often be initially managed, radiographed, and the cervical spine radiographically "cleared" prior to removal of the helmet in the Emergency Department.[14] Although there is some information that plain radiographs can be inadequate to visualize the bony structures if the helmet and pads remain on the patient.[15,16] The current common use of CT scans to clear the cervical spine make this not as important as most helmets and pads are nonmetallic.[4,17]

Helmet removal is warranted emergently in patients who are apneic, without an adequately sustainable airway, those at risk for airway compromise from a helmet being left in place, if it interferes with airway management, and those who have uncontrollable hemorrhage.[14] Helmets that are loose fitting or that do not adequately stabilize the head and neck should be removed. Other indications to remove a helmet include if it prevents proper patient immobilization, or if the face mask cannot be removed. **When a helmet is removed, any pads and neck support devices attached to the pads must be removed to maintain the cervical spine in a neutral position and prevent secondary injury.**

CONTRAINDICATIONS

Adhere to strict cervical spinal cord injury precautions throughout the prehospital period. Do not remove the helmet unless absolutely necessary. It is not possible to completely exclude a spinal cord injury or vertebral fractures in the field.

Do not remove the helmet until the cervical spine has been "cleared" of any injury in the Emergency Department. Delay removal if the patient is unconscious, has an abnormal mental status, is under the influence of ethanol or drugs, is intoxicated or potentially intoxicated, has distracting injuries, if there is evidence of a spinal cord injury, if a complete physical examination cannot be performed, if the cervical spine has not been radiographically cleared, or if the patient has neck pain. The only exception is if the patient's airway and breathing cannot be supported with the helmet in place.

EQUIPMENT

- Long backboard
- Head and neck immobilizer
- Adjustable cervical collar
- Scissors or shears suitable to cut the face mask
- Cast saw with spare blades
- Screwdrivers, flat head and Phillips head
- Face mask removal tools
- Towels

PATIENT PREPARATION

The hemodynamically stable and helmeted patient should have radiographs of the cervical spine, be physically assessed, be determined not to be intoxicated, and have a normal mental status prior to removal of their helmet.[14,18] This includes a complete neurologic examination. Explain the removal procedure and its possible complications to the patient and/or their representative. Explain all the potential risks involved in helmet removal, including the possibility of worsening an underlying spinal cord injury. The risk of permanent central nervous system damage should be stated as well as the fact that the precautions to avoid such injury are not foolproof but will be observed as carefully as possible. Answer any questions or concerns of the patient or their representative. **If the patient is awake and alert, instruct them to tell you immediately if they experience numbness, pain, paresthesias, or tingling during the removal procedure.**

Remove any removable parts if they were not detached from the helmet prior to arrival in the Emergency Department. The face mask, face shield, and/or visor can often be removed with a flat or Phillips head screwdriver or an electric screwdriver. If the screws cannot be removed because they spin in place or are rusted, cut the plastic clips holding the face mask onto the helmet. A variety of tools are available to aid in face mask removal.[19] The hospital's maintenance department can provide an anvil pruner, bolt cutters, or PVC pipe cutter. Commercial devices have been designed to remove a face mask. These include the FM extractor (Sports Medicine Concepts, Genesco, NY) and the Trainer's Angel (Trainer's Angel, Riverside, CA). Unfortunately, these commercial devices are not often available in the Emergency Department.

Carefully look for any damage to the patient's helmet. External damage to the helmet may be the only initial indication of the severity of the impact. Inspect the integrity of the helmet shell for fit and structural breaks. The patient may be wearing eyeglasses or sunglasses under the helmet. Remove the glasses before helmet removal begins. Contact lenses may remain in place until the helmet is removed.

The helmet will cause flexion of the cervical spine when a patient is placed supine. This flexion is even more pronounced in a child due to their large occiput. Place rolled towels or sheets under the patient's shoulders to eliminate the excessive flexion of the cervical spine. Such flexion is minimal and requires no towels under the shoulders if the patient is wearing shoulder pads in addition to a helmet.

TECHNIQUES

MANUAL ONE-PERSON TECHNIQUE

Helmet removal can be performed by one or two people. Reserve the one-person technique for extreme interventions (**Figure 192-2**). With only one person present, it is necessary to pad voids behind the patient's neck and shoulders (**Figure 192-2A**). **The goal is to keep the head and neck in the neutral position as much as possible while removing the helmet.**

Stand above the patient's head looking down toward their feet. Place the heels of both hands on the sides of the helmet (**Figure 192-2B**). Insert the index, middle, ring, and little fingers into the space between the patient's head and the helmet. Gently spread open the helmet with both hands to create clearance between the helmet padding and the patient's face and ears (**Figure 192-2B**). Slowly and gently remove the helmet (**Figure 192-2C**). **Stop removing the helmet immediately if the patient experiences pain or neurologic symptoms and use a 2-person or cast saw technique.** If the helmet is of the full-face type, gently tilt it posteriorly and continue to pull the helmet off until the nose is cleared. Return the helmet to a neutral position after the nose is cleared. **Avoid cervical spine hyperextension during this stage of helmet removal.**

Stop removing the helmet when the bottom of the helmet is just above the patient's occiput. Move the fingers of both hands onto the patient's occiput while keeping the heels of both hands on the helmet (**Figure 192-2D**). The fingers will now maintain stabilization and immobilization of the head and neck. Push the helmet off the patient's head using the heels of both hands while maintaining immobilization of the patient's head and neck (**Figures 192-2E & F**).

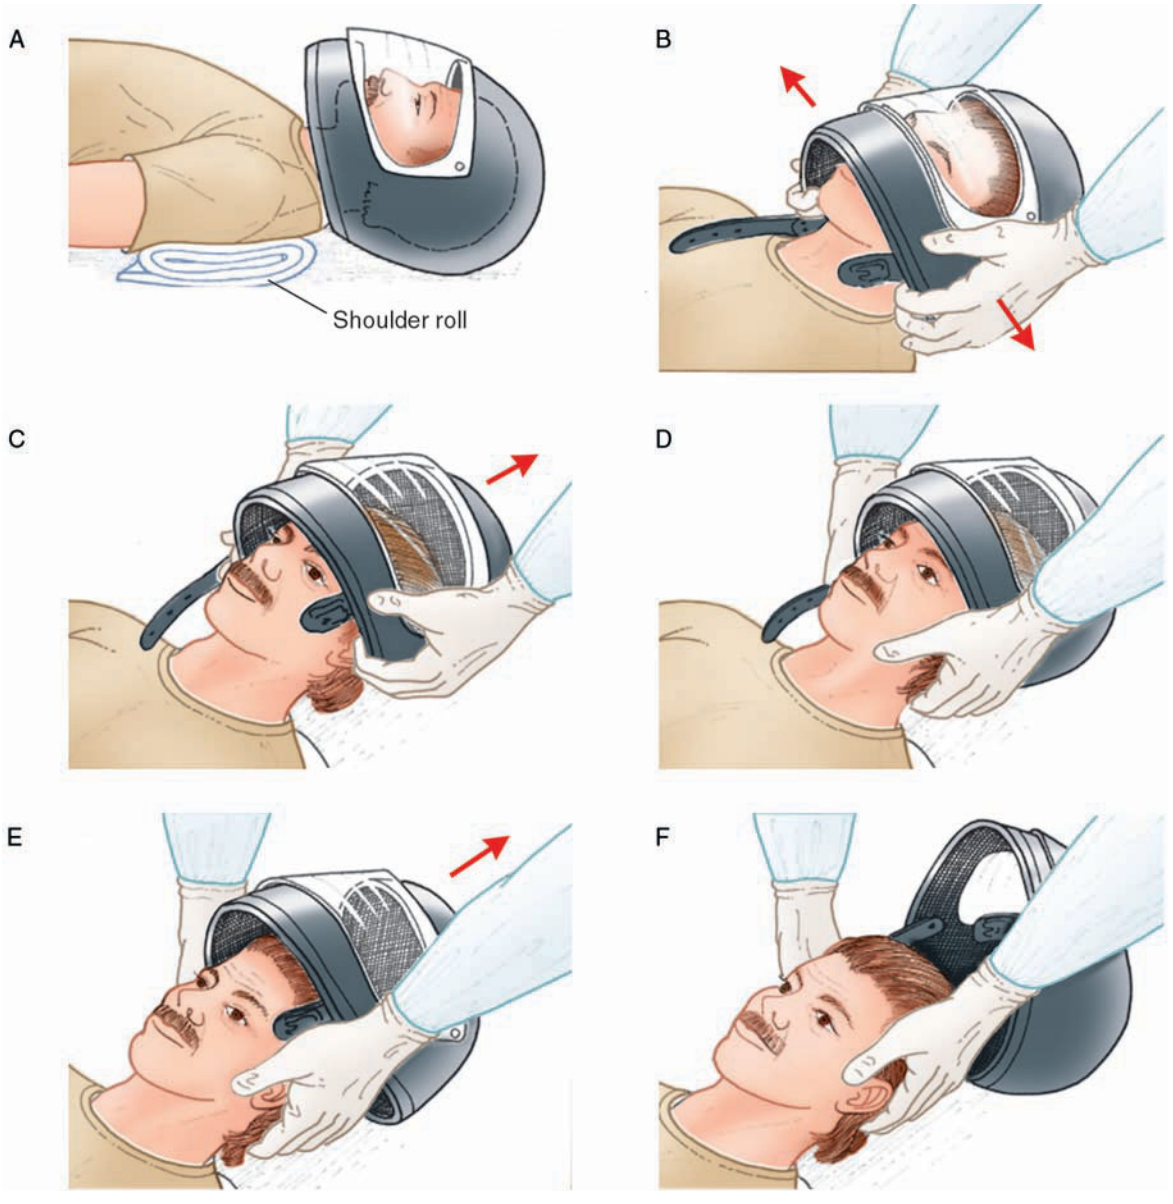

FIGURE 192-2. The one-person helmet removal technique. **A.** Patient positioning. **B.** The base of the helmet is spread open. **C.** The helmet is removed to expose the occiput. **D.** In-line immobilization is applied with the fingers. **E.** The helmet is pushed off with the heels of the hands. **F.** The helmet is removed while in-line immobilization is maintained.

Remove the shoulder pads if present. Maintain the head manually in-line until immobilization can be accomplished with a cervical collar, backboard, sandbags, and tape.[5,14,18]

MANUAL TWO-PERSON TECHNIQUE

The two-person technique has the same goals as the one-person technique (**Figure 192-3**). The assistant provides in-line immobilization while the helmet is removed.[5,14,18] Instruct an assistant to stand at the patient's side, at the level of the patient's neck and shoulders. Place one of the assistant's hands under the patient's occiput and upper neck. Place the assistant's other hand under the patient's mandible so that the mental process (chin) rests in the assistant's first web space (**Figure 192-3B**). Place the tip of the assistant's thumb on the angle of the patient's mandible. Place the index and long finger of the assistant's hand on the contralateral angle of the patient's mandible. Instruct the assistant to hold this position and maintain in-line immobilization of the patient's head and neck.[5,20]

The procedure to remove the helmet is similar to that described for the one-person technique. Stand above the patient's head looking down toward their feet. Place the heels of both hands on the sides of the helmet (**Figure 192-3B**). Insert the index, middle, ring, and little fingers into the space between the patient's head and the helmet. Gently spread open the helmet with both hands to create clearance between the helmet padding and the patient's face and ears (**Figure 192-3B**). Slowly and gently remove the helmet (**Figure 192-3C**). **Stop removing the helmet immediately if the patient experiences pain or neurologic symptoms and use the cast saw technique.** If the helmet is of the full-face type, gently tilt it posteriorly and continue to pull it off until the nose is cleared. Return the helmet to a neutral position after the nose is cleared. **Avoid cervical spine hyperextension during this stage of helmet removal.** Completely remove the helmet (**Figure 192-3D**).

Maintain the head manually in-line until immobilization can be accomplished with a cervical collar, backboard, sandbags, and tape.[5,14,18] The Emergency Physician's hands should be applied

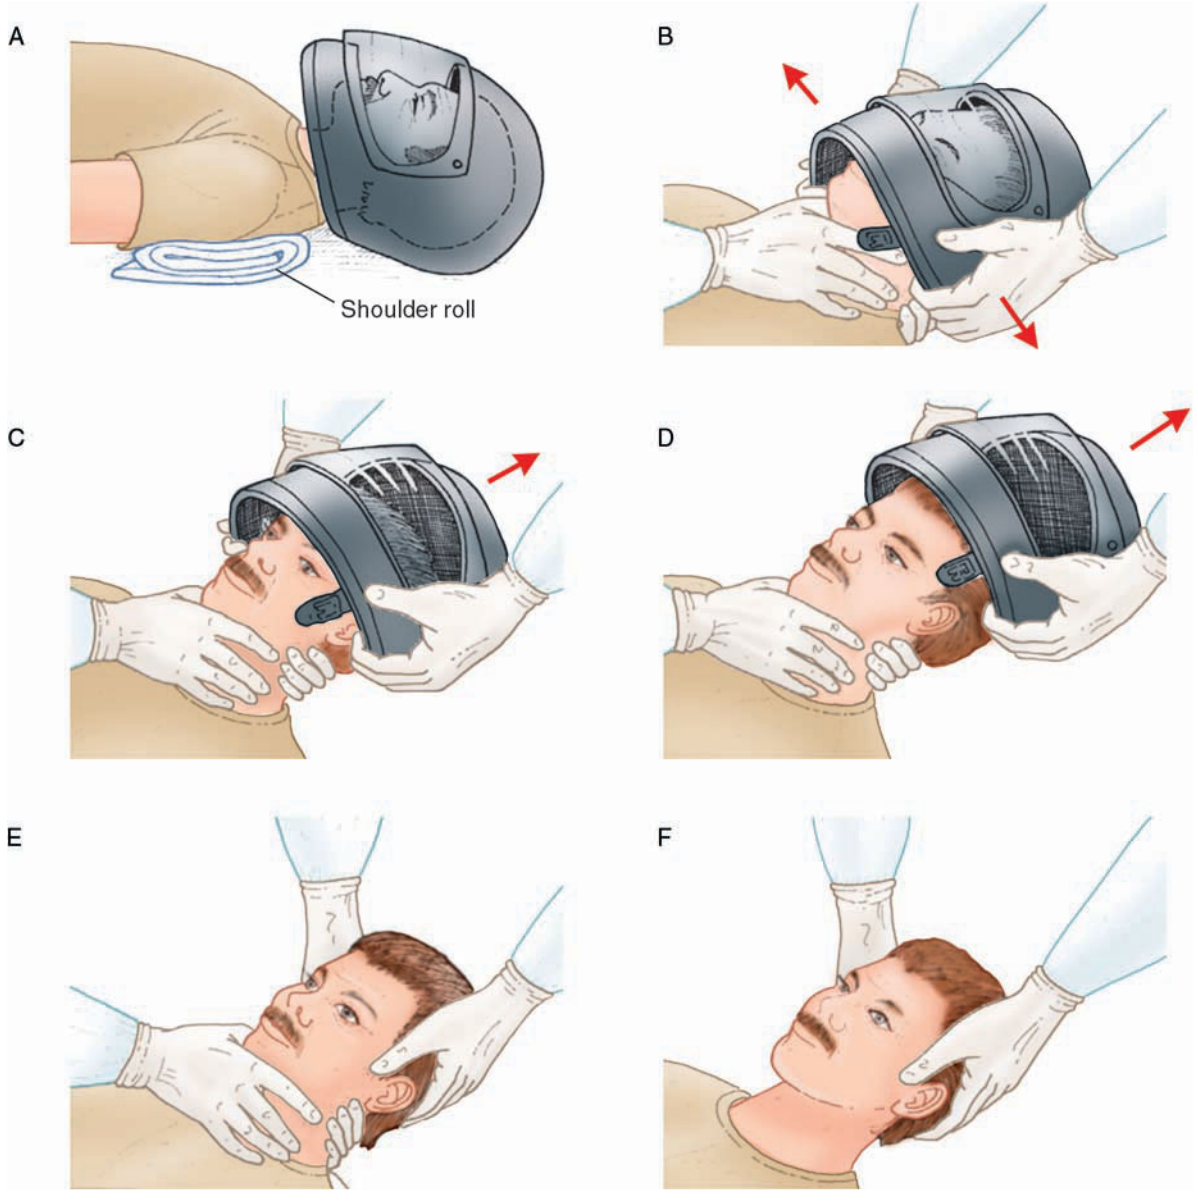

FIGURE 192-3. The two-person helmet removal technique. **A.** Patient positioning. **B.** An assistant provides in-line immobilization. The base of the helmet is spread open. **C.** Remove the helmet to clear the nose. **D.** The helmet is removed while the assistant continues in-line immobilization. **E.** The Emergency Physician provides in-line immobilization, in addition to the assistant. **F.** The assistant has removed their hands and the Emergency Physician maintains the in-line immobilization.

to the patient's head and neck to maintain in-line immobilization (**Figure 192-3E**). Instruct the assistant to remove their hands (**Figure 192-3F**). Remove the shoulder pads if present. Instruct the assistant to apply a cervical collar and secure the patient's head. The Emergency Physician can now release hold of the patient.

CAST SAW (BIVALVE) TECHNIQUE

A cast saw (**Figure 192-4**) can effectively be used to cut through the shells of most helmets (**Figure 192-5**). This technique allows for removal of the helmet without cervical spine movement.[14,18,21] **Cut the helmet off any patient with a neurologic injury, abnormal cervical spine radiographs, if there is a concern for head and neck trauma, or if the helmet is extremely snug-fitting to prevent cervical spine movement.** This technique requires the presence of two providers.[14,18,21]

Protect the patient from secondary injury from the cast saw, the helmet cutting process, and the sharp edges of the helmet.

FIGURE 192-4. The cast saw.

FIGURE 192-5. The cast saw (bivalve) technique. **A.** Patient positioning. **B.** An assistant provides in-line immobilization. **C.** The helmet has been cut with a cast saw. **D.** The anterior portion of the helmet is removed. **E.** The posterior portion of the helmet is removed. **F.** The Emergency Physician provides in-line immobilization, in addition to the assistant. **G.** The assistant has removed their hands and the Emergency Physician maintains the in-line immobilization.

Instruct the responsive patient to keep their eyes closed throughout the cutting and removal process to prevent corneal foreign bodies, corneal abrasions, and globe penetration. Place a moist towel over the patient's face for protection. Explain that there may be sounds of material or Velcro being torn or pulled with the helmet and not to be alarmed. Warn the patient about the noise associated with cutting the helmet with the cast saw. Protect the patient's eyes from exposure to foreign body penetration or abrasions if they are unresponsive. This includes taping the eyelids closed and placing a moist towel over their face.

Instruct the assistant, as described above for the two-person technique, to stabilize and immobilize the patient's head and neck (**Figure 192-5B**). Cut the helmet from ear to ear in a coronal plane with the cast saw (**Figure 192-5C**). **Carefully cut the padding and straps with a heavy scissors. Use care to not cut the patient's ears as well not force the tips of the scissors into their ears or scalp.** Remove the anterior portion of the helmet (**Figure 192-5D**). Gently slide out the posterior portion of the helmet while the assistant maintains in-line immobilization of the head and neck (**Figure 192-5E**). The Emergency Physician should then support the

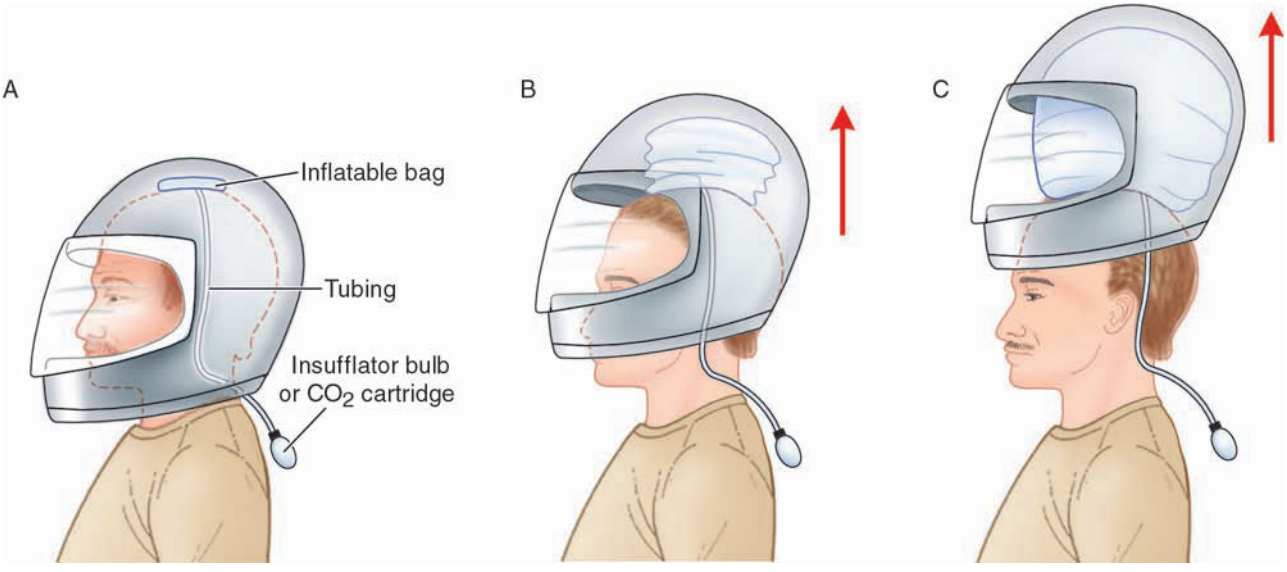

FIGURE 192-6. The Eject Helmet Removal System. **A.** The system in place between the helmet and the patient's head. **B.** Inflation of the airbag releases the helmet and begins to elevate it off the head. **C.** The airbag is further inflated until the helmet is removed from the head.

patient's head and maintain in-line immobilization (**Figure 192-5F**). Instruct the assistant to slowly and carefully remove their hands (**Figure 192-5G**). Remove the shoulder pads if present. Instruct the assistant to apply a cervical collar and secure the patient's head. The Emergency Physician can now release hold of the patient.

ALTERNATIVE TECHNIQUES

A novel device is the Eject Helmet Removal System (Shock Doctor Inc., Minneapolis, MN). This device was formerly produced by another company under the name of HATS OFF Emergency Helmet Removal System. This simple, easy to install, and low cost device has been recommended or required for use my many professional athletic, car racing, and motorcycle racing associations and organizations. The device consists of an accordion-folded airbag, tubing that exits the airbag and clips onto the edge of the helmet for easy access, and an insufflation bulb (**Figure 192-6**).

It is available in two forms. The first is the individual unit that can be purchased and installed in the helmet by the person wearing the helmet. The second is the EMS Kit for EMS and healthcare personnel to use if the device is not preinstalled by the helmet wearer. The EMS Kit contains several of the devices, insufflation bulbs, an insertion tool, and CO_2 cartridges that can be used instead of the insufflation bulb.

The device can be preinstalled by the helmet wearer. The folded airbag is placed inside the top of the helmet, either over or under the lining depending on the helmet design. The tubing is run from the airbag, either under or between the padding. The distal end of the tubing attaches to the edge of the helmet with a clip.

The device is simple to use. One person is required to provide in-line immobilization to the cervical spine. A second person is required to activate the device and remove the helmet. If the device is preinstalled in the helmet, locate the tubing insufflation port. Attach the insufflator bulb (**Figure 192-6A**). Squeeze the insufflator bulb to inflate the airbag. Alternatively, attach the CO_2 cartridge to inflate the airbag. As the airbag inflates, it will elevate and lift the helmet off the patient's head (**Figures 192-6B & C**).While one person maintains cervical spine immobilization, the other person should remove the helmet followed by removal of the pads if present. Apply a cervical collar and secure the patient's head.

If the device is not preinstalled, it can be easily placed inside the helmet. One person is required to provide in-line immobilization to the cervical spine. A second person is required to insert the device, activate it, and remove the helmet. Use the insertion tool to slip the airbag into the helmet and position it near the top of the patient's head. The remainder of the procedure is exactly as described above.

ASSESSMENT

Reassess the patient after removing the helmet and securing their head and neck.[22] Examine the patient for secondary injury due to the helmet removal procedure. These include lacerations and avulsions to the ear and nose, corneal abrasions, and corneal foreign bodies. Perform a complete head, eyes, ears, nose, and throat examination looking for injury. Perform and document a complete neurologic examination to ensure there is no change from the initial examination and that the helmet removal did not result in an iatrogenic injury.

AFTERCARE

Clean and vacuum any helmet debris if the helmet was cut with the cast saw. This will prevent any of this material from getting into the patient's eyes or nose as well as preventing them from inhaling the debris.

COMPLICATIONS

The most concerning aspect of helmet removal is adequate immobilization of the patient's head and neck during the procedure. Gross movement of the head and neck can result in displacement of fractures, spinal cord injury, or exacerbation of a partial spinal cord injury. **Avoid any movement of the head and neck when there is a strong suspicion of a spinal cord injury or severe head trauma.** Some movement of the patient's head or neck is likely to occur during helmet removal. **Minimizing the amount of motion is paramount.**

Secondary injury to the ears, eyes, and nose can be avoided by using careful technique. Spreading open the sides of the helmet before removal in the one-person or two-person techniques will

eliminate traction injuries to the scalp and ears. Tilting the helmet posteriorly will allow the chin portion of the helmet to clear the nose and avoid traction injuries to the nose.

A separate set of complications is applicable to the cast saw (bivalve) technique. Proper education of the patient is required to prevent them from moving because of the noise and vibration associated with this technique. Covering the patient's eyes and face with a moist towel (or gauze squares) will prevent corneal abrasions, corneal foreign bodies, globe penetration from foreign bodies, oral and nasal foreign bodies, and the inhalation of any debris. Use caution to prevent cutting the patient's ears or scalp when cutting the helmet padding. The cut edges of the helmet are extremely sharp. Careful removal will prevent cutting the patient's ears or scalp.

SUMMARY

The Emergency Physician who cares for trauma victims must be aware of the different types of helmets available and the means to safely remove them. Proper assessment of the helmeted patient will determine the need for emergent helmet removal. A thorough physical assessment and radiographic studies may take place prior to removing the helmet if the patient is stable upon initial assessment. By using proper techniques, helmets may safely be removed without causing secondary injury.

193 Hazmat Patient Management

Atilla B. Üner

INTRODUCTION

Hazardous materials (hazmat) incidents occur most often during the transport of chemicals or at industrial site accidents. Hazmat incidents may strike any community at any time.[1] Every Emergency Department must be prepared to respond to victims of a hazmat exposure.

Decontamination is the procedure of eliminating or reducing to a safe level any harmful substances on persons and equipment.[2] **Decontamination of victims in the field should always be performed by Emergency Medical Service (EMS) providers or before the patient enters the Emergency Department.** However, this does not always occur. Patients may be too ill for lengthy decontamination procedures prior to transport. Exposed patients may leave the scene and present to the Emergency Department on their own.[3–5] Basic decontamination by Emergency Department personnel can be safely performed outdoors in a designated decontamination area.[6,7]

Exposure to a hazmat contaminated patient who has been inadequately decontaminated or not decontaminated at all is a real possibility. This can result in exposure and secondary injury to healthcare personnel, other patients, and visitors.[5] The Emergency Department may be closed in part or in whole until the facility can be decontaminated. The panic and fear induced by rumors or odors can lead to unnecessary facility closure, delayed or inadequate patient treatment, and psychogenic illness in both healthcare personnel and bystanders.[3,4]

The three primary goals for the Emergency Department are to isolate and contain the contamination; decontaminate and treat exposed patients while protecting staff, other patients, and visitors; and maintain normal services, or reestablish them, as soon as possible.[3]

Early recognition of potentially hazmat contaminated patients will aid in preventing secondary contamination and Emergency Department closures. Numerous clues may identify a patient for hazmat contamination at triage.[3,4] These include accidents at agricultural or industrial sites, accidents involving chemical transports, suspected mass casualty incidents, a cholinergic toxidrome, mucous membrane irritation, chemical burns, soiling with unidentified liquids or powders, intentional overdose with chemicals, unexplained unconsciousness or cardiac arrest, and symptoms occurring in Paramedics or Emergency Medical Technicians (EMTs) after patient transport.

Information management is critical to the response.[4] Designate a person to obtain as much information as possible on the involved substance. Even preliminary and general information is useful and should be immediately conveyed to the treating Emergency Physician.[1] The maintenance of material safety data sheets (MSDS) is mandatory for each chemical used or stored at an industrial site or during transport. Request information on the MSDS from fire or EMS services at the scene. Further information resources are listed after the "References" section of this chapter. Verify all information for accuracy by cross-referencing several sources.[4]

This chapter describes a general approach to the management of the hazmat contaminated patient. The Emergency Department response and patient management will have to be tailored to the specific agent(s) and circumstances, such as number of patients and facility resources. All Emergency Departments are strongly encouraged to conduct regular inservice training sessions and drills on hazmat decontamination procedures. Information on hospital-based decontamination best practices is available from the United States Department of Labor, Occupational Safety & Health Administration.[7]

ANATOMY AND PATHOPHYSIOLOGY

Hazardous materials can enter the body through inhalation, absorption, and ingestion.[8] The total dose is a function of the concentration and properties of the substance, the exposure time, and the exposure route. There is a dose–response relationship between the absorbed dose and toxic effects for most toxic chemicals.[8] The effects can be local, systemic, and quite variable for different agents.

Inhalation is the most common route of exposure. It may lead to local irritation, airway obstruction, and/or pulmonary systemic absorption. Absorption through intact skin is facilitated by fat solubility, open wounds, burns, exposure of the eyes and mucous membranes, and by dermal contamination underneath soiled clothing leading to an occlusive dressing effect.[2,4] The axillae, groin, and skin folds have a thin epidermal layer that facilitates the absorption of a contaminant. Children have a larger surface area to body weight ratio and more permeable skin, making them more vulnerable to absorption of toxins.[9] Ingestions can be accidental or intentional.

Patients exposed to hazardous materials may show any or all of the following: local effects such as chemical burns, respiratory tract effects of inhaled toxins, systemic effects of absorbed toxins, associated trauma, psychiatric reactions (e.g., agitation and anxiety), or contamination without apparent injury.[4]

The hazard to personnel, or risk of secondary contamination, is determined by the dose of the hazardous material that is carried by the victim and absorbed by the caregiver.[10] Toxic liquids and solids can pose a dermal contact hazard.[3] Solids or volatile liquids can pose an inhalational hazard.[3] Most gases or vapors dissipate quickly and are unlikely to pose a secondary contamination hazard.[7,10] However, the risk to emergency personnel is real.[4,5,11] Contamination with corrosives or pesticides may indeed cause illness in personnel.[4,10,11] Toxins can rarely be emitted from vomitus

(e.g., hydrogen cyanide after cyanide salt ingestion) or exhaled breath (e.g., after ethylene oxide exposure).[2]

INDICATIONS

Decontaminate any potentially contaminated patient prior to their entry into the Emergency Department.[11] The more toxic the substance, the more rapidly the decontamination should be performed. Pesticides and corrosives are common and worrisome contaminants.[10] Asymptomatic contaminated patients can be triaged for decontamination before those with symptoms to prevent toxicity if the risk of toxicity is high. Decontaminate symptomatic patients before asymptomatic patients if the risk of toxicity is low.[4] Initiate any life support measures simultaneously with decontamination.[4] Patients who have been decontaminated or exposed to gases or vapors without signs of skin or eye irritation do not require further decontamination.[2,4,6]

Patients should never be made to wait in their contaminated clothing. They need to be given the means to undress in privacy, change into clean clothing, and await decontamination by hospital personnel.

The absence of a system to isolate wastewater is not a contraindication to water decontamination. **When in doubt, decontaminate the patient.** Dilution will suffice to reduce the hazardous substance to a safe level.

CONTRAINDICATIONS

Contraindications to water decontamination include contamination with metallic sodium, lithium, calcium, potassium, cesium, and rubidium.[1,12] Other contraindications to water decontamination include exposure to dusts of pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium.[1,12] These substances react violently with water and can cause secondary injury.[1,12] Cover the patient and/or substance with mineral oil, remove the substance with forceps, and store it in a container with mineral oil.[4,12] However, many of these substances may already have reacted with moisture on the patient's skin.[1,12,13] Rapid removal of the chemical agent is better than allowing continuing injury to occur.[6,13] Adding large amounts of water to the small amount of residual chemical on the patient's body poses little risk of creating a serious reaction hazard.[13,14]

Patients soaked in flammable liquids pose special problems. Water decontamination may be inadequate to completely remove the substance from the patient's skin. Do not cardiovert or defibrillate the patient until the material is completely removed from the skin, so as to prevent an explosion or a fire.[6]

The use of chemical agents for neutralization is contraindicated. These substances may cause secondary injury, toxicity, or react with another substance in an adverse manner. Use large quantities of water for decontamination (e.g., a shower) rather than a neutralization agent.[6]

EQUIPMENT

Personal Protective Equipment (per Person)

- Scrub suit and closed shoes
- Plastic shoe covers
- Protective goggles
- Water resistant face mask
- Latex gloves
- Chemical resistant (i.e., nitrile) gloves
- Chemical resistant coverall suit with booties and hood
- Duct tape
- Rubber apron
- Butyl rubber gloves
- Chemical resistant rubber boots or shoe covers
- Respiratory protection (i.e., PAPR with assigned protection factor 1000)[7]

Patient Decontamination

- Decontamination unit located outside of the hospital
- Designated decontamination facility inside the hospital
- Decontamination stretchers, if applicable
- Portable wading pools for ambulatory patients
- Warm running water source with a hose and soft-stream nozzle
- Portable barriers to assure privacy and protect from wind
- Liquid hand or dishwashing soap
- Liquid shampoo
- Soft-bristled brushes
- Devices to decontaminate hands and nails (e.g., surgical scrub sets)
- Eye irrigation equipment

Miscellaneous Supplies

- Polyethylene plastic bags
- Name tags
- Yellow tape and signs to mark decontamination zones
- Scissors to cut clothing
- Scrub suits, towels, and blankets for patients before and after decontamination

The Occupational Safety and Health Administration (OSHA) requires level B protection for responders to an unknown chemical hazard, with a positive-pressure self-contained breathing apparatus and chemical resistant clothing.[3,8,11] The high cost of such equipment and constant skills retraining required to use it may prohibit some hospitals from purchasing it and has made compliance difficult.[8] The OSHA has published best practice guidelines for hospital-based chemical decontamination procedures, including detailed recommendations for personal protective equipment (PPE).[7]

Hospital gowns, standard Tyvek suits, surgical masks, and latex gloves are not considered adequate protection.[4,10,12] Personal protective equipment is available through specialized dealers and requires training to provide reliable protection.[4,8,11,12] The minimum protection recommended for hospital decontamination personnel includes a scrub suit, a chemical resistant suit with booties and hood, plastic shoe covers, at least two layers of gloves (surgical and nitrile) taped at the sleeve, protective eyewear, and respiratory protection.[4,7,8]

There is little consensus on how to provide respiratory protection. The required level of respiratory protection, if any, will depend upon the agent, the dose, prior training, and decontamination circumstances.[4,8,11] The OSHA has published guidelines under which the use of powered air-purifying respirators (PAPR) is sufficient.[7] The use of PAPRs requires regular training. Respiratory protection is rarely necessary if decontamination is performed outdoors.[10] Information obtained about the contaminant will aid in determining the level of protection required.

PATIENT PREPARATION

Patients should be initially received in a secured area outside of the Emergency Department. Clearly mark the area with yellow tape or other similar device. This is considered a contaminated

"hot zone." Triage, a primary survey, and any required immediate lifesaving interventions (e.g., Basic Life Support and CPR) may be performed here by appropriately protected personnel.[4,8,15] Rapid removal of clothing is essential as absorption is time dependent, and contaminated clothing can act as an occlusive dressing or continue to off-gas contaminant.[13] **Patients should not wait for decontamination in their contaminated clothing**. Instead, patients who are able should remove their own clothing and be given clean clothing or blankets for warmth and modesty. Children should not be separated from their caregivers if at all possible.[9]

Patients who present to the Emergency Department with real or imagined contamination are under high stress and are likely to act out if left unattended. Early self-removal of clothing will help alleviate fears and provide real early decontamination benefit.

The decontamination area is also considered a contaminated "hot zone."[4] **Perform basic life support and immediate life-saving measures only in the decontamination area.**[12] However, the extent of medical treatment in the decontamination area will need to be decided on a case-to-case basis. Treatment of cardiac dysrhythmias and wounds or administration of toxin-specific antidotes may have to be initiated prior to complete decontamination.[12,15] **Keep in mind that invasive procedures prior to decontamination may provide a percutaneous route of contamination with the hazardous substance.** Devices, such as monitors, used in the decontamination area will have to be decontaminated after use.[12] Use long leads, if available, that extend into the clean support area to prevent having to decontaminate monitoring devices.[12] **Patients are considered safe to move into the contamination reduction area ("warm zone") and then the Emergency Department (support area, "cold zone") only when decontamination is completed.** Perform a secondary survey, including a search for any toxidromes, and begin definitive medical treatment after decontamination.[4]

DECONTAMINATION TECHNIQUE FOR CHEMICAL AGENTS

Don personal protective equipment before approaching the contaminated patient.[4] This will prevent the healthcare worker from becoming contaminated, now making them a patient, and requiring the healthcare worker to be removed from duty. Suggested minimum personal protective equipment and its application is described here. Wear standard work attire, such as a scrub suit, and closed shoes (no clogs or slippers). Place plastic shoe covers over shoes. Don goggles and a water resistant face mask if no PAPR is worn. This is for splash protection only. Don latex gloves followed by nitrile or other chemical resistant gloves. Don a chemical resistant coverall suit with booties and a hood. Tape the sleeves to the gloves with duct tape. Don a butyl rubber apron and butyl rubber gloves for protection against water and chemicals. This protocol provides no respiratory protection. Don a PAPR if respiratory protection is desired or required.

Perform a primary survey and treat any life-threatening conditions with basic life support interventions.[4] Remove all of the patient's clothing. This includes shoes and jewelry. Cut off the clothing if necessary. Place the clothing in a plastic bag and seal it with duct tape. Place this bag into another bag and seal it to "double bag" the clothing. Double bag any jewelry and watches separately if time and circumstances permit. This allows for possible later decontamination and salvage. Label the bags with the patient's name or medical record number. Patients may assist with their own decontamination. **Do not irrigate the patient prior to complete clothing removal.** Chemicals on clothing will soak through wet clothing and onto the skin, resulting in additional injury or absorption.[2,6]

Remove any visible chemicals on the patient's body by gently washing off liquids or brushing off solids. Avoid skin irritation or injury, as both will lead to increased absorption of any remaining chemicals. Avoid aerosolization of the contaminant. Blot any heavy liquids with absorbent towels.[2,6]

Patients with open wounds require the area surrounding the wound to be gently washed with water. Irrigate the wound with clean water. Cover large wounds with plastic wrap to prevent runoff into the wound during the remaining decontamination procedure.[2] **Do not delay copious water irrigation if this wound care cannot be accomplished rapidly.**

Begin copious water irrigation with warm water using low water pressure (normal shower pressure) for 3 to 5 minutes. Use liquid soap, shampoo, and soft brushes to gently cleanse the skin and any body hair.[5] Thoroughly rinse the patient after soaping and shampooing. Repeat the procedure until all visible contamination is removed. **Do not forget to thoroughly clean any mucous membranes, the nails, the external auditory canals, the axillae, the groin, and any other skin folds.** Use cleaning devices such as surgical scrub sets for nail folds or syringes to flush the external auditory canals.

Irrigate the eyes, if contaminated, for 5 minutes. Remove any contact lenses and place them in a double bag. A Morgan lens may be used if the globe is intact. Irrigation with running water is also an option but may be less thorough than with a Morgan lens. A nasal oxygen cannula may be placed on the bridge of the nose if both eyes are affected.[2] Allow water to flow through the cannula and direct it from the medial canthus outward. Refer to Chapter 155 for the details regarding eye irrigation.

Do not let caregivers carry children in a wet decontamination environment as they may fall and injure themselves and the child. Instead, have decontamination personnel carry the child. It may take two providers to safely carry a struggling wet child while wearing personal protective equipment.[9] An alternative is to use a gurney or wheelchair.

The nonambulatory contaminated trauma patient or a patient with altered mental status may need to be decontaminated on a specialized stretcher that is equipped to catch wastewater. Autopsy tables from the morgue may be used after covering the surface with plastic. Enough decontamination personnel must be available to maintain cervical spine immobilization while log-rolling the patient as the decontamination process is performed.

DECONTAMINATION TECHNIQUE FOR BIOLOGICAL WEAPONS AGENTS

Biological weapons agents include bacteria, spores, viruses, and toxins. Chemical decontamination renders biological weapons agents harmless by the use of disinfectants.[14] **Most biological warfare agents are transmitted by inhalation; therefore, respiratory protection is highly recommended.** Treat dermal exposures immediately with soap-and-water decontamination using a soft brush followed by rinsing with copious amounts of water. This alone is often sufficient to avert contact infection. Wash with a dilute bleach (hypochlorite) solution to eradicate any remaining biological agent.

Mix one part Clorox bleach and nine parts water, as standard stock Clorox is a 5% solution, to make a 0.5% sodium hypochlorite solution. The diluted bleach solution must be made fresh daily with a pH in the alkaline range. Diluted and undiluted bleach solutions evaporate quickly. Store the bleach solution in closed and distinctly marked containers to avoid confusing the 5% and 0.5% solutions. Wash the contaminated areas with a soaked cloth or swab for 10 to 15 minutes with the 0.5% sodium hypochlorite solution. **A contact time of 10 to 15 minutes is required.**[14] Rinse thoroughly with water.

The dilute bleach solution is contraindicated for application into the eyes, into open brain and spinal cord injuries, or for surgical irrigation of the abdomen. However, it may be used for lavage of

other noncavity wounds and removed by suction to an appropriate disposal container. Within 5 minutes, the now contaminated bleach solution will be neutralized and is considered nonhazardous.

Use a 5% hypochlorite solution (undiluted Clorox) to decontaminate fabric, clothing, and equipment. **A contact time of 30 minutes prior to normal cleaning is required for the decontamination of equipment.** The 5% bleach solution is corrosive to most metals and injurious to most fabrics. Thoroughly rinse and oil metal surfaces after completion.

Physical methods to render biological weapons agents harmless include heat and radiation. Dry heat requires 2 hours of treatment at 160 °C to render biological agents completely harmless. Autoclaving is effective. Steam at 121°C and 1 atmosphere of overpressure (15 psi) will reduce the required time to approximately 20 minutes, depending upon volume.

Rooms in fixed spaces that become contaminated are best decontaminated with gases or liquids in aerosol form (e.g., formaldehyde). This is combined with surface disinfectants, in most cases, to ensure complete decontamination. Solar ultraviolet radiation that reaches the earth's surface has a certain disinfectant effect, often in combination with drying, and will aid in the decontamination of outdoor decontamination facilities. Chlorine-calcium or lye may be used if it is necessary to decontaminate terrain.

ASSESSMENT

Move the patient after decontamination to the contamination reduction zone ("warm zone"). Assess the patient and initiate any required advanced life support measures. **There are no objective criteria to assess whether decontamination was sufficient.** There is, however, evidence that copious water irrigation and soap cleansing are highly effective in removing many chemical contaminants.[4] Measure the tear film pH if the eyes were exposed to corrosive agents. Continue eye irrigation until the pH is neutral. This may take up to 15 minutes. Assess all wounds. Thoroughly irrigate any wounds. **Transfer the patient into the support zone (Emergency Department or "cold zone") when they are deemed decontaminated.**

HEALTHCARE PERSONNEL DECONTAMINATION TECHNIQUE

Healthcare personnel must remove their personal protective equipment in an organized fashion to prevent self-contamination after decontamination of the patient.[8] This is a suggested protocol for the minimum personal protective equipment, which may need to be altered if more sophisticated equipment is to be decontaminated and recycled.

Remove the tape securing the gloves to the suit. Place the tape in a plastic bag. Remove the outer gloves, turning them inside out as they are removed. Place the gloves in the plastic bag. Remove the suit, turning it inside out as it is removed. Place the suit in the plastic bag. Seal the bag with duct tape. Remove the plastic shoe cover from one foot and step over the "clean line." Remove the other shoe cover and put that foot over the line. Place both shoe covers in a plastic bag at the line. Remove the goggles and mask. Place them in the plastic bag. Seal the plastic bag. If a PAPR if worn, an assistant is required to prevent contamination of reusable equipment. The assistant dons gloves and supports the battery pack while the belt is loosened and the hood is removed. Hold the hood away from the body to avoid contamination. Detach the hose. The assistant places the pack and hose in a bag for reprocessing. Place the hood in a separate bag for reprocessing or disposal and seal the bag with duct tape.[16] Remove the inner gloves. Place them in a plastic bag and seal it. Close off the dirty area until the level of contamination is established and the area is properly decontaminated. Move to a shower area. Remove the scrub suit and seal it in a plastic bag. Shower thoroughly with soap and water. Dress in normal work attire.

AFTERCARE

Further patient management will depend on the type of exposure and other circumstances. Perform a thorough secondary survey to detect occult trauma or medical illness. Monitoring for cardiac dysrhythmias or for noncardiogenic pulmonary edema may be necessary after exposure to certain chemicals.[2,6] Some toxins necessitate treatment with specific antidotes, which should be initiated as soon as possible.

Dilute ingested chemicals with 4 to 8 ounces of water. Activated charcoal (1 g/kg) may be given to prevent further absorption.[6] Ingestion of corrosive agents may necessitate early endoscopy, in which case charcoal should be withheld.[6] Induction of emesis is rarely indicated and may pose a hazard to the patient (if they ingested corrosives or hydrocarbons) and to healthcare personnel (if the patient ingested cyanide).[2,6] Refer to Chapters 59, 60, and 61 for the details of gastrointestinal contamination.

COMPLICATIONS

Hypothermia may be caused or worsened by the decontamination procedures.[2,6] This must be anticipated and treated accordingly. Children are especially vulnerable to hypothermia.[9] Residues of highly toxic chemicals remaining in skin folds or under nails may pose a risk to the patient and caregivers.[6] This should be searched for and removed. Toxic vomitus may pose a risk to healthcare personnel, even after adequate decontamination.[2,6] Emesis must be contained and discarded appropriately.

SUMMARY

Emergency Departments must be prepared to decontaminate and treat victims of hazardous materials exposures at any time. Procedures must be developed, practiced, and incorporated into the hospital's mass casualty incident plan. Lack of preparation and practice will expose medical personnel to greater risks and lead to less than optimal patient care. This chapter presents a general approach to decontamination procedures, which must be adapted to the individual circumstances and type of exposure.

194 Physical Restraints

Cheryl Person, Dean Sagun, and Mark Fanning

INTRODUCTION

In recent years, psychiatric emergency services have become a major point of entry into the mental health system and a principal treatment site for many patients with chronic and severe mental illness.[1] Emergency Department (ED) patients with altered mental status, emotional and psychological disturbances, head trauma, psychiatric illness, or other medical conditions may be aggressive, physically injurious, or violent.[2,3] The aggression may be exhibited toward themselves or toward the healthcare personnel who are caring for them.[4] **Given the volatile nature of some presenting conditions, physical restraints might be necessary to ensure the safety of the patient and the healthcare personnel.** One prospective study found that 0.07% of ED patients were restrained

during the 1-year study period.[5] Consistent with clinical practice, most patients in this study were restrained for agitation, disruptive behavior, or violent behavior.

Physical restraints are the direct application of physical force to a patient without patient consent to restrict their freedom of movement. The use of restraints for managing behavioral emergencies is allowed only when all other less restrictive measures have failed and severely aggressive or destructive behaviors place the patient or others in imminent danger. The Centers for Medicare and Medicaid Services (CMS) defines physical restraint as "any manual method, physical or mechanical device, material or equipment attached or adjacent to the patient's body that they cannot remove and that restricts freedom of movement or normal access to one's body."[6] The use of restraints in the ED may help to prevent patients from physically harming themselves or others. Imminent safety concerns are the only justification for the application of physical restraints.[6] Once applied, physical restraints must be used for the shortest time possible and with the least restriction possible.[6,7] If used properly and in the appropriate patient, physical restraints are humane and effective in the management and treatment of the patient while ensuring the safety of the patient and the healthcare personnel.

This chapter will present the rationale and technique for using both locked-door seclusion and physical restraints in the ED. This chapter focuses on the aggressive, dangerous, and/or violent patient. It does not review the techniques for physically restraining the young child during brief diagnostic or therapeutic procedures.

LEGAL CONSIDERATIONS

Informed consent is required before Emergency Physicians can lawfully treat competent adult patients, all of whom have the right to refuse medical treatment. Refer to Chapter 1 for a complete discussion of the informed consent process. United States courts have consistently upheld the idea that a competent adult would consent to treatment to maintain health or life and also that a patient could be restrained to protect others or self as long as the reasons for interventions are clearly documented.[8] Even in an emergency setting, the competent adult retains their right to refuse treatment. **Coercive measures, including restraints and threat of restraints, cannot be used solely because a patient refuses treatment.** It is never appropriate to restrain a competent patient against their will solely because they are refusing recommended treatment.[9] The Joint Commission (TJC), which governs hospitals, have required specific training elements for personnel who will be applying physical restraints. They also require hospitals to have clearly delineated policies as to who is certified as capable of applying restraints. The elements of training include the use of nonphysical interventions and the demonstration of these skills.

INITIAL APPROACH TO THE PATIENT

It is important to attempt to use verbal de-escalation techniques prior to initiating physical restraints. All of these techniques should be carried out in a calm voice that is clear, slow, and low in volume. This approach can assist the Emergency Physician in engaging the patient and calming the situation. Gently question the patient as to why they are distressed. Allow the patient time to think about the question prior to offering an array of potential choices. Common reasons why ED patients get agitated include being made to undress and put in hospital attire, being hungry, being frightened in a medical facility, being frustrated at the perceived lack of concern on the part of healthcare providers, being in pain which they do not feel is being promptly addressed, and not understanding why things are happening. **Addressing the patient's specific concern can often de-escalate the agitated patient.**

If the patient is still unable to communicate their needs or is too agitated to tolerate questioning, begin to orient them to their environment. Explain in clear language what needs to occur. For example, "Mr. Smith, you are in the ED because you are having a fever, and we now need to get you dressed in a hospital gown. Can you do that for me? May I help you?" **Allow the patient some control to make decisions about the sequence of events as much as safety permits.** For example, if the patient first wants to use the restroom or drink water, allow the patient to do these things first. Patients who are frightened or confused often de-escalate with these techniques.

It is often possible to encourage the patient to take oral or intramuscular medication prior to the use of physical restraint. The ability to begin a patient on needed medical treatment (i.e., benzodiazepines for alcohol withdrawal or antipsychotic agents for paranoia) may allow the patient to de-escalate and eliminate the need to initiate physical restraint. These patients must be carefully monitored including constant observation, pulse oximetry, and vital signs at regular intervals and telemetry if appropriate.

CONTRAINDICATIONS

Physical restraints should not be used for the sake of convenience or if a competent adult refuses treatment. It should not be used for patients who are currently not demonstrating behaviors that would put them, staff, or others in imminent danger. Patients with a history of violence but exhibiting no active imminent aggression also cannot be restrained. It is an urgent intervention that should be used only when less restrictive interventions have failed.

Because of the potential severity of the complications associated with the use of physical restraints, they must be immediately released when the patient is no longer demonstrating dangerous behavior. Hospitals must ensure appropriate staffing levels to meet this dynamic need. Every acute care hospital has developed policies and procedures for the monitoring and documentation associated with the use of physical restraints. A sample of the required documentation can be found in **Table 194-1**. The Emergency Physician

TABLE 194-1 Typical Documentation Requirements for the Physical Restraint of a Patient

Physician orders
- Date and time of order
- Description of specific behavior which placed patient, staff, or others in imminent danger
- Alternatives to restraint employed (e.g., verbal de-escalation)
- Patient response to alternatives

Ongoing assessment
- Family notification of restraint as appropriate
- Documentation of personnel involved in the application of restraint, including security and other trained staff
- Patient's reaction to restraint
- Patient's pre-existing medical or psychiatric condition that may increase the risk of harm
- Description of behaviors that patient needs to demonstrate to release restraints

Conclusion of restraint
- Documentation of the expected behavior demonstrated by the patient that led to release of restraints
- Debriefing of the patient regarding the episode of restraints including their reaction to the application of restraints
- Debriefing of the staff as appropriate
- Discontinuation of the restraint order

must be cognizant of these requirements and be able to follow these policies and procedures. Asphyxiation and strangulation are the two most serious complications of physical restraint. Personnel must be available to continuously monitor the patients' respiratory status through the application of restraint.

The use of leather restraints significantly increases the risk of rhabdomyolysis, skin breakdown, and neurovascular complications, even when used correctly. Patients should demonstrate the ability to break free from soft restraints or require the additional security of leather restraints prior to the application of leather restraints. Leather restraints are thus to be considered a restraint of last resort.

Seclusion should not be used if the patient is unstable, must be medically monitored, or if they overdosed on medications and/or poisons. Seclusion is also contraindicated if the room cannot be constantly monitored visually, either electronically with close-circuit video or by direct observation through a window.

EQUIPMENT

- Gloves
- Additional personal protective equipment, if indicated
  - Gown
  - Face mask with an eye shield or goggles
  - Cap
- Standard ED bed
- Hospital approved restraint devices, 2- and 4-point
- Philadelphia collar, various sizes
- Additional personnel

The following equipment may be necessary for putting a patient in physical restraints. First, utilize personal protective equipment (PPE) if contact with the patient's body fluids may occur. Second, only devices manufactured for the express purpose of restraining a patient should be used. Restraints are available in a variety of styles (Humane Restraint, Waunakee, WI, www.humanerestraint.com). They are made of a number of materials (e.g., polyurethane, polypropylene, leather) with Velcro or buckles to secure them. Use a standard ED bed for 2-point and 4-point restraints. Padding material must be utilized to protect the patient's bony prominences. Soft restraint manufacturers usually include this already attached to the restraint. Leather restraints are physically stronger and less constricting than soft restraints. These are more effective in the truly violent patient than soft restraints. Makeshift restraints (i.e., gauze rolls) are difficult to apply and must be tied extremely tight to hold the patient. These makeshift restraints must be avoided in the ED because of the increased risk for injury to the skin, peripheral nerves, extremity vasculature, and respiratory difficulties (if placed around the chest).

The restraints, personnel, and a plan should be assembled and ready prior to initiating physical contact with the patient. This will reduce the risk of asphyxiation due to a prolonged physical contact time with the patient. A sufficient number of personnel must be available. They should all be approved for applying restraints to protect both the patient and the staff. At least one of the staff members should be a female if the patient is female. It is best to have security standing ready to assist if needed. Their mere presence and visibility to the patient as a "show of force" is often enough to calm the patient. Emerging practices may include a scribe to document the initiation of restraint, to ensure the safety of the patient during the application of restraints by keeping time, monitoring the patient's status, and confirming respirations. An Emergency Physician order for physical restraint is required (**Table 194-1**). It must be documented within 1 hour of the application of the restraints. Thus, it can be documented after the restraints are initiated.

PREPARATION

Appropriate use of restraints requires prior planning and education of physicians, nurses, and security staff. Without sufficient training and safeguards, physical restraints may pose a danger to the patient as well as the staff.[2,10] To ensure the safety of a patient and the staff, the Emergency Physician must provide a timely diagnosis and an appropriate acute management plan. **The "ABCs" of the emergency evaluation of aggressive and impulsive behavior include safety, diagnosis, and management. Safety is the first priority when confronted by a potentially violent patient.** Adequate evaluation, diagnosis, and management is impossible without proper safety mechanisms.

The application of physical restraints requires the understanding that physical/mechanical restraints are devices that can be used to prevent patient interference with medical treatment, reduce risk for falls and subsequent injury, and/or keep the patient from harming themselves or others. **Physical restraint should only be used as a last resort for maintaining patient safety. The alternatives to physical restraint should be continually evaluated.** It is important to be familiar with hospital procedures for ordering physical restraints, including documentation requirements (**Table 194-1**). It is also advantageous to have personnel on hand who are trained in the application of physical restraints and have demonstrated competencies in the area (usually nursing staff).

The Emergency Physician must understand the indications and purposes for use of the different types of restraints and their respective functions (e.g., wrist restraints to prevent arm movement). The Emergency Physician should observe and document the type of behavior that has led to the need for physical restraint (e.g., attempting to harm oneself or others, removing IV catheters or other equipment) and the type of restraint prescribed (**Table 194-1**). The treatment team (i.e., Emergency Physician and nursing) should each document the situation, the alternatives to physical restraint that were attempted along with their lack of success. Review the manufacturer's directions for assembling and placing the physical restraint. Lower the bed as low to the floor as possible. Visually inspect the bed to ensure it is free of objects that may be trapped under a physically restrained patient.

Gather all the supplies required for the physical restraint procedure. Assemble the personnel required for safety during the physical restraint procedure. One or two people will usually be physically applying the restraints. It is common to need up to four additional personnel to hold the patient during the application of the restraints. Understanding the nature of the aggressive behavior and the physicality of the person who will need to be restrained may help determine how many additional personnel are required. **It is always better to have more people than needed than not having enough. It is dangerous for the patient and the staff to have fewer people available to help than is needed. It is often better to have a "show of force" with multiple staff members and security present and visible to the patient. The mere presence of multiple people convey the message you are serious, often makes the patient more compliant, and gives the patient an excuse to cooperate with the application of physical restraint.** Although the application of physical restraints is time limited, it is a personnel intensive process. In a busy ED, be aware that other agitated patients may take this opportunity to elope from the facility.

Communicate with the patient and family. Evaluate whether the patient or family members require special considerations regarding communication (e.g., due to illiteracy, language barriers, or deafness). Make arrangements to meet these special needs

if necessary. Briefly assess the patient and family for knowledge deficits and anxiety regarding the physical restraint procedure. Assign a staff member to provide information and emotional support as needed.

Family members should not be present for the physical restraint procedure. They may become agitated themselves during the procedure and make it an unsafe environment for staff. They may also serve as an agitating influence on the patient. All family should be politely asked to wait in the lobby or family room until the patient is secure. Inform the family that they may return once the patient is restrained and any procedures have been completed. They should also be informed that under no circumstances should they attempt to loosen or remove the physical restraints, as this should be done solely by hospital staff. Assign a staff member to escort the patient to the lobby or the family room.

All staff involved must have a knowledge of proper patient positioning. **Do not restrain a patient with one or both arms positioned above their shoulders. These "arm-elevated" positions can result in respiratory compromise. Patients must be restrained in the supine position with their arms by their sides. The restraints must always be tied to the bed frame and not the side rails.**[11] The patient can experience significant pain and injuries if the bed rails are lowered while the restraints are tied to them.

TECHNIQUES

LOCKED-DOOR SECLUSION

One form of physical restraint within the ED is locked-door seclusion (LDS). LDS provides a low stimulus environment that is free of dangerous objects. It is a less restrictive form of physical restraint that is an appropriate and viable alternative if the patient is more likely to be an escape risk, dangerous to others, or dangerous to themselves. Patients who are violent or self-destructive may be placed in LDS. Agitated patients can be placed in LDS by security that are authorized and trained to physically escort patients. A "show of force" often makes the patient more cooperative. ED staff can assist a patient who is not physically threatening, but for whom the regular ED environment provides too much stimulation to allow effective treatment to occur. In all cases, security should be present to prevent injury to the patient or the staff. Agitated patients may require that all treatment, including changing into hospital attire, commence in the LDS setting.

Hospitals who have LDS capability should have built the room according to TJC parameters to provide safety, reduced stimulation, and less risk of patient self-injury. These rooms should have very limited equipment and supplies other than a bed so that the patient does not injure themselves. A patient can inflict significant self-injury with simple things such as blood collection tubes, needles, and tongue depressors to name a few. **Once occupied, the LDS room must be continuously monitored via video or direct 1:1 monitoring through a window or portal.** State law varies on what type of monitoring and documentation is required. **It is important to recognize that a patient is not absolutely safe in LDS.** Highly agitated patients can injure themselves in such a context. The most likely cause of death in LDS is a cardiac event. It is especially important that a physical examination proceed as rapidly as possible after the patient is placed in LDS in order to address and correct any underlying causes of aggression and/or agitation (e.g., head trauma, diabetic ketoacidosis, hypoxia, etc.).

PHYSICAL RESTRAINTS

Perform hand hygiene and apply personal protective equipment as needed. Introduce yourself and your plan to the patient in a calm manner. Assemble all the required personnel in the room. Provide privacy by closing the door to the room and/or pulling the curtain around the patient's bed if in a shared patient room.

FIGURE 194-1. Soft wrist restraints should have a gap of one to two fingers breadths between the patient's wrist and the restraint.

The Emergency Physician should not physically participate in holding the patient or the application of physical restraints. This allows the Emergency Physician to maintain the physician–patient relationship required to subsequently evaluate, manage, and treat the patient. With the help of trained assistants, physically assist the patient into a comfortable supine position that allows easy access to the area of the body to which the restraint will be applied. Apply the soft restraints to the patient's wrists, leaving approximately 1 to 2 cm distance between their wrist and the restraint. It should fit snugly but not constrict (**Figure 194-1**).

Apply and tie the two long ends or strapping to the bed frame as a unit (**Figure 194-2**). They should be attached to the portion of the frame that moves when the head of the bed is raised and lowered. **They should not be attached to the side rails.** Attaching the restraints to the side rails increases the patient's risk for injury when they are lowered. Make a slip knot with the strapping (**Figure 194-2**). This allows for easy removal in case of an emergency. Secure the restraints to the bed frame in such a manner that both wrists remain at the patient's sides to reduce shoulder injury risk. **Never restrain the patient with one or both arms above their shoulders to ensure that the patient does not experience respiratory compromise.** The slip knot is easily released by pulling on the free ends of the strapping (**Figure 194-3**).

The 2-point soft restraint of the wrists is less restrictive than the 4-point restraint of all limbs. Apply the 4-point restraints to both wrists and ankles. Apply the soft restraints to the patient's ankles similar to that of the wrists. Leave approximately 1 to 2 cm distance between the ankle and the restraint (**Figure 194-4**). They should also be attached to the bed frame.

Soft restraints are less restrictive than leather restraints. The method for determining which type of restraint is required must be determined by clinical experience and the current situation involving the specific patient and their behavior. Patients who are physically frail and nonviolent may benefit from 2-point soft restraints. However, if they are able to move too freely and are agitated, 4-point restraints may be necessary for patient safety. Severely agitated, aggressive, and dangerous patients may require leather restraints. **The goal is to utilize the least restrictive restraint method while ensuring the safety of the patient and the staff.**

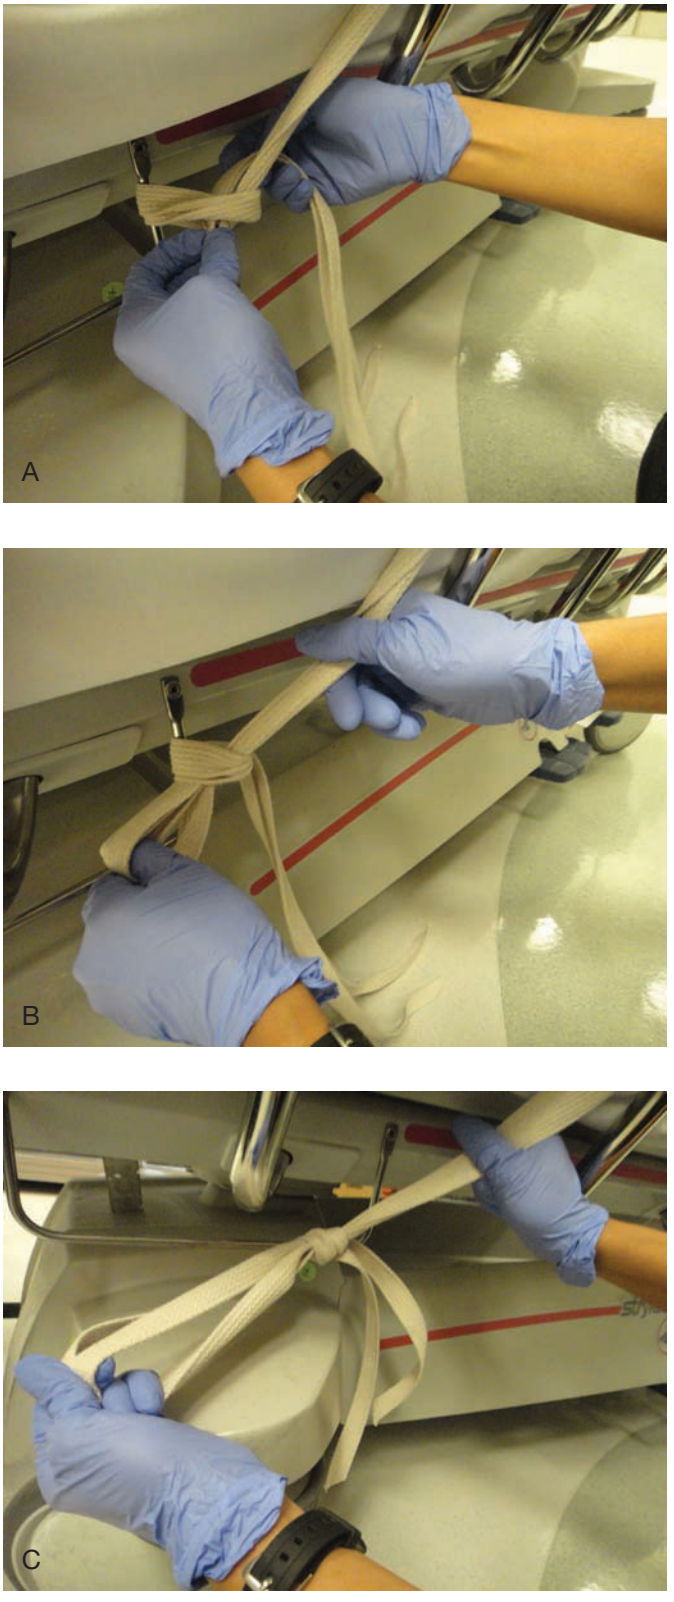

FIGURE 194-2. Soft restraints are attached to the bed frame using a slip-knot. **A.** Starting the slip knot. **B.** Making the slip knot. **C.** Tightening the slip knot.

Other restraint devices have been used in conjunction with extremity restraints. Apply a Philadelphia collar to minimize the potential for biting and head banging. An alternative, and more readily available in the ED, is to apply a standard cervical collar that is used for the trauma victim. This standard cervical

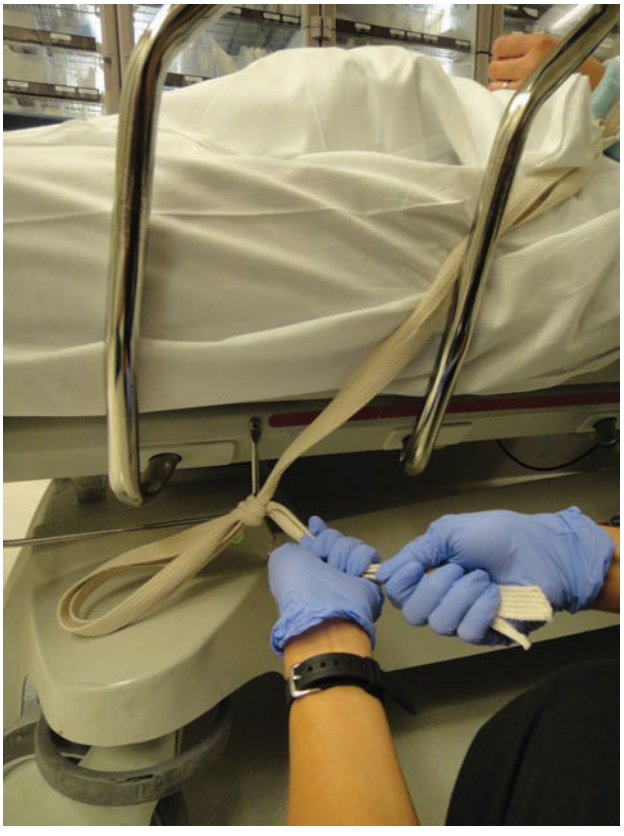

FIGURE 194-3. Pulling the loose end of the soft restraint will immediately release the knot.

FIGURE 194-4. Soft ankle restraints should have a gap of one to two fingers breadths between the patient's ankle and the restraint.

collar should be exchanged as soon as possible with the softer Philadelphia collar to prevent the standard collar from injuring the patient. **Never use a torso restraint or sheet around the torso.** Limiting chest movement and respirations can result in respiratory compromise and death. Use a device specifically designed to be wrapped around the patient's hips and that attaches to the bed frame. Chemical restraint can be safely administered once the patient is physically restrained.

PEDIATRIC PATIENTS

Pediatric patients are rarely restrained for aggressive and violent behavior. The very young are commonly restrained for diagnostic and therapeutic procedures.[25] These are brief episodes of discrete restraint for specific indications. The same general indications, contraindications, and concerns should be used with children as in an adult. Young children should not be placed in LSD by themselves. This can result in them becoming more frightened and agitated. Allow the parent or guardian to remain in the LDS room if it is safe for them to do so.

Technically, the procedure is the same for pediatric patients that require physical restraint for aggressive and violent behavior. However, the restraint time requirements are different. Limit the time an adult is physically restrained or in seclusion to 4 hours. Physical restraints and seclusion must be limited by decreased time intervals in pediatric patients: 2 hours for children and adolescents ages 9 to 17 and 1 hour for patients under 9 years old. After this time period, document an assessment and a new order for the continued use of physical restraints or seclusion. As appropriate in older children, release the restraints every 1 to 2 hours and assist the patient to the bathroom, and/or offer food and fluids.[11] It is wise to document patient assessments at more frequent intervals than that with an adult. Follow your hospital's policies regarding documentation and assessments.

Frightened young children who are not able to respond rationally to their circumstances may be soothed when held by an adult, termed therapeutic holding. This helps the pediatric patient regain control of their emotions and is used as an alternative to mechanical restraint or seclusion.[2,12–16] If it is used in the ED for other procedures, it is considered part of ongoing care. This requires specific training beyond the scope of this chapter. Adolescents may need to be separated from friends or family members who are causing their behaviors to escalate.

ASSESSMENT

Patients who are restrained require constant observation by specifically trained personnel. The complication rate for a patient in physical restraints has been estimated at 5.4% to 7%, although none were life threatening.[5,15] Evaluate the patient every 15 minutes for signs of injury according to hospital protocol for the type of restraint. Documentation of monitoring includes confirming airway patency, breathing, and circulation. At regular intervals monitor IV catheters, urinary catheters, drainage tubes, and other equipment to verify correct positioning and the absence of occlusion by the restraints. Assess the needs of the patient and/or family members. Offer additional information and emotional support as needed. Continually assess whether restraint of the patient is necessary. Evaluate the appropriateness of restraint use, including the level and characteristics of the patient's activity at least once every 4 hours. Note whether the patient continues to exhibit the behaviors (e.g., agitation, combativeness) that have made restraint necessary. The treating Emergency Physician must perform and document a face-to-face evaluation of the patient within 1 hour of the application of physical restraints.[11] Provide written information as appropriate to reinforce patient/family teaching. Document the procedure in the patient's medical record, including all patient/family teaching and the need for follow-up education, if any.

Patients will need to be continuously monitored if they are restrained secondary to violent and self-destructive behaviors. State laws vary on monitoring if the patient is placed in restraints for nonviolent and non-self-destructive behavior, but they may be monitored less frequently. Hospital policies determine these parameters such that they meet legal, TJC, and CMS requirements.

AFTERCARE

Once the restrained patient has calmed down, an organized approach should be taken to remove the restraints. Talk with the patient about removing the restraints and review the patient's ability to stay calm and follow instructions. This process is known as debriefing.[11] Some Emergency Physicians release all restraints at once. **However, releasing the patient's restraints in a stepwise approach may prove safer.** First, release one of the patient's arms. Inform the patient that if they remain calm, other restraints will be removed. **The patient must be observed to ensure that they do not release their other restraints once an arm is free.** Wait a short period of time before releasing the patient's opposite arm if in 2-point restraints or their opposite leg if they are in 4-point restraints. If the patient was in 4-point restraints, wait a short period of time then release the remaining two restraints at the same time. An alternative in the 4-point restrained patient is to initially remove both leg restraints followed by one arm then the other. **The patient should never be left with only one arm restrained without a staff member at the bedside because this allows too much mobility and may cause harm to both the patient and the staff members if the patient becomes combative or falls from the bed.[2] Never leave a patient restrained only by their legs as they can become injured if they fall off the bed.**

Discuss with the patient the reason restraints were required. Include in the discussion the alternatives that were first tried and that failed, thus requiring physical restraint. Review the behaviors that should be avoided in the future that will prevent the application of physical restraints.

COMPLICATIONS

The use of physical restraints can result in asphyxia, strangulation, and sudden death if they are incorrectly applied or if the patient is not appropriately monitored.[17–21] Patients restrained in the prone position or who are under the influence of stimulants are at an increased risk of complications.[22–24] Never restrain a patient in the prone position as this can compromise their respiratory function. Tightly applied restraints or the patient fighting against the restraints can result in abrasions, skin breakdown, contusions, extremity fractures, joint dislocations, neurovascular damage, or rhabdomyolysis leading to acute renal failure.[2] Consider the use of chemical restraint (Chapter 195) to minimize these potential complications and to be able to release the physical restraints.

DOCUMENTATION

Thorough documentation of the incidents involving the use of restrictive physical intervention is essential (**Table 194-1**). No single set of documentation guidelines has been drawn up to define what exactly should be recorded after such incidents have occurred.[15] The documentation standards for restraint and seclusion episodes include the circumstances leading to their use monitoring requirements, and staff debriefing.

SUMMARY

Patients come or are brought to the ED seeking relief from a variety of maladies. However, on occasion, they display behavioral disturbances which create imminent danger for themselves and others. Alternatives to physical restraint must be attempted and documented before the initiation of physical restraints. At times, it is necessary to physically restrain a person. This chapter provides the rationale, medicolegal justification, and commonly used techniques for physical restraint in the ED.

195 Chemical Restraint

David K. Duong and Hemal Kanzaria

INTRODUCTION

Acute agitation, psychosis, and violent behavior are common presentations in the Emergency Department (ED). It has been estimated that 32% of EDs in teaching hospitals report daily verbal threats and that 25% restrain at least one patient per day.[1,2] Management of the agitated patient presents a complex challenge of minimizing the risk of potential violence while enabling appropriate clinical evaluation of the agitated state. The underlying diagnosis is often unknown and treatment must often be rendered urgently with limited time for decision making. Such presentations can interfere with the ED evaluation and treatment as well as compromise both patient and staff safety. These behavioral emergencies may require pharmacologic intervention to reduce agitation, resume a more normal physician–patient relation, and facilitate safety.

The use of chemical restraint implies that medications are used to control behavior and confine a patient's bodily movement, but without an assessment and treatment plan.[3] However, this is rarely the case in the ED, as medications to manage behavioral emergencies are administered as part of an evaluation and plan of care. For the purposes of this chapter, chemical restraint will refer to the emergent use of medications to control dangerous behavior in a patient.

GENERAL CONSIDERATIONS

Behavioral emergencies provide complicated medical and ethical considerations. The benefits of chemical restraint should be seriously considered against the potential side effects of the medication. Emergency Physicians must be aware of alternatives to chemical restraint as well as the careful assessment, reevaluation, and treatment of the acutely agitated patient. Ideally, chemical restraint provides a calming, rather than sedating, effect with a continued emphasis on doing no harm to the patient while simultaneously reducing the risk of violence.[4,5] An objectively good response to chemical restraint may still leave the patient feeling traumatized and angered. **To the extent possible, allow the patient to participate in treatment decisions.** This can be achieved through simple tasks such as asking the patient if they have a medication preference or offering a choice between potential medications.[5] If this approach fails, attempt further verbal de-escalation or a "show of force" before any physical or chemical restraint.[6]

EDs should have written policies regarding restraint use and monitoring as mandated by the Centers for Medicare and Medicaid Services (CMS) and The Joint Commission (TJC).[3,7] Both CMS and TJC have protocols for the use of restraints. The CMS defines chemical restraint as use of a medication to restrict a patient's behavior or freedom of movement but is not the standard treatment or dosage for the patient's underlying condition. Both CMS and TJC recognize the legitimate use of restraint for the acute medical or surgical patient to prevent patient injury and alleviate violent behavior that places the patient, staff, or others in immediate danger. Both organizations identify restrictions, including that restraints must only be used when less invasive interventions have failed; must be ordered by a licensed clinician (can be a nonphysician); require the patient to be evaluated by a Physician within 1 hour after restraint initiation; and cannot be written as a standing or as needed order.[3,8–10]

A brief consideration of the legal and ethical implications of chemical restraint deserves mention. In general, consent for evaluation and care is implied during an emergency. The courts assume a competent lucid adult would consent to treatment necessary to maintain health or life.[11] Emergency Physicians must also consider whether the patient has the decisional capacity to refuse offered care. The more life threatening the emergency, the greater should be the Emergency Physician's comfort in treatment. If there is doubt as to the competency of the nonconsenting patient, it is best to err in favor of treatment.[11] If the patient is competent, then some leeway must be given to patient preference for treatment. **The Emergency Physician must document their thought process and justification for administering chemical restraint.** The covert administration of chemical restraint may be problematic and no universal ethical standard has been established in an ED setting.[12,13] It is also always advisable to review the ED and hospital restraint protocols that have been vetted through the hospital administration and legal review.

INDICATIONS

There is no precise definition of clinical agitation or violent behavior in the ED that necessitates chemical restraint.[14] Experts have agreed that explosive and/or unpredictable anger, intimidating behavior, restlessness, pacing, excessive movement, physical and/or verbal self-abusiveness, demeaning or hostile verbal behavior, and impulsive or impatient behavior are components of clinically significant agitation.[5] A history of violence (regardless of diagnosis), male sex, drug abuse, and alcohol abuse are associated with violent behavior.[11,14–16] However, there is no reliable way to clinically predict which patients will be imminently violent. The history and physical examination will usually determine which patients are agitated, violent, or have imminently violent potential. Verbally engage the patient to the extent possible to obtain preliminary information and assess their potential for verbal de-escalation. The patient should ideally be asked about their intent to harm themselves or others, if they possess a weapon (on their person or at home), a history of recent violence, current alcohol or illicit drug use, medical conditions, and psychiatric conditions. **The possibility of violence should be taken seriously and acted upon quickly.**

Chemical restraint may, however, be necessary if verbal interaction is not adequate to alleviate violent behavior. For most agitated patients, de-escalation through verbal communication should be attempted before initiating chemical restraint. However, the Emergency Physician must gauge the potential to manage agitation and violence through verbal and behavioral interaction given the clinical situation and available resources. Not every violent patient can be managed in a stepwise fashion. Do not delay appropriate intervention for violent behavior. The ultimate decision to use chemical restraint, either alone or after less restrictive alternatives, is a clinical decision that must be made at the time the behavior is occurring.

TABLE 195-1 Contraindication to Specific Medications used for Chemical Restraint[22]

Agent	Contraindications
Lorazepam	Hypersensitivity to lorazepam or any component of formulation Acute narrow angle glaucoma Significant sleep apnea Severe respiratory insufficiency
Midazolam	Hypersensitivity to midazolam or any component of formulation, including benzyl alcohol Acute narrow angle glaucoma Concurrent use of CYP3A4 inhibitors (i.e., amprenavir, atazanavir, ritonavir)
Haloperidol	Hypersensitivity to haloperidol or any component of formulation Significant Parkinson's disease Severe CNS depression Bone marrow suppression Severe cardiac or hepatic disease
Droperidol	Hypersensitivity to droperidol or any component of formulation Known or suspected QT prolongation
Risperidone	Hypersensitivity to risperidone or any component of formulation
Olanzapine	Hypersensitivity to olanzapine or any component of formulation
Ziprasidone	Hypersensitivity to ziprasidone or any component of formulation History of (or current) prolonged QT interval Concurrent use of other QTc prolonging agents Recent MI or history of arrhythmia, uncompensated heart failure

CONTRAINDICATIONS

Attempts should be made to determine if the patient has any known allergies through a review of the medical record, through collateral history from the patient's family, and any known medical or psychiatric providers. A known allergy to a specific medicine is a contraindication to its use and to use of other medications within the same class. Dosing adjustment and caution should be used when administering medication in patients who are elderly, debilitated, have comorbid medical conditions, or a history of side effects with the use of such medications. Contraindications to the specific medications (classes) described in this chapter are listed in **Table 195-1**. **Chemical restraint is not indicated for a patient who refuses to cooperate or intensely stares. It is also not appropriate to use chemical restraint for punishment or for the convenience of staff.**

EQUIPMENT

- Personal protective equipment (gloves, mask, goggles or face shield, and gown)
- Alcohol pads
- Syringes, various sizes
- Needles, various gauges
- Pharmaceutical agents
- Resuscitation equipment
- Defibrillator
- Oxygen source
- Oxygen masks
- Nasal oxygen cannulas
- Oral airway
- Nasal airway
- Bag-valve mask device
- Continuous pulse oximetry
- Capnography, if available
- Continuous cardiac monitoring
- Intravenous access supplies
- Equipment for physical restraint

PATIENT PREPARATION

Do not attempt to chemically restrain a patient until they are searched for dangerous objects and disarmed by hospital security or police. Identify a single team leader for the chemical restraint process. This is generally the Emergency Physician, who should assign roles and instruct other involved providers.[15,17] If the patent is voluntarily willing to take oral medications, less preparation is required compared to that for an agitated patient that is unwilling to take medications. Safely make attempts to decrease external stimuli, such as offering to place the patient in a more quiet area in the ED. **Consider how many staff members may be needed to intervene and formulate this team prior to any intervention.** It may be prudent to have more staff members readily available if needed. For instance, a patient may be so physically combative as to require five people, one person to restrain each limb by immobilizing at the major joint and a fifth person to hold the head. If possible, brief the team on what is expected and of possible dangers. Universal precautions should always be used to protect the healthcare provider.

Always approach the patient face-to-face and not from behind or without warning. Staff must appear calm and in control, speaking in a nonprovocative, nonconfrontational, and noncondescending manner. **Within a room, the patient should not obstruct a staff member's ability to exit the room.** Thus, staff should initially not have the patient between them and a door until the situation is under reasonable control.

Always leave the door to the room open to facilitate escape if the staff feel they are not safe. The open door also allows additional staff to enter and assist. It may be necessary to have security nearby and aware of the situation.

CHEMICAL RESTRAINT AGENTS

Improvements in pharmacologic treatment of the acutely agitated or psychotic patient have been recently made, resulting in more medication choices. The medication selected should be based on diagnostic or etiologic considerations, onset and duration of action, efficacy, route of administration available, patient's history of response to the medication, patient preference, ease of administration, and potential for adverse effects (**Table 195-2**).[4,5] **The ideal agent for sedation of the acutely agitated patient in the ED is one that is rapidly effective without causing excess sedation, easily administered, available via multiple routes of administration, and safe.**[18,19] Here, we present a summary of the pharmacologic options available for chemical restraint based upon the currently available evidence.

BENZODIAZEPINES

Benzodiazepines have achieved popularity because of their tolerability and safety. These medications bind to the alpha subunit of the $GABA_A$ receptor to enable inhibitory neurotransmission.

TABLE 195-2 General Choices for Chemical Restraint Based Upon Consensus Guidelines[5,29,30]

Provisional diagnosis	First-line medication	Second-line medication	Comments
No data available, patient willing to take oral medications	Lorazepam PO (first choice) Risperidone PO	Olanzapine PO Haloperidol PO Quetiapine PO	
No data available, patient unwilling to take oral medications	Lorazepam IM (first choice) Ziprasidone IM Olanzapine IM Haloperidol IM		
Psychotic disorder, unwilling to take oral medications	Haloperidol IM + Benzodiazepine IM or Olanzapine IM	Ziprasidone IM Ziprasidone IM + Benzodiazepine IM Haloperidol IM Benzodiazepine IM	
Schizophrenia	Olanzapine PO Risperidone PO Risperidone PO + Benzodiazepine PO Haloperidol PO + Benzodiazepine PO	Quetiapine IM Ziprasidone IM	If IM meds required, use Olanzapine, Haloperidol + Benzodiazepine, Ziprasidone, or Ziprasidone + Benzodiazepine
Mania	Olanzapine PO Risperidone PO	Quetiapine PO Ziprasidone PO Haloperidol PO	If IM meds required, use Olanzapine or Haloperidol + Benzodiazepine
Alcohol withdrawal or stimulant toxicity	Benzodiazepine PO or IM		
Conduct disorder (pediatric)	Nonpharmacologic means	Benzodiazepine PO or IM	

Note this table is adapted from information based on expert consensus panel recommendations. These recommendations should not replace clinical judgment for the needs of a given patient and clinical scenario.

Lorazepam and midazolam are the most often used benzodiazepines in the ED. They are an effective monotherapy for the initial treatment of the undifferentiated acutely agitated ED patient.[20] Multiple studies have shown that benzodiazepines reduce agitation and are as effective as haloperidol alone.[5,21] They should be used when no past medical history is available, no specific treatment is indicated (i.e., personality disorder), or when benzodiazepines have specific benefits (e.g., EtOH intoxication). Benzodiazepines have fewer significant side effects than conventional antipsychotics. They have been associated with excessive sedation and rarely paradoxical disinhibition. **Combination therapy with a typical antipsychotic may be more effective than either benzodiazepine agent alone.**

Clonazepam, diazepam, and flunitrazepam are benzodiazepines which have been shown to be potentially effective in reducing agitation. However, this information is based upon extremely small studies in hospitalized patients with known psychiatric diagnoses. Moreover, there have been inconsistent results and flunitrazepam is not available in the United States.[20] Diazepam has erratic absorption after intramuscular (IM) administration and its active metabolite make this medication less useful in the ED. Therefore, these benzodiazepines will not be discussed.

Benzodiazepines are contraindicated if the patient has a known allergy to a benzodiazepine (**Table 195-1**). Administer benzodiazepines cautiously and adjust the dose in patients who are elderly, debilitated, have respiratory insufficiency or sleep apnea, hepatic disease, or renal disease. The most common side effects of benzodiazepines include excessive sedation and respiratory depression, which can be found in over 10% of patients receiving these medications.

Emergency Physicians should be careful not to overdose benzodiazepines, especially with the possible adverse effects of excessive sedation and respiratory depression. Use flumazenil to reverse benzodiazepine-related sedation. The initial dose is 0.2 mg IV over 30 seconds. This can be redosed at 0.3 mg IV over 30 seconds if the desired level of consciousness is not obtained.[22] **Extreme caution should be exercised if flumazenil is administered. Its use may result in withdrawal seizures if the patient is chronically taking benzodiazepines.**

LORAZEPAM

Lorazepam has excellent absorption after IM administration with a rapid onset of action and a short duration of action (**Table 195-3**). The medication has minimal risks when used as a single dose or short-term administration.[19] The onset of action varies slightly depending upon the formulation administered. Sedative effects are achieved within 15 to 30 minutes of IM administration. Peak plasma concentration is achieved within 60 to 90 minutes with a duration of action of approximately 8 hours.[22,23]

TABLE 195-3 Profiles of Benzodiazepines Used for Chemical Restraint[4,5,20,22]

Agent	Dose (mg)	Route	Onset of action	Elimination half-life (h)	Metabolism	Excretion	Dosing limit	Side effects
Lorazepam	2 or 4	IV IM PO	5–10 min IV 15–30 min IM 20–30 min PO	10–14	Hepatic	Urine	12 mg/d	Respiratory depression, excess sedation
Midazolam	5	IV IM PO	3–6 min IV 10–20 min IM 10–30 min PO	1–4	Hepatic	Urine	30 mg/d	Respiratory depression, excess sedation

Lorazepam PO or IM is recommended as first-line therapy for undifferentiated agitation, alcohol-related agitation, and substance-induced agitation.[5] Expert consensus guidelines suggest optimal lorazepam dosing as 1 to 3 mg PO or 0.5 to 3 mg IM. Studies in the acutely agitated patient show that 2 or 4 mg lorazepam IM is as effective in reducing agitation and violent behavior with significantly fewer side effects compared to 5 mg haloperidol IM.[5,20,21]

MIDAZOLAM

Midazolam is a water-soluble benzodiazepine with good IM absorption, rapid time to onset, rapid time to recovery, and with minimal side effects (**Table 195-3**). Traditionally this medication has been used more for conscious sedation than rapid tranquilization. Sedation is achieved within approximately 15 minutes, while peak effect occurs at 30 to 60 minutes. The mean duration of action of IM midazolam is 2 hours. This medication is metabolized by the liver and excreted in the urine.[22]

Midazolam has a shorter time to onset of sedation and more rapid time to arousal compared to lorazepam and haloperidol.[24] One potential limitation includes the short half-life, which may require frequent re-dosing to maintain tranquilization.[19,25] As with all the benzodiazepines, midazolam can cause significant respiratory depression. Midazolam appears to be safest at a dose of 5 mg and without the concomitant use of narcotics.[4,25–27]

COMBINATION THERAPY

Medications can often be combined to achieve synergistic therapeutic effects while reducing potential adverse outcomes. For example, previous studies have focused on combining benzodiazepines with typical antipsychotic agents. **Combination treatment allows for lower doses of antipsychotic medication to achieve adequate sedation. Moreover, a lower incidence of extrapyramidal symptoms (EPS) may be due to benzodiazepine prophylaxis or treatment of antipsychotic-induced side effects.[23]**

The combination of lorazepam and haloperidol is the most commonly studied and utilized combination therapy in clinical practice. **A combination of 2 mg lorazepam with 5 mg haloperidol has been shown to more rapidly reduce agitation than either agent alone, and with fewer side effects relative to haloperidol alone.** The combination can be mixed together in the same syringe and administered IM if used immediately.[21,28] It is important to note that studies supporting these data do not control for re-dosing. Nevertheless, current ACEP guidelines recommend that the combination of a benzodiazepine and haloperidol may produce more rapid sedation than monotherapy in the acutely agitated psychiatric patient in the ED.[20]

ANTIPSYCHOTICS

Typical, also known as first-generation or conventional, antipsychotics and benzodiazepines have historically been the mainstay of treatment for acute agitation and psychosis. These medications have been available in parenteral formulations for years. However, conventional antipsychotics and benzodiazepines can cause serious adverse effects. The utility of atypical, also known as second-generation, antipsychotics is expanding as rapid-acting preparations become available. Atypical antipsychotics have differing mechanisms of action, a broader spectrum of response, and a lower side effect profile.[29]

Choosing the initial antipsychotic medication depends upon the patient's mental health and medical history, the need for concurrent sedation, and the side effect profile (**Table 195-4**). A typical or atypical antipsychotic drug can be used as monotherapy in the acutely agitated patient with known psychiatric illness. Use an oral preparation of either an antipsychotic or benzodiazepine in the cooperative but agitated patient. Options for the oral treatment of agitation related to schizophrenia or mania include olanzapine, risperidone, risperidone in combination with a benzodiazepine, or haloperidol in combination with a benzodiazepine. Use IM preparations for uncooperative schizophrenic patients. Options include olanzapine, ziprasidone, haloperidol in combination with a benzodiazepine, or ziprasidone in combination with a benzodiazepine. IM benzodiazepines are preferred over newer atypical antipsychotics in patients where no history is available or the underlying illness is undifferentiated.[5,29,30]

TYPICAL ANTIPSYCHOTICS

HALOPERIDOL AND DROPERIDOL

Haloperidol is a butyrophenone antipsychotic. It blocks dopaminergic D_1 and D_2 receptors in the brain. It is the best studied of all the typical antipsychotics, though the majority of studies have been conducted in psychiatric patients with unclear applicability to the undifferentiated acutely agitated ED patient.[20] The peak serum concentration is achieved in approximately 20 minutes after IM

TABLE 195-4 Profiles of Antipsychotics Used for Chemical Restraint[5,22,23,29]

Class	Drug	Dose	Route	Onset of action (min)	Elimination half-life (h)	Metabolism	Elimination	Dosing limits	Side effects
Typical antipsychotic	Haloperidol	2.5–10 mg	PO IM IV	30–60	18	Hepatic	Urine + feces	30 mg	EPS, NMS
	Droperidol	5 mg	IV IM	10–30 IV 10–20 IM	1–4	Hepatic	Urine + feces	30 mg/d	Prolonged QTc
Atypical antipsychotic	Ziprasidone	10 mg q 2 h or 20 mg q 4 h	PO IM	15–20	7 PO 2–5 IM	Hepatic	Urine + feces	40 mg/d	Prolonged QTc
	Risperidone	2 mg q 2 h	PO	<90	20	Hepatic	Urine + feces	12 mg/d	Orthostatic hypotension, prolonged QTc at max dose
	Olanzapine	5–10 mg q 2–4 h	PO IM	180–360 PO 15–45 IM	21–54	Glucuronidation and cytochrome P450 mediated oxidation	Urine + feces	20–40 mg/d PO 30 mg/d IM	Orthostatic hypotension, prolonged QTc at max dose

administration (2 to 6 hours after PO administration), while adequate sedative effects can be expected within 30 to 60 minutes for both IM and IV administration. The duration of effect is approximately 24 hours.[6,22,23]

Dose–response studies have demonstrated that a single dose of 7.5 to 10 mg of haloperidol may produce the best outcome with the fewest side effects. Higher doses yield lesser degrees of improvement while increasing the risk of adverse effects.[4,5,31] **While the utility of haloperidol as monotherapy is limited, the traditional combination therapy of haloperidol with a benzodiazepine is a first-line option for schizophrenia, mania, and psychosis.**

Droperidol is another butyrophenone neuroleptic that inhibits dopaminergic transmission. It is closely related to haloperidol but only available in a parenteral formulation. Compared to haloperidol, it has rapid absorption with a quicker onset of action (15 to 30 minutes) and a much shorter half-life (2.2 hours).[22,23] The peak effect is achieved within 30 minutes of IM administration and the duration of effect is 6 to 8 hours. Consequently, compared to haloperidol, it has been shown to be more effective at acutely reducing agitation while requiring fewer repeat doses and causing fewer side effects.[23] This medication has also been compared to benzodiazepines. Droperidol produces better sedation, requires fewer repeat doses, and results in a shorter ED length of stay compared to lorazepam alone.[19,20,32–34] Despite these promising results, continued use of droperidol became controversial after the FDA issued a black box warning in 2001 secondary to the drug's potential for QTc prolongation.[35]

Emergency Physicians should be aware of relevant side effects associated with typical antipsychotics. This includes EPS, cardiac arrhythmias, and neuroleptic malignant syndrome. Haloperidol has been associated with acute dystonias, parkinsonism, and akathisia. The frequency of EPS associated with haloperidol use varies significantly across studies, but has been cited to affect between 0% and 50% of patients.[21,34] These side effects are of particular concern given that they may lead to increased patient agitation and medication refusal. Anticholinergic medications such as benztropine (0.5 to 2 mg IM or IV) or diphenhydramine (50 mg IM or IV) may be used to prevent or treat EPS. Droperidol has a lower incidence of EPS in the acute setting.[33,34,36] Caution should be used when administering typical antipsychotics in patients with Parkinson disease, anticholinergic toxicity, PCP intoxication, or movement disorders. There was concern that antipsychotic agents lowered the seizure threshold in mice, but this has not been found in humans.[11]

Typical antipsychotics cause QT interval prolongation, most likely due to their quinidine-like cardiac affects.[6,19] While there have been reports of sudden death occurring with chemical restraint using typical antipsychotics, haloperidol is considered to have a low risk of causing QTc prolongation. Droperidol is recognized for its potential for causing dose-dependent prolongation of the QTc and subsequent dysrhythmias. However, multiple reviews of large series of patients receiving droperidol have concluded that while this medication can be associated with prolonged QT interval, there is not conclusive evidence that it can cause life-threatening cardiac events. ACEP guidelines recommend that if rapid sedation is needed, and after consideration of the possible adverse affects, droperidol may still be preferable to haloperidol.[20] Despite this, droperidol use has dramatically decreased since the FDA black box warning. **When using antipsychotic medications, it is important to understand the potential effects on the QTc interval. The likelihood of QTc interval change is increased when patients are already taking other medications that prolong the QTc, or when they have certain comorbidities.** Caution should be used, especially in patients with cardiac disease or those taking antipsychotics chronically. **If possible, obtain an ECG prior to the administration of a typical antipsychotic.** Withhold typical antipsychotic medication if the QTc is above 500 ms or if the patient has risk factors associated with QT prolongation. If administered, do not give additional doses if the QTc increased by >25% after administration.[19]

There has been additional concern that typical antipsychotics may be affiliated with neuroleptic malignant syndrome (NMS), which is characterized by mental status changes, muscular rigidity, fever, and autonomic instability. The risk of this complication may increase in patients receiving large amounts of typical antipsychotics over a short period of time, and may be further exacerbated in those who are poorly hydrated and restrained in a poorly ventilated holding room. It has been estimated that NMS is a rare complication seen in approximately 0.2% to 1% of patients using typical antipsychotics, thus these patients should be monitored for such physiologic changes.[4,6,23]

ATYPICAL ANTIPSYCHOTICS

With the advent of newer neuroleptic medications available in IM formulations, atypical antipsychotics are considered a breakthrough for the treatment of agitation and psychosis (**Table 195-4**). Currently olanzapine, ziprasidone, and risperidone are available in rapid-acting forms that can be used to treat acute agitation. These medications are generally well tolerated and do not cause excessive sedation compared to typical antipsychotics. This can lead to shorter ED stays and increased patient participation in care. These medications show promise to be as effective as the typical antipsychotics with a better side effect profile.[29] Caution regarding QTc prolongation should still follow the general considerations as with typical antipsychotics discussed above.

The use of atypical antipsychotics for treatment of acute agitation holds great promise. There is currently limited data on the use of these medications in the undifferentiated agitated patient. Most studies have been conducted in selected, consented, and less agitated individuals compared to the typical unselected, involuntary use in ED patients.[20]

ZIPRASIDONE

Ziprasidone is a benzylisothiazolylpiperazine antipsychotic with serotonin-dopamine antagonist effects. It was the first available atypical antipsychotic in the IM formulation. The IM preparation achieves peak concentration in 30 to 45 minutes and has a duration of effect of at least 4 hours.[19,22,23]

Multiple randomized controlled trials demonstrate that 20 mg IM ziprasidone is effective at rapid tranquilization of the agitated patient with a psychiatric history. There seems to be a dose–response effect, as studies have shown increased efficacy when comparing 2, 10, and 20 mg doses. The 20 mg dose is well tolerated without evidence of increased EPS, dystonia, akathisia, respiratory depression, excessive sedation, tachycardia, or clinically significant QTc prolongation.[37,38] Ziprasidone appears to be comparable in efficacy to droperidol, midazolam, and haloperidol in combination with a benzodiazepine.[25,39] It may be more effective and better tolerated than IM haloperidol at treating acute psychosis.

Ziprasidone's high serotonin-2A/dopamine-2 ratio neurotransmitter affinity results in a low incidence of EPS compared to conventional antipsychotics. Ziprasidone appears to cause greater prolongation of the QTc interval compared to haloperidol, olanzapine, and risperidone.[40] However, this medication has not been associated with torsade de pointes, sudden cardiac death, and only rarely increases the QTc interval over 500 ms.[19,40] In summary, ziprasidone seems to be a safe and well-tolerated medication for the treatment of acute agitation, but should not be used in patients who are at risk for QTc prolongation.

RISPERIDONE

Risperidone is a benzisoxazole antipsychotic medication with serotonin-dopamine antagonist effects. Due to its serotonin ($5\text{-}HT_2$) and dopamine (D_2) antagonism, risperidone has a low risk of EPS. This medication comes as an orally disintegrating tablet, and thus should be placed on a patient's tongue using dry hands. The tablet will dissolve within seconds. It achieves peak plasma concentration within 1.5 hours.[22,23]

The combination of 2 mg PO risperidone plus 2 mg PO lorazepam has been shown to be equivalent to 5 mg IM haloperidol in combination with 2 mg lorazepam in reducing agitated psychosis in the emergency setting. Patients receiving the oral combination were also less somnolent and thus could be appropriately examined. Such data suggest that oral risperidone is an acceptable agent for the agitated but cooperative patient.[20,41]

OLANZAPINE

Olanzapine is another atypical antipsychotic with combined serotonin-dopamine antagonist effects. The medication is available in both an orally disintegrating tablet and an IM formulation. The IM preparation achieves peak plasma concentration in 15 to 45 minutes (5 hours for PO form) and has a duration of action of up to 24 hours.[22,23]

IM olanzapine effectively treats acute agitation in patients with schizophrenia, bipolar mania, and dementia. Olanzapine appears effective at reducing agitation with a quicker onset of action, while having a lower incidence of dystonia and EPS when compared to haloperidol for the treatment of agitated schizophrenic inpatients.[42] IM olanzapine was shown to be more effective than IM lorazepam at acutely reducing agitation and required less re-dosing in agitated patients with bipolar mania.[43] IM olanzapine was as effective with quicker onset of action compared to IM lorazepam for the treatment of agitated patients with Alzheimer's disease and vascular dementia.[44] A Cochrane review of olanzapine use for agitation remarked that data for the oral formulation is insufficient and essentially remains untested. While each of the above trials was industry-sponsored, they conclude that IM olanzapine has some value in managing acute aggression.[45]

Pooled analysis of QTc data demonstrated a favorable QTc profile for olanzapine in the treatment of schizophrenia, dementia, and bipolar mania.[46] However, studies have showed significantly higher rates of orthostatic hypotension in patients receiving IM olanzapine and ACEP guidelines recommend orthostatic vital signs to be taken if repeated dosing occurs.[19,20,47,48] Of note, olanzapine has been affiliated with a number of fatalities. Cardiopulmonary depression, bradycardia, and hypotension were noted in these cases.[5,20,23] Review of the fatalities demonstrated that patients tended to have significant comorbidities and often received concomitant benzodiazepines or excessive olanzapine dosing. **The combination of a benzodiazepine and olanzapine should not be given concomitantly as a result of this evidence.**[5,20,23]

ASSESSMENT OF SUCCESS

Consensus guidelines endorse calming without sedation or with mild sedation to the point of drowsiness (without sleep) as the most appropriate goal.[5,15,49] This allows the resumption of a more normal patient–physician relationship, the ability to obtain informed consent, and ensures the safety of both the patient and the staff. Such an approach may be associated with fewer injuries, shorter length of stay in the ED, and a quicker transition to the next appropriate level of care.[4] Sleep has been previously treated as an endpoint of chemical restraint. However, it eliminates the potential for patient participation in decision making and is not a guarantee of safety. **The desired therapeutic objective of reduction in agitation or aggression with minimal sedation to allow for a timely assessment and treatment of any medical condition that requires acute intervention.**

If success is not achieved, further dosing or an alternative medication may be required. Though timing of repeated doses depends upon the pharmacokinetics of the medications employed, most of the agents should exert their effects by 30 to 60 minutes. If there is no improvement in agitation or violent behavior, administer another similar or higher dose of the initial medication. **Consider administering lorazepam unless olanzapine was used.** If a combination of an antipsychotic and benzodiazepine was used, this may be repeated. Switching medications is only advised after three to four doses of the medication were given with insufficient effect or two doses of medication had no effect. Switching from one antipsychotic to another antipsychotic is generally not advised due to the different adverse effect profiles of the separate antipsychotics.[5,50] However, if a conventional antipsychotic was administered that resulted in EPS, an atypical antipsychotic may be used if further dosing is needed.[51]

AFTERCARE

After chemical restraint is employed, the staff must continue to interact with the patient in a calm, nonjudgmental, and noncondescending manner. Patients still require a staff member to observe them throughout their ED stay. As with any other ED patient, the issues of elimination and hydration should be anticipated and addressed. If the patient is calm and alert, the degree and frequency of vital sign and cardiopulmonary monitoring is dictated upon medical concerns and the patient's clinical status. If the patient is sedated, they should have frequent cardiac, neurologic, and pulmonary monitoring, as well as frequent vital sign and respiratory assessments. Additionally, initiate aspiration precautions and the changing of positions to prevent pressure sores. The chemically restrained patient must be evaluated for side effects and adverse reactions, such as orthostasis, dystonic reactions, akathisias, EPS, and NMS.

Document the indication and description of the chemical restraint process, the outcome, and any complications. It is also prudent to document the less restrictive alternatives that were considered or performed prior to chemical restraint. If during the interaction with the patient, it is discovered that a specific person(s) is in danger, they should be warned and the local police notified, especially if there is a situation where it is not possible to prevent a violent patient from leaving the ED (Tarasoff v. The Regents of the University of California, Supreme Court of California, 1976).

Psychiatric consultation should be a part of the evaluation of the violent patient. Standard medical clearance should be documented, including resolution of abnormal vital signs, resolution of mental status and behavioral abnormalities, stability of ambulation and mobility, and ability to understand and follow discharge instructions.

ALTERNATIVES

The management of the patient exhibiting dangerous behavior usually requires several techniques that are used sequentially or in concert with other techniques. Though some of these techniques may be used as alternatives, they are generally used in conjunction with chemical restraint.

As stated above, verbal de-escalation is usually the first approach to the violent patient and may be the only intervention necessary. The overarching principle with verbal de-escalation is that

staff convey their professional concern for the well-being of the patient.[11,14,15] Though a full description of verbal de-escalation techniques is not in the scope of this chapter, there are a few critical points to note. During the interaction with a violent patient, use a nonjudgmental, calm, and neutral approach. Give assurance that they will not be harmed and use empathic statements. Healthcare providers should be clear with limits on dangerous and violent behavior and the actions that will be taken to mitigate such behavior and actions. One should avoid lying to or arguing with the patient as these can represent a challenge to the patient to justify violent behavior and actions.[14]

A "show of force" is intended to deter dangerous behavior by having a daunting number of staff and security present in front of the violent patient. Ideally, personnel in the show of force should remain neutral and not provoke the patient, while a single team leader interacts with the patient to de-escalate the behavior.[11,14]

Physical restraint is another alternative that may be employed in place of, or temporarily in conjunction with chemical restraint. Both CMS and TJC have standards for use of physical restraints. The use of physical restraints is discussed in Chapter 194.

THE PREGNANT PATIENT

The safety, efficacy, and fetal outcome of using isolated doses of an antipsychotic medication and/or a benzodiazepine during pregnancy have not been directly studied and there is no strong evidence of any teratogenic effects from their use.[52,53] Benzodiazepines are considered fairly safe to use during pregnancy, as no definitive association between benzodiazepines and teratogenicity has been shown. Given the lack of evidence proving or disproving teratogenicity, the benefits of administering short-term doses of benzodiazepines generally outweigh the risks in emergent situations.[54,55] Though most benzodiazepines cross into breast milk, this is not usually a concern in the agitated ED patient who typically receives short-term therapy.

A consensus panel of expert Emergency Psychiatrists recommends using haloperidol as a first-line agent in the agitated pregnant patient.[30] Successful use of haloperidol and risperidone, with and without lorazepam, have been described.[56] There is limited experience with the use of ziprasidone, olanzapine, and quetiapine in the medical management of the agitated pregnant patient.[56] Atypical antipsychotic use has thus far not been linked to congenital malformations.[56,57]

Monitor women in their second and third trimester for inferior vena cava obstruction if chemically restrained and placed in the supine position. Place them in the left lateral decubitus position. They may be at an increased risk of aspiration due to lower esophageal sphincter relaxation during pregnancy. The pregnant patient's respiratory status must be carefully monitored. The normal increase in respiratory rate and decrease in tidal volume can be effected if the patient is oversedated or somnolent.

THE PEDIATRIC PATIENT

In general, chemical restraint of the pediatric patient should follow the overarching themes of chemical restraint in the adult. Every reasonable attempt possible should be made to obtain parental consent for the medical management of a violent pediatric patient. If an emergent situation precludes parental consent, further communication attempts and early discussion with the patient's parent(s) must be pursued. The child should be offered the option of taking the medication orally prior to the IM or IV routes of administration. This may help instill trust and help engage a likely frightened child, as even the idea of a needle may increase the agitation of a child and family members.[58–60] If minors are discharged, they should be in the care of a responsible adult who understands and agrees with the discharge plan.

TABLE 195-5 Medications Used for the Chemical Restraint of Pediatric Patients[58,60]

Drug	Formulation	Dose
Lorazepam	PO/IM/IV	0.05–0.1 mg/kg/dose (max 2 mg/dose)
Diazepam	PO/IM/IV	0.04–0.2 mg/kg/dose (max 10 mg/dose)
Haloperidol	PO/IM/IV	0.025–0.075 mg/kg/dose (max 5 mg/dose)
Risperidone	PO	0.25 mg (school age) to 2 mg (late adolescent)
Olanzapine	PO/IM	2.5 mg (school age) to 10 mg (late adolescent)
Diphenhydramine	PO/IM/IV	1 mg/kg/dose (max 50 mg)

The agents most commonly used for the chemical restraint of the pediatric patient are lorazepam, haloperidol, risperidone, and antihistamines.[5,61] Intranasal administration of midazolam has been studied for conscious sedation, but not for chemical restraint. Thus, use of intranasal midazolam cannot be recommended until there is further experience with this route of administration.[62,63] Benzodiazepines may cause paradoxical disinhibition, in which there is increased agitation. This is more common in children with developmental delay and organic brain syndromes.[60] For children with established attention deficit disorder, there is no data to support the use of stimulants to control behavior.[64]

The use of haloperidol and droperidol in pediatric patients should follow the same guidelines as in adults and are viewed as generally safe in children. Atypical antipsychotic use in pediatric patients is becoming more frequent. Olanzapine is approved for pediatric use and available in IM and orally disintegrating tablet form (**Table 195-5**). Risperidone is an effective and safe alternative.[64] Experience with ziprasidone use in the ED for pediatric patients is extremely limited and there is no available pediatric dosing for this medication. Diphenhydramine can be an effective agent due to its sedative effect. Extrapyramidal side effects may be treated with diphenhydramine (1.25 mg/kg/dose IV or IM) or benztropine (0.02 to 0.05 mg/kg/dose IV or IM).

SUMMARY

Acute agitation and violent behavior may be due to a variety of medical and psychiatric etiologies and is not an uncommon finding in ED patients. At times it may be appropriate to use pharmacologic intervention to calm the agitated patient in order to facilitate the appropriate diagnostic and therapeutic workup while ensuring patient and staff safety. Typical antipsychotics and benzodiazepines have been the traditional options, but the use of atypical antipsychotics is expanding with the development of new rapid-acting formulations with less adverse effects. Given the medical, ethical, and legal complexities involved in the treatment of acute agitation, it is advisable to review CMS, TJC, and hospital policies regarding chemical restraint. Emergency Physicians should be aware of the indications, as well as the risks and benefits, of chemical restraint.

penile aspiration and irrigation, 988
Procaine, 789, 790, 791, 805*t*
Procedural sedation, and analgesia, 854
adult discharge instructions, 867*t*
aftercare, 866
agents available for, 859*t*–861*t*
agent selection, 857–858
American Society of Anesthesiologist's (ASA), 857*t*
assessment, 866
benzodiazepines, 858
diazepam (Valium), 858
lorazepam (Ativan), 858
midazolam (Versed), 858
complications, 866–868
contraindications, 855–856
dissociative agents
ketamine (Ketalar), 862–863
ketamine–propofol, 863
drug profiles, 858
equipment, 856
indications, 855, 856*t*
inhalation agents
nitrous oxide, 865
miscellaneous agent
chloral hydrate, 865
DPT, 865
opioids
alfentanil (Alfenta), 862
fentanyl (Sublimaze), 862
meperidine (Demerol), 862
morphine, 858–862
sufentanil (Sufenta), 862
patient preparation
informed consent, 856
personnel competency/credentialing, 856
risk–benefit assessment, 856–857
pediatric discharge instructions, 867*t*
pregnancy categories, 867*t*
protocol, sample, 866
Ramsay Scale, 855*t*
reversal agents
flumazenil (Romazicon), 865–866
naloxone (Narcan), 866
sedative hypnotics
barbiturates, 863–864
dexmedetomidine, 865
etomidate (Amidate), 864
fospropofol, 865
methohexital (Brevital), 864
pentobarbital (Nembutal), 864
propofol (Diprivan), 864–865
thiopental (Pentothal), 864
technique, 866
terminology, 855
Progressive multifocal leukoencephalopathy, 760*t*
Prolapsed rectum reduction, 446
aftercare, 449
alternative techniques, 448

equipment, 448
indications, 448
patient preparation, 448
technique, 448
rectal prolapse reduction technique, 449*f*
taping buttocks open in prone patient, 448*f*
Prolapsed uterus reduction, 948–952
aftercare, 951
anatomy and pathophysiology, 949–950
assessment, 951
complications, 951–952
contraindications, 950
equipment, 950
indications, 950
patient preparation, 950–951
pessaries, types of, 951*f*
placement, indications for, 950*t*
techniques
pessary, fitting of, 951
uterine reduction, 951
uterine procidentia, 949*f*
Prophylactic broad-spectrum antibiotics, 1206
Pulmonary artery catheter (PAC), 287, 344, 346*f*, 348, 350
Pulmonary artery (Swan-Ganz) catheterization, 344
anatomy and pathophysiology, 345
cardiac anatomy, 345*f*
complications, 348, 350

contraindications, 346
data interpretation, 348
equipment, 346
indications, 346
indications for pulmonary artery catheter placement, 346*t*
patient preparation, 347
pressure waveforms recorded by the pulmonary artery catheter during insertion, 348*f*
pulmonary artery catheter, 347*f*
pulmonary capillary wedge pressure, 345*f*
recognized complications of pulmonary artery catheterization, 350*t*
technique, 347
Pulmonary capillary wedge pressure, 345*f*, 346
Pulmonary embolism, 327
Pulpal/periapical abscesses, 1141–1143
Pupillary dilating agents, eyedrop administration, 1021

Q
Quincke spinal needle, 750

R
Radial head subluxation ("nursemaid's elbow") reduction, 553
aftercare, 556
anatomy and pathophysiology, 553–554, 554*f*
assessment, 555
indications, 554
patient preparation, 555
radial head subluxation, 554
techniques, 555
hyperpronation, 555, 556*f*
supination and flexion, 555, 556*f*
Rapid sequence induction, 60
aftercare, 64
assessment, 64
complications, 64, 64*t*
contraindications, 61, 61*t*
equipments, 61
indications, 61, 61*t*
patient preparation, 62*t*
pharmacologic
adjuncts to intubation in premedication phase, 62*t*
properties of neuromuscular relaxants, 62*t*
special considerations in pediatric patients, 63–64
techniques, 62–63
Rapid sequence induction (RSI) of anesthesia, 60
Rectal foreign body extraction, 458
aftercare, 464
anatomy and pathophysiology, 459
anesthesia, 460, 460*f*
assessment, 463–464
complications, 464
contraindications, 458
equipment, 459
indication, 459
patient positioning for removal of rectal foreign bodies, 461*f*
patient preparation, 459–460
sampling of methods to remove rectal foreign bodies, 463*f*
techniques, 460
digital extraction technique, 461
endotracheal tube technique, 461
Foley catheter technique, 461
miscellaneous techniques, 462–463
ring forceps or tenaculum technique, 462
spoon technique, 461–462
vacuum extraction technique, 462
Rectal prolapse. *See* Prolapsed rectum reduction
Regional anesthesia. *See* Anesthesia; Regional nerve blocks

intraoral approach, 807
scalp block, 809
supraorbital nerve block, 806
supratrochlear nerve block, 806
human body, dermatomal chart of, 804*f*
indications, 803
infraclavicular approach to brachial plexus block, 817*f*, 818*f*
intercostal nerve, 826*f*
block, 827*f*
interscalene approach to brachial plexus block, 814*f*
intraoral approach
to infraorbital nerve block, 807*f*
to mental nerve block, 808*f*
lateral femoral cutaneous nerve block, 832*f*
maximum doses, 805*t*
median nerve block, 820*f*
nerves and anatomical areas, 802*t*
obturator nerve block, 832*f*
patient preparation, 805
peroneal nerve block, 837*f*
popliteal fossa nerve block., anterior/posterior approach, 836*f*
posterior tibial nerve block, 841*f*
posterolateral scalp, regional anesthesia of, 808*f*
radial nerve block, 823*f*
regional anesthesia procedure note, 805*t*
saphenous nerve block, 830*f*
scalp block, 810*f*
sciatic nerve
anterior approach, 835*f*
classic/posterior approach, 834*f*
course of, 833*f*
sensory innervation of hand, 819*f*
superficial peroneal nerve block, 838*f*
supraorbital and supratrochlear nerve block, 806*f*
supraorbital foramen, 806*f*
technique, 805
anatomic landmark technique, 805
US-guided technique, 805–806
techniques for lower extremity
ankle block, 841
common peroneal nerve block, 837–838
deep peroneal nerve block, 839–840
digital block of toe, 841
femoral nerve block, 826–828
lateral femoral cutaneous nerve block, 831
obturator nerve block, 831–833
popliteal fossa nerve block, anatomical/posterior approach, 835–837

Regional nerve blocks (*continued*)
posterior approach, 833–834
posterior tibial nerve block, 840–841
saphenous nerve block
at ankle, 831
at knee, 828–831
sciatic nerve block
anterior approach, 834–835
classic, 833–834
lateral approach, 835
lithotomy approach, 835
superficial peroneal nerve block, 838–839
sural nerve block, 840
toe, digital block of, 842*f*
ulnar nerve block, 821*f*
upper extremity, regional anesthesia techniques
brachial plexus block, 811–813
axillary approach, 815–817
infraclavicular approach, 817–819
interscalene approach, 813–815
supraclavicular approach, 812–813
digital nerve block of finger, 824
intermetacarpal nerve block, 824
median nerve block
at elbow, 819
at wrist, 819–820
radial nerve block
at elbow, 822
at wrist, 822–824
ulnar nerve block
at elbow, 820–822
at wrist, 822
wrist block, 824
Rehabilitation therapy, 576
Retrograde guidewire intubation, 139
aftercare, 143
assessment, 143
complications, 143
contraindications, 139
equipment, 139–140
indications, 139
patient preparation, 140
technique, 140
alternative techniques, 140–143
endotracheal tube advanced over guidewire, 142*f*
guidewire inserted through needle, 142*f*
retrograde guidewire intubation, 141*f*
Retrograde urethrography
aftercare, 980
alternative technique, 979–980
anatomy and pathophysiology, 976–977
assessment, 980
complications, 980
contraindications, 977
cystography technique, 979
equipment, 977–978
indications, 977
patient preparation, 978
retrograde urethrography techniques
brodney clamp technique, 979
foley catheter technique, 978
syringe technique, 978–979
Retrograde urethrography and cystography, 976–980
Retromandibular vein, 300*f*
Rigid rectosigmoidoscopy, 453
aftercare, 458
anatomy and pathophysiology, 454
anatomy of colon, 454*f*
assessment, 458
complication, 458
contraindications, 454
equipment, 454–455
indications, 454
patient preparation, 455–457, 456*f*, 457*f*
technique, 457–458
insertion and advancement of rigid rectosigmoidoscope, 457*f*
rigid rectosigmoidoscope rotation, 458*f*
Ring cutter technique, 687–688
Ring removal
aftercare, 690
alternative techniques, 689
anatomy/pathophysiology, 684–685
assessment, 689–690
caterpillar technique, 686*f*
complications, 690
contraindications, 685
equipment, 685
GEM ring cutting system, 689*f*
indications, 685
latex glove technique, 688*f*
oval shape, 690*f*
patient preparation, 685
ring cutters, manually operated, 689*f*
rubber band technique, 688*f*
string technique, 686*f*
with umbilical tape, 687*f*
techniques
caterpillar technique, 686
glove technique, 687
lubricant technique, 685–686
ring cutter technique, 687–688
rubber band technique, 687
string technique, 686–687
vice-grip pliers technique, 688–689
vice-grip pliers, 690*f*
Risperidone
for chemical restraint, 1225*t*, 1226*t*, 1229, 1230
Rosenbaum pocket vision screener
visual acuity, 1011*f*
Rotary knee dislocation reduction, 576
Rubber band technique, 687

indications, 870
patient preparation, 870
pelvic ultrasonography, US transducers, 870*f*
pelvis, free fluid, 877*f*
retroverted uterus, sagittal view of early pregnancy, 878*f*
retroverted uterus, TVS of, 874*f*
ruptured ectopic pregnancy, sagittal view of, 883*f*
TAS, coronal view of nonpregnant uterus, 872*f*, 873*f*
TAS, sagittal view of, 871*f*
nonpregnant uterus, 871*f*
transabdominal sonography, 870–873
ovaries/adnexa, 872–873
uterus/vagina, in coronal plane, 872
uterus/vagina, in sagittal plane, 871–872
transvaginal sonography (TVS), 870, 873–877
adnexa, in coronal plane, 876–877
adnexa, in sagittal plane, 875
adnexal mass adjacent to ovary, 882*f*
corpus luteum cyst, 879*f*
early pregnancy failure, sagittal view of, 879*f*
incomplete spontaneous abortion, sagittal view of, 880*f*
nonpregnant uterus, coronal view of, 875*f*, 876*f*
nonpregnant uterus, sagittal view of, 874*f*, 875*f*
normal ovary, coronal view of, 876*f*
ovaries, in coronal plane, 875–876
pseudogestational sac, sagittal view of, 881*f*
uterus/vagina in coronal plane, 875
uterus/vagina in sagittal plane, 874–875
tubal ring representing, 882*f*
Umbilical cord, 371*f*
Umbilical vessel catheter, 375*f*
Umbilical vessel catheterization, 369
aftercare, 375
anatomy and pathophysiology, 370
assessment, 375
catheter inserted into umbilical artery, 374*f*
complications, 375–376
contraindications, 371
determine correct length of catheter, 373*f*, 375*f*
equipment, 371
fetal circulation, 370*f*
indications, 371
patient preparation, 371
positioning of tip of umbilical artery catheter, 372*f*
positioning of tip of umbilical vein catheter, 374*f*
preparation for catheter insertion, 373
preparing umbilical cord stump, 372*f*
techniques, 371, 372
umbilical vein catheterization, 374
umblical multiple-lumen catheters, 374–375
Uncooperative patients, eyedrop administration, 1021
Universal choking sign, 1181
Upper airway obstruction
abdominal thrusts (*See also* Heimlich maneuver)
in conscious patient, 1183, 1183*f*
direct laryngoscopy, 1184–1185
in unconscious patient, 1183–1184, 1183*f*
aftercare, 1185
anatomy and pathophysiology, 1181
choking, relief of, 1181–1185
in infants, 1182*f*
complications, 1185
digital removal (finger sweep), 1181
foreign body removal, 1181–1185
infants, back blows and chest thrusts in, 1181–1183
orotracheal intubation, 1185
Upper extremity casts, 599
coaptation splint, 599
dorsal ("clam digger") splint, 601
finger splints, 602
long arm cast, 603
posterior long arm splint, 599–600
radial gutter splint, 600
short arm cast., 602*f*, 603, 603*f*
sugar tong splint, 599
thumb spica splint, 601–602
ulnar gutter splint, 600
volar splint, 600–601
Upper extremity escharotomy, 744
Upper extremity technique
local anesthetic agent, injection of, 845–846
pneumatic tourniquet, application of, 844–845
pneumatic tourniquet, deflation of, 846
Urethral catheter, 1189, 1195, 1196
Urethral catheterization, 953–963
aftercare, 961–962
anatomy and pathophysiology, 953–954
assessment, 961
commonly uses, 955*f*
complications
difficulty removing catheter, 962
general complications, 962
leakage around catheter, 962
contraindications, 954
digital assistance, 958*f*
equipment, 954
female catheterization techniques, 960–961
female genitourinary tract external anatomy, 953*f*
female urethral catheterization, 961*f*
filiform/follower catheters
insertion of, 959*f*, 960*f*
penis demonstrating insertion, Midsagittal section of, 959*f*
photographs of, 958*f*

foley catheter insertion, 956*f*
indications, 954
infant/children catheterization techniques, 961
male catheterization techniques
coudé catheter, 957
difficult urethral catheterization, 957
digital assistance, 957
filiform/follower catheters, 957–960
foley catheter insertion, 955–957
male genitourinary tract
anatomy of, 954*f*
patient preparation, 954–955
penis, secure method, 957*f*
transabdominal spinal needle, longitudinal US view, 962*f*
urinary drainage bag
patient instructions, 961*t*
Urokinase, 337, 338*f*
Uterine atony, 894, 918, 919, 920
Uterine hypotonia, 919
Uterine prolapse, 948, 949, 950*t*, 951
Uterine reduction, 951
